The author finds that amateurs and even expert photographers often fail to take the trouble to understand their work, and are ignorant, not only of the principles upon which it is founded, and which are therefore the only safe guides to its successful application, but also of many simple practical and commercial facts concerning it. So he has prepared this volume in sections varying in length from a line or two to a page or two, each with a conspicuously printed heading indicating the subject treated. The arrangement is exactly the old style of question and answer, except that the question is put in the form of a statement or title, such as "What a landscape lens is," "When one mav dilute the developer," and so on. The information is generally of the kind that would be called elementary, tending in parts perhaps to be too superficial, and may be accepted as evidence that even in Germany, where education is so well systematised, the general knowledge concerning so common an applied science as photography is behind the needs of the times. Many convenient and some apparently novel methods are given, as, for example, to facilitate necessary calculations. A drawback to the book from the point of view of the English reader is that in the lists of makers of different kinds of lenses, sensitive materials, &c., although there are included some little-known German firms, English firms appear to be ignored altogether.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by Dr. A. E. Shipley, F.R.S., assisted by G. A. K. Marshall. Rhynchota. Vol. v., Heteroptera. Appendix by W. L. Distant. Pp. xii+362. (London: Taylor and Francis; Calcutta: Thacker, Spink and Co.; Berlin: R. Friedländer and Son, 1910.) Price 10s.

In this supplementary volume, Mr. Distant describes a large number of species which have recently come into his hands, but most of which have already been described in advance of the present work in the *Annals and Magazine of Natural History*, the *Annales de la Soc. Ent. de Belgique*, &c.; and thus he completes his work on the Indian Heteroptera. This volume extends from the family Lygæidæ to the family Corixidæ, and we are informed that "A further volume, which will form an appendix to the Homoptera, will complete the enumeration of the Indian Rhynchota, with the exception of the families Psyllidæ, Aphididæ, Aleurodidæ, and Coccidæ." The species here described extend from Nos. 2769 to 3135, and are illustrated by 214 excellent illustrations in the text. The first page is devoted to controversial questions of nomenclature, and a few bibliographical notes.

Nigeria and its Tin Fields. By A. F. Calvert. Pp. xvi+188+259 plates. (London: Edward Stanford, 1910.) Price 3s. 6d.

This book is intended to provide information concerning Nigeria, to which special attention has recently been directed by the revelation of vast alluvial tin deposits in the province of Bauchi (northern Nigeria). The author discusses the present means of communication, the possibility of railway development, and the character of tin deposits, which are situated about 3000 to 4000 feet above sea-level. He states that it is estimated that the tin deposits are scattered over an area of about 2500 square miles, that the tin produced is considered to be some of the best ever imported into Europe, and that it commands a price equal to, if not higher than, that of the Straits tin. Details are given of the companies which are at work, and the new mining regulations are stated in full. One interesting feature of the book is the large number of illustrations, which are collected together at the end.

Mathematical Papers for Admission into the Royal Military Academy and the Royal Military College for the Years 1905–10. Edited by E. J. Brooksmith and R. M. Milne. Various papers, separately paged. (London: Macmillan and Co., Ltd., 1911.) Price 6s.

The editors have provided answers to the questions set during the past six years for candidates seeking admission to the Royal Military Academy and College. Teachers whose duty it is to prepare candidates for these examinations should find the publication a convenience.

Huxley and Education. By Prof. H. F. Osborn. Pp. 45. (New York: Charles Scribner's Sons, 1910.)

Prof. Osborn's address at the opening of the college year at Columbia University last September is here printed in the form of a book for the pocket. Some of his remarks remind one of the aphorisms of his old master, Huxley. To quote one example:—"Do not climb that mountain of learning in the hope that when you reach the summit you will be able to think for yourself; think for yourself while you are climbing."

William Ford Stanley. His Life and Work. Edited by Richard Inwards. Pp. 82. (London: Crosby Lockwood and Son, 1911.) Price 2s. 6d. net.

The first five chapters of this book are autobiographical, and in the remaining four the editor gives an interesting account of the late Mr. Stanley's active life. There are two appendices, the first being an article on technical trade schools, which was the last paper written by Mr. Stanley, and the second the events in Mr. Stanley's life arranged in chronological order. The book will be interesting to many readers.

Die Elemente der Entwicklungslehre des Menschen und der Wirbeltiere. By Prof. O. Hertwig. Vierte Auflage. Pp. viii+458. (Jena: Gustav Fischer.) Price 9.50 marks.

The first edition of this work on the leading facts of embryological science was noticed in Nature of April 26, 1900 (p. 610). The work has been enlarged by about fifty pages, and there are now 399 figures instead of the 332 in the original edition. For students familiar with the German language, the volume provides an excellent introduction to embryology.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Daylight Saving?

MAY I make a few observations with regard to Prof. Milne's article in NATURE of April 6 on Daylight Saving? Leaving aside the inquiry as to whether the clerks of Cornwall are happier than those of Kent, to which I am not able to give an answer (though it is possible that, as these counties differ in other respects than that considered, a mere yes or no might have little value as evidence), one may direct attention to the next argument as to workers who have to commence their work at 6 in the morning. The graphic account which Prof. Milne gives as to the hardships which these workers would have to suffer under the proposed scheme, would be heart-rending, had he not thoughtfully supplied the remedy in his last paragraph. Why should they not start work an hour later in summer? later, that is, according to the new setting of the clocks? This is a "simple solution" on Prof. Milne's own showing.

In my practical engineering days I found that one of my greatest privations was due to the fact that my evenings had to terminate (in order that I might rise early in the mornings) earlier than those of my friends, and evening engagements were generally inconveniently late. Now, under the proposed scheme all evening engagements, except such as are organised by these workers for their own convenience, would take place an hour earlier (absolute time), and consequently the effect of the change would be probably, if anything, an advantage to the 6 o'clock workers, provided they accepted the simple solution suggested. In fact, their day *is now* disjointed from that of the rest of the world, and under the new scheme this defect would be at least partially remedied.

Prof. Milne's fifth paragraph seems to be inconsistent with his simple solution. I am surprised to hear the "half-asleep" argument seriously brought forward. If one rises and retires an hour earlier, but works, takes meals, &c., at the old times, the argument is valid, but not, I think, when work, &c., fall in automatically with the new times of rising and retiring. On a journey to Vancouver and back I altered my watch more than twenty times, but felt no inconvenience whatever, because all engagements altered in the same way.

As to defects, inconvenience to meteorologists, steamship companies, &c., we must, of course, try to weigh these as justly as possible against the advantages of the scheme, but I think that technical and academic points, and even practical questions like the adjustment of steamship and boat-train times, should not be allowed to weigh very heavily against any large amount of real advantage to the workers of the country which the scheme might be calculated to afford.

With regard to the last paragraph of the paper, one may remark that the solution suggested, that business people should begin work an hour earlier in summer, really leads us on inevitably to the daylight proposal itself. For if business (apart from factories, &c., with which I have already dealt, which form an obvious exception) begins and ends an hour earlier, then the general activities of the country must follow suit. It would be impracticable, for instance, for shops to open at 7 instead of 8 and close at 6 instead of 7 (say) at night, while the shopping public still ordered their doings according to the old times; and if all business and other people adopted the plan suggested, then all other pursuits engaged in by them must follow. Thus all engagements, trains, and what not must be altered.

Now, manifestly, by far the simplest mode of carrying out this change would be to alter the clocks, and then allow all the activities of life to go on to the same time schedule as before. Not only is this the simplest way, but I think it will be admitted that it is the *only way* which would have the slightest chance of being *actually realised* in practice.

In conclusion, I may say that my object in writing has not been to support the daylight saving proposal itself, but rather to direct attention to what seemed to me to be vulnerable points in the arguments (as arguments) under discussion.

L. SOUTHERNS.

IN my note on the so-called Daylight Saving proposal, I repeated a suggestion made by many, viz., that a simple solution to the whole question would be to commence work one hour earlier during the summer, and do this without confusing ourselves and others without altering the clocks. Why Mr. Southerns quotes me as saying *one hour later* I do not know. The main point, however, to which practically no reference is made is that the majority of workers in Great Britain will, if the time-saving scheme comes into force, have to rise at 4 a.m. instead of 5 a.m. for six months in the year. This is increasing darkness and not saving daylight. It is all very well to say that the total population in Great Britain will, if they go to bed one hour earlier, save two and a half million pounds on illumination, but it would only be fair if the promoters of this new-fangled idea would tell the inhabitants of Great Britain how many millions they would have to spend on extra illumination required in the morning. You cannot make a piece of cloth longer by cutting off one end and sewing it on the other.

Mr. Southerns says that he is "surprised" at hearing what he aptly terms the "half-asleep argument." To be surprised at an argument, however, is not the best way to refute it. Thus I may be surprised, even greatly astonished, at much that Mr. Southerns says in his letter, but I do not expect that the most dramatic exhibition of my personal feeling will carry conviction to his or anyone else's mind. I am therefore compelled to relate a few facts which have a direct bearing on this matter. Of these facts Mr. Southerns is evidently without knowledge, and it may be assumed that others who support this remarkable Bill are in a like state of darkness.

In the first place, as the result of innumerable experiments and observations by many distinguished investigators, it has been definitely ascertained that bodily and mental efficiency are not maintained at the same level throughout the day, and that the course of efficiency, if plotted diagrammatically, describes a curve with a morning maximum between ten and eleven; an afternoon maximum about five, and in late workers a third elevation, which has been termed "end-glow." With the afternoon and evening measures of efficiency I am not concerned; what I wish to emphasise here is that there is a gradual increase in bodily and mental efficiency from the hour of waking up to between ten and eleven in the great majority of workers of all kinds; *i.e.* that sleep imposes an inertness the influence of which passes away, only slowly on arising. There is, in fact, what Dr. Howard Marsh, in an interesting book on "The Diurnal Course of Efficiency," calls a "warming-up period."

Now for the important matter of habit. The results of experiments show that the immediate effect of breaking habits is apt to be detrimental to the output of work, whatever that habit may be. So firmly does habit impress itself upon the reaction of man to his environment, that Patrick and Gilbert, for instance, show that in subjects kept awake for seventy-two hours, and subjected to tests every six hours, the worst results were obtained invariably *at the periods ordinarily devoted to sleep*, thus showing the recurrent nature of an established habit, and how important is the influence of this upon the output of work, hence for some time after the shifting of time, should it be brought about, we should anticipate that the efficiency of workers would be impaired.

J. MILNE.

Seiches in Windermere.

WINDERMERE is peculiar as regards seiches, since it is nearly divided in two by islands and shallow water near the middle. On account of this the two halves of the lake oscillate independently, but an oscillation can be detected which is due to the uninodal seiche of the whole lake. Because of the shallow water near the middle, this has only a small amplitude and a very long period (69·7m.), and is soon damped out.

A recording apparatus was first set up near the upper

end of the lower half of the lake. The water, however, was shallow in this part of the lake, and the records are rather disturbed by local effects due to wind. The periods of the seiches detected here were 20·4 minutes, 11·9 minutes, and 3·3 minutes. The 20·4-minute and 11·9-minute periods are due to the uninodal and binodal seiches of the lower half of the lake. The 3·3-minute period is probably

Fig. 1.—Recording Limnograph.

due to a transverse seiche. The maximum range recorded was about an inch.

After this, the recording apparatus was set up at the head of the lake. The upper half of the lake being much deeper than the lower half, better records were obtained. The maximum range recorded was about 1½ inches. The periods here were well marked, and had the following times:—69·7 minutes, due to the uninodal seiche of the whole lake; 14·1 minutes and 6·6 minutes, due to the uninodal and binodal seiches, respectively, of the upper half of the lake; also a well-marked, short period of 3·4 minutes. This last period is probably due to the trinodal seiche, and also to a transverse seiche, which has nearly the same period. In some cases, the movement due to this oscillation alone was nearly an inch.

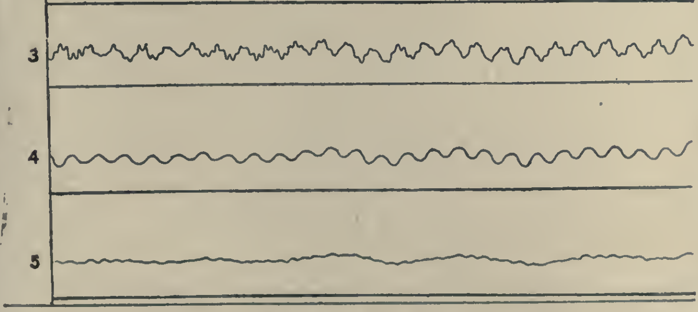

Fig. 2.—Traces obtained at Head of Windermere.

The figure shows some of the traces obtained. Nos. 1, 2, and 3 are typical traces obtained at the head of the lake. Nos. 4 and 5 are obtained from No. 3 by Prof. Chrystal's method of residuation. The 3·4-minute period is seen in the original trace. No. 4 shows the 14·1-minute and 69·7-minute periods, and is obtained by residuating out the 3·4-minute and 6·6-minute periods. No. 5 shows the 6·6-minute and the 69·7-minute periods, after the 3·4-minute and the 14·1-minute periods have been residuated out. In Nos. 1 and 2 the rate of movement of the paper was one inch in 18·8 minutes, and in No. 3 one inch in 23·2 minutes.

During the later experiments a form of apparatus was used which proved quite satisfactory, and, being simple to construct, may be worth briefly describing. A strip of paper, from a continuous roll fixed on the base of the instrument, passes up and over a horizontal wooden cylinder, 3 inches in diameter, and driven by clockwork. After passing half-way round the cylinder, the paper passes under a small roller carried on springs. This roller presses the paper against the wooden cylinder, and, since the paper passes half-way round the cylinder before passing under the roller, there is no possibility of it slipping.

A horizontal lever is pivoted to the base of the instrument, one end of which projects outwards, and is connected to the float by a string, while the other end carries a weight. The pen and holder are carried by a horizontal rod, which is supported by two upright arms, being fixed to them at each end by pivots. One of these arms is fixed to the lever, at the place where it is pivoted to the base of the instrument, while the other arm is pivoted direct to the base. As the float moves up and down, this horizontal rod moves backwards and forwards, parallel to the axis of the wooden cylinder. On the horizontal rod are bearings, which carry the light frame holding the pen, which rests on the top of the wooden cylinder. When the lever is half-way up or down, the bearings of the pen are about the same height as the top of the wooden cylinder, then, as the float moves the lever up and down, the pen moves in an almost straight line across the paper on the top of the cylinder.

This apparatus is simple to construct, and, since the only friction is in the pen and the four pivots, the whole system moves very freely, and a float 5 inches in diameter will work it easily, while Chrystal's "waggon" recorder requires a 10-inch float. Gordon Dobson.

Caius College, Cambridge, April 19.

The Flight of Exocœtus.

Practical difficulties will prevent the settlement of the question as to whether or no a flying fish supports itself by movement of its fins by the method suggested by a correspondent in Nature of February 9, viz. kinematograph photography.

Anatomy and phylogeny converge to the support of those observers who declare that the "wings" are motionless during "flight."

(1) Any resemblance to the huge musculature of birds is out of the question, but if the wings vibrate to any purpose, something resembling in scale the muscular and nervous specialisation found in insects should obtain here. Has anything of the sort been found? On the contrary, the muscular development of Exocœtus is, like that of other fish, directed to propulsion by the tail.

(2) The structure and habits of the lower members of the family, Hemiramphus and Belone, indicate stages in the evolution of Exocœtus. The former is able to make great leaps nearly parallel to the surface, of such force, indeed, that the natives here tell me of men who have been pierced by the elongated lower jaw two inches deep in the flesh of the leg when wading among them. "When it is out of the water it is quite mad and strikes whatever is in the way, whether a man or a boat, and so kills itself," to quote their description.

Belone can almost fly, its effort having the appearance of running on the surface on the tip of its tail, suggesting some use of this member, but not of the normal-sized fins, in extending the range of "flight." These two steps in the evolution of the habit of Exocœtus distinctly lead to the

idea of a parachute leap, but do not at all support an evolution of flight by beating wings.

Exocœtus is the natural parallel of the aëroplane, which, it is hoped, will rise from and descend upon water with ease and perfect safety. The flying fish, however, frequently strikes a wave with one fin and is overturned, or strikes it with violence. It would be very interesting to know whether Belone does aid itself by its tail, and so is in some way a parallel to the hydroplane boat.

The Stinging Tree of Formosa.

WITH reference to the letter on the Stinging Tree of Formosa in NATURE of March 2, it would be interesting if your correspondent would throw light on the exact mechanism by which the sting in *Laportea pterostigma* and *L. crenulata* is produced. *L. crenulata* is locally abundant in some parts of India. The curious point is that the leaves are often glabrous. Moreover, the stinging effects are, apparently, sometimes experienced without actual contact with the plant. I was one day walking through the hot, steaming forests near the Tista River, in British Sikhim, with a friend. The Laportea was abundant, and we carefully avoided it. On our way home my friend was seized with the peculiar stinging sensations of the Laportea in several parts of his body. These lasted several days, and on the night immediately after being stung became so bad that he was unable to get any rest and became feverish.

On another occasion I had to cut a survey line through dense forest with an undergrowth of *L. crenulata*. The coolies avoided the leaves as much as possible, and cut the stems low. Some of them were stung on the body, but all were attacked in different degrees with sneezing, violent catarrh, and ultimately vertigo. I myself, although at some distance from the actual cutting operations, though I had to walk up the cut line, suffered to a less degree in the same way. Yet I have often dashed a leaf across the back of my hand with no ill effects! Sir J. Hooker and others have noted that the effects are worse at some times of the year than at others. The inflorescence, it should be noted, is covered with hairs, and I have only been able to account for the facts above described by supposing that it is these deciduous hairs of the inflorescence which get into the clothes and become inhaled when the tree is shaken.

Fundamental Notions in Vector Analysis.

I SHALL be much obliged if you will kindly permit me, through the columns of NATURE, to make some suggestions regarding fundamental conceptions in vector analysis, a subject which was vigorously discussed in this journal about twenty years ago (NATURE, vols. xliii., xliv., xlvii., xlviii., xlix.). The discussion showed that the slow progress of vector analysis was in a large measure due to the want of unanimity as to its fundamental notions and notations, and to an unfortunate aspect peculiar to it, viz., a strong conviction on the part of the advocate of any one of the various systems of vector analysis, that the other systems, if allowed to grow, will do more harm than good, while it may be noticed that in our ordinary scalar analysis, although several systems (*e.g.* Cartesian, polar, pedal, trilinear, &c.) exist side by side, there is no such feeling. My object now is to suggest a system which, while it aims at a reconcilement between the various systems, will contain the best features of each of these known systems.

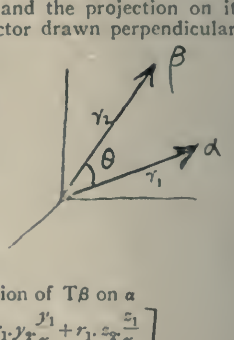
Dr. Knott (NATURE, vol. xlvii., p. 590) justifies the introduction of the quaternion as a fundamental conception by saying that it is only a generalisation to the case of vectors of the quotient (in the case of scalars) of two lengths. But a great objection is that the quaternion—a hybrid conception, in part a scalar and in part a vector—is not *by itself* capable of being defined in terms of the three fundamental entities, magnitude, direction, and position, as every *fundamental* conception ought to be. No such thing can, however, be said of the fundamental notions of the non-quaternionists, the scalar product and the vector product, which are defined in terms of only the fundamental notions of geometry and trigonometry. I may also repeat an argument of Prof. Gibbs (NATURE, vol. xlvii., p. 463) that the introduction of the scalar product and the vector product as fundamental conceptions will meet Prof. McAulay's observation (*Ph. Mg.*, vol. xxxiii. 1892, p. 477) that the arrest in the development of vector analysis is due to the circumstance that quaternions are "independent plants that require separate sowing and consequent careful tending." Besides, as is pointed out by Prof. Gibbs (NATURE, vol. xliii., p. 511), it is not desirable that the simpler conceptions should be expressed in terms of those which are by no means so. It is not sufficient to say, as has been argued (Heaviside, NATURE, vol. xlvii., p. 533), that vector analysis should have a purely vectorial basis; for that would only be a play of words.

Now, although the non-quaternionists thus avoid certain initial difficulties in presenting the subject, some of them, viz., Mr. Heaviside and Prof. Macfarlane, have made innovations which not only have no justification, but have created insuperable difficulties. We must have $\alpha^2=-1$, and we must recognise the versional character of the vector; the principles of vector algebra must differ as little as possible from the principles of scalar algebra, and we cannot be blind to the usual meaning of equations such as $ij=k$, &c., as was pointed out by Dr. Knott (NATURE, vol. xlviii., p. 148; vol. xlvii., p. 590). All these difficulties and others have arisen from an attempt to oust the conception of a quaternion, whether in the initial or at any later stage. So supreme is the contempt that Gibbs, while dealing with the theory of dyadics, regards $\alpha\beta+\lambda\mu+\gamma\nu$, a sum of expressions analogous to the quaternions, as indeterminate, merely symbolic, having physical meaning only when used as operator, although scalars and vectors are derived from it.

It is unfortunate that the advocates of vector analysis cannot work in harmony with one another, recognising superiority of each other in particular respects. Although Gibbs admits that the quaternionic method has advantages in certain cases, he would not tolerate its existence in the field of vector analysis, or rely upon it in places where he has found advantages.

With regard to the question of notations, I may refer to NATURE, vol. xlvii., p. 590, where Dr. Knott rightly says that the symbols used by the quaternionists for the scalar product and the vector product express at once and clearly the nature of the functions they represent, and that it is not proper to use the sign of ordinary multiplication in a case which does not admit of one of the factors being carried over to the other side as a divisor.

I shall now work out the successive stages of introducing the proposed system. We shall begin with the scalar product, $S\alpha\beta$, and the vector product, $V\alpha\beta$, defining the former as a quantity equal to minus the product of the length of one of the vectors, α, β, and the projection on it of the other, and the latter as a vector drawn perpendicular to the plane of the vectors, of a length equal to the area of the parallelogram determined by them, so that rotation round it from α to β through an angle less than 180° is positive. We see that we shall have



$$S\alpha\beta=S\beta\alpha,\quad V\alpha\beta=-V\beta\alpha.$$

Now if we take $\alpha=ix_1+jy_1+kz_1$

$$\beta=ix_2+jy_2+kz_2$$

we have,
$$\begin{aligned}S\alpha\beta &= -T\alpha T\beta\cos\theta\\ &= -T\alpha\times\text{ projection of }T\beta\text{ on }\alpha\\ &= -\left[r_1.x_2.\frac{x_1}{r_1}+r_1.y_2.\frac{y_1}{r_1}+r_1.z_2.\frac{z_1}{r_1}\right]\\ &= -(x_1x_2+y_1y_2+z_1z_2\end{aligned}$$

$$\begin{aligned}V\alpha\beta = {} & i\text{ (projection of area of parm. }\alpha,\beta\text{ on }x\text{ plane)}\\ & +j\text{ (projection of area of parm. }\alpha,\beta\text{ on }y\text{ plane)}\\ & +k\text{ (projection of area of parm. }\alpha,\beta\text{ on }z\text{ plane)}\\ = {} & (y_1i_1z_2-y_2z_1)+j(z_1x_2-z_2x_1)+k(x_1y_2-x_2v\end{aligned}$$

$$\begin{aligned}\therefore\ S\alpha\beta+V\alpha\beta &= -(x_1x_2+y_1y_2+z_1z_2)+i(y_1z_2-y_2z_1)+\\ &\quad j(z_1x_2-z_2x_1)+k(x_1y_2-x_2y_1)\\ &= (ix_1+jy_1+kz_1)(ix_2+jy_2+kz_2)\\ &= \alpha\beta.\end{aligned}$$

We thus arrive at an auxiliary, $\alpha\beta$, connected with the fundamental notions by the relation, $\alpha\beta = S\alpha\beta + V\alpha\beta$, an auxiliary the geometrical meaning of which will be seen below.

We then note the special case $\alpha^2 = S\alpha^2 = -(T\alpha)^2$ so that $\frac{1}{\alpha} = -\frac{\alpha}{T\alpha^2}$. With the help of this relation, we shall assign meanings to $S\frac{\beta}{\alpha}$, $V\frac{\beta}{\alpha}$:

$$S\frac{\beta}{\alpha} = S\frac{-\beta\alpha}{T\alpha^2} = \frac{-S\beta\alpha}{T\alpha^2}$$

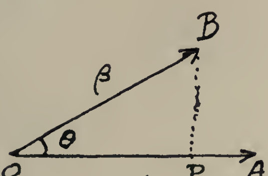
$$V\frac{\beta}{\alpha} = V\frac{-\beta\alpha}{T\alpha^2} = \frac{-V\beta\alpha}{T\alpha^2}$$

From these we have $S\frac{\beta}{\alpha} + V\frac{\beta}{\alpha} = -\frac{1}{T\alpha^2}(S\beta\alpha + V\beta\alpha)$

$$= \frac{-\beta\alpha}{T\alpha^2}$$

$$= \frac{\beta}{\alpha}$$

Apart from this, the following geometrical consideration will justify our introduction of the quotient and the conception of an operator :—



$$S\frac{\beta}{\alpha} + V\frac{\beta}{\alpha} = S\frac{-\beta\alpha}{T\alpha^2} + V\frac{-\beta\alpha}{T\alpha^2}$$

$$= \frac{T\beta . T\alpha \cos\theta}{T\alpha^2} + \epsilon . \frac{T\beta . T\alpha \sin\theta}{T\alpha^2}$$

where ϵ is an unit vector $+r$ to plane α, β

$$= \frac{T\beta \cos\theta}{T\alpha} + \epsilon . \frac{T\beta \sin\theta}{T\alpha}$$

$$= \frac{OP}{OA} + \frac{PB}{OA} = \frac{OB}{OA} = \frac{\beta}{\alpha}$$

We have *now*, but not earlier, the conception of our auxiliary, whether the product $\alpha\beta$ or the quotient $\frac{\beta}{\alpha}$, as an operator turning one vector into another, the former β^{-1} into α and the latter α into β; this would, as usual, justify our calling by their old name (quaternion) these auxiliaries which we have here *obtained from* our fundamental conceptions, the scalar product and the vector product. We may now proceed further and introduce into our system the conception of the axes and the angle of a quaternion. We may, and as a matter of fact shall, use the quaternion whenever we find it expedient, but we must not make it our fundamental notion.

In view of the diversity of opinion shown above, some modification and reconcilement on the lines suggested above or on some other lines are absolutely necessary, if the advocates of vector analysis are earnest in their desire to see it universally applied, and the Cartesian and other methods completely overthrown.

MAUMATHA NATH RAY.

Calcutta Mathematical Society, Senate House,
March 2.

This method of approach to the quaternion vector analysis is practically that adopted by Prof. Joly in his "Manual of Quaternions." The method is unsatisfactory, because it makes too great a demand at the outset upon the learner's faith. Why should $S\alpha\beta$ be put equal to $-ab\cos\theta$? The answer is, of course, because that is the simplest way of getting a vector algebra applicable to Euclidean space, and at the same time associative in its vector products. But the existence of so many varieties of non-associative vector algebra shows how absolutely unimportant this latter consideration is to many who find vector analysis useful. In these varieties not only is there no explicit recognition of a quantity $\alpha\beta$, where α and β are vectors, but there is a perfect hatred of the mere suggestion of it as a quantity worthy of general discussion, except (be it noted) in the particular case in which α is perpendicular to β. Mr. Ray shows, by a simple Cartesian process, how easily we may arrive at the recognition of this product if we start with the geometrical definitions of Hamilton's $V\alpha\beta$ and $S\alpha\beta$. But the method is unconvincing to the man who prejudges the whole matter by barring out the quantity or symbolic form $\alpha\beta$ as being fundamentally foreign to any well-regulated system of vector analysis! If they would not listen to Hamilton, Tait, or Joly, will they listen to any other quaternionist, charm he never so wisely?

C. G. K.

An Abnormal Zebra.

In reference to the note by Prof. Ridgeway on a photograph of a zebra, or boute-quagga, skin from the Athi Plains of British East Africa, published in NATURE of April 20, I write to say that a copy of the same photograph was received at this museum from Mr. Woosnam.

As I have mentioned in a note in *The Field* of April 22, Mr. Woosnam stated that there were only one or two of such abnormally marked animals running in a herd of *granti* at any one time. It is therefore clear that there is no ground for regarding the variation as of racial value. On this point Mr. O. Thomas, to whom the photograph was sent by Mr. Woosnam, is in complete accord with myself.

R. LYDEKKER.

London, S.W., April 24.

A Robin and his Young.

LAST summer a pair of robins built their nest in an old fish-basket that was hanging in a shed at the back of my house. All went well until the young birds were about a week old—then happened what appeared to me to be a catastrophe. My Aberdeen terrier pup "Bebe," who must have had some natural desire to catch the mother bird, managed one morning to make a meal of her.

Contrary to what I should have expected, the male bird kept close to his young family. Day by day I turned over part of the garden to supply him with a little help in his task. In due course he taught the whole of his young family to fly.

I have made inquiries, but cannot find anyone who has had a similar experience, and wondered what your readers might know about such cases.

CHARLIE WOODS.

"Vectis," 2 Wellmeadow Road, Lewisham, S.E.,
April 18.

PROPOSALS FOR THE REFORM OF THE CALENDAR.

THE importance of a uniform and simple calendar is not a question which affords any ground for dispute. Whether regarded from the point of view of the chronologist, striving to evolve order out of regnal years and intercalary months, or from that of a business man in Cairo, transacting affairs with clients who adhere severally to the Moslem, the Coptic, the Hebrew, the Julian, and the Gregorian calendars, the diversity of system from time to time, from place to place, and between creed and creed, is an exasperating and unmixed misfortune. The New Year festival is celebrated by the motley races which go to make up the population of Singapore on dates which extend over several months. In Constantinople, until quite recently, even the division of the day was a source of grave inconvenience, since the day ended at local sunset. The persistence of such anomalies shows how hard is the way of the reformer. Tradition and religious scruple, and even the mere inertia of custom, are leagued against him. From the point of view of the whole world, a far greater advance would be made by any large step towards the adoption of one universal calendar than by making small theoretical improvements in a par-

ticular system, however important that system may be. Whatever happens, it is certain that the Gregorian calendar in its main features will survive. For this reason alone its reform is not to be lightly undertaken. A universal appeal can only be based on fixity of tenure as a necessary condition. The French Republican calendar should at least be useful as an awful example. Even the Chinese are considering the advisability of eliminating the lunar element from their calendar and following European practice. Hence changes in our calendar can only be admitted after their necessity has been absolutely proved, and then only with the utmost deliberation. It is not a matter in which a false step can be easily retraced.

It is an unfortunate fact that a calendar of ideal simplicity is precluded by the nature of things. Much difficulty would have been avoided had the tropical year, the synodic month, and the mean solar day been commensurate periods of time, and if, moreover, the number of days in a year had contained certain simple factors. With the Julian calendar, it is true, the lunar month has been placed out of consideration. But the week remains as a fundamental unit of time in human affairs. If only the year had contained 336 days, absolute simplicity would then have been attainable. We should then have had four equal quarters of three months each, each month containing exactly four weeks. As things are, we must be content with something less simple, and, even so, commensurability between the year and the week can only be obtained by placing one day (or two days in the case of leap year) outside the ordinary run of the calendar. This is the suggestion of Mr. Philip, of Brechin, who has proposed that the first day of the year should be thus set aside under the name of New Year's Day, while in leap years a second day of the same kind should be intercalated between the months of June and July. The idea is not, of course, original in principle, for it was used by Auguste Comte in a slightly different way, and has been attributed to Littré. It offers the only means of avoiding a change in the calendar from year to year, and is to this extent attractive. But it has the great disadvantage of introducing discontinuity at the very point where continuity has been preserved in the face of many other changes. The week can boast a most ancient lineage, uninterrupted by the slightest break. Prejudice in its favour must be anticipated, and weighty reasons must be adduced if this feeling is to be overcome.

It has already been pointed out that nature is greatly to blame for not having given us a year of exactly 336 days. Even when the one or two inconvenient extra days have been specially provided for, there remain over just 28 days, and it is in the disposal of these that the calendar reformers have expended their ingenuity. Comte's plan was simply to form them into a thirteenth month, with the extra days at the end of the year. Apart from the peculiar nomenclature in which his philosophy found expression, it is far from clear that this plan has been improved upon by contemporary reformers. The only drawback seems to lie in the introduction of an extra month, and in the fact that a quarter must contain three months and an additional week.

Another proposal is that of Mr. T. C. Chamberlin, which was fully described in these columns (February 2). This consists in dividing the 28 days into four special weeks placed at the end of each quarter. That this scheme should appear rather crude is not unnatural, and to this extent stronger support may be expected for a plan proposed by Mr. John C. Robertson at the fourth International Congress of Chambers of Commerce held in London in June of last year. This would incorporate the extra weeks in each third month, so that each quarter would consists of three months, containing respectively 28, 28, and 35 days. In this way each month would begin with a Sunday, but it is far from certain that the advantage thus gained would be generally regarded as a fair equivalent for the patent disadvantage involved in the disparity between the months. It would appear that approximate equality was more important in the months than in the quarters.

This consideration seems to have had weight with those responsible for the Calendar Reform Bill presented to Parliament by Mr. Robert Pearce. The Swiss Government, at the instance of the London Congress of Chambers of Commerce already mentioned, has invited an international conference on the subject of the calendar, a proposal now receiving the attention of the British Government, and the Bill is intended as a basis for imperial conference. It is proposed to divide the reduced year of 364 days into four similar quarters, each containing three months of 30, 30, and 31 days respectively. With twelve months no better approach to equality is possible. Moreover, the calendar becomes fixed, in the sense that any given date will fall on a particular day of the week, *e.g.* Christmas Day will always be on a Monday. But there will not be that simple correspondence between the day of the month and the day of the week provided by the other schemes. In practice it will be just as necessary to consult an almanac as at present, and the only difference will be that the almanac will be the same for every year. Is this an appreciable benefit? Almanacs are so common, and so often distributed gratuitously, that few people would probably feel the change from year to year, were it not for a circumstance which has purposely been left for separate consideration. As a matter of curiosity, it may be noted that the Royal Academy of Sciences at Stockholm receives a considerable income from a monopoly in the sale of almanacs.

The circumstance just alluded to is the varying incidence of Easter. Owing to the public holidays associated with this festival, and for other reasons, the desire for a fixed date has been very generally felt and often expressed. The Western Church has followed the ecclesiastical moon as defined by the Council of Nice, and the time seems ripe for removing this last remaining vestige of a lunar cycle from our calendar. It is understood that the Pope has raised no objection to this being done, and it is not to be supposed that the other churches concerned will prove "katholischer als der Papst" in this matter. The German Reichstag will be asked to pass a resolution in favour of the appointment of a definite Sunday on which Easter shall be celebrated. The Bill before Parliament proposes that April 14 shall be Easter Sunday. The fixing of this festival is an integral part of the schemes described above for reforming the calendar, and will engage the attention of the diplomatic conference proposed by the Swiss Government. The precise date must be fixed by international agreement, and the mere verbal definition of the date will naturally be facilitated if a fixed calendar has been previously adopted. But the two questions are essentially independent, and Easter can be fixed with all the precision required for practical purposes without any change in the present calendar. Thus if Easter were defined as the Sunday following April 10, it would never be more than three days from April 14, and would fall automatically on the latter date if the scheme now before Parliament were afterwards adopted. But other dates will probably be suggested for consideration.

The internal arrangement of our calendar is in the

nature of things a compromise, and the divergence between the schemes which have been brought forward proves that the reformers are by no means of one mind. The ordinary man does not seem impressed with the necessity for a change. It is alleged that the business man feels some inconvenience, but the English accountant would surely gain far more benefit from a decimal currency than from a fixed almanac. Meanwhile the Board of Trade is very properly taking steps to learn the opinions of the merchants and traders of the country.

It is, of course, mere child's play to invent a calendar. The objection to interrupting the consecutive run of the weeks must be strongly felt. One wonders therefore that none of those who appear to be so much impressed with the advantage of subdividing a year of 364 days have not, so far as we are aware, suggested another plan for getting rid of the superfluous days. This could be done by using the week instead of the day as the unit of intercalation. We begin by allotting 364 days to the common year. We then add at the end of every fifth year (the date ending with 0 or 5) a special "leap" week. This in itself would make the year on the average too long. We therefore omit the "leap" week every fifty years, when the date ends in 25 or 75; and, further, we omit the week at every century which is divisible by 4 (the reverse of the Gregorian rule). The result is to add 71 weeks or 497 days in 400 years, thus making the average length of the year 365·2425 days, or exactly the same as the mean Gregorian year. The special week would probably be found a nuisance, but it would only come once in five years, and it has been seriously proposed to introduce four such weeks into every year! Of course, under this plan, the date of the equinox would wander eight days on either side of the mean date. At the sacrifice of simplicity it would be more correct to intercalate eleven weeks in each successive period of 62 years, at the intervals:

6,6,5, 6,6,5, 6,6,5, 6,5 years.

By this rule the equinox would be kept within four days of a given date, while the mean length of a year would be slightly more accurate than in the Gregorian system. Such a variation from the mean date would not be likely to constitute a practical objection. The idea, however, is only suggested in order to illustrate the unexhausted possibilities which lie before the would-be calendar reformer.

H. C. P.

THE UNVEILING OF NUBIA.[1]

LESS than four years ago practically nothing was known of the true history of that stretch of the Nile Valley, immediately above the First Cataract, which is known to us to-day as Nubia, beyond a few ancient Egyptian stories of raids and conquests, and the tales, often enough fantastic and unreal, of Greek and Roman tourists. In one brief winter's work (1907–8) Dr. Reisner and his collaborators have changed all that. For they have recovered from the soil of Nubia the materials for reconstructing the main phases of the history of that country's strange vicissitudes during the last fifty centuries, as well as a great mass of precise information concerning that crucial period in her evolution, when, about twenty-seven centuries before the Christian era, she began to lag behind Egypt and take her own wayward course, which earned for her the ancient byword "wretched" Nubia.

It has now been demonstrated that in predynastic times, *i.e.* before Upper and Lower Egypt became united under Menes, the first king of the first dynasty (*circa* 3400±100 B.C.), and until the end of the third dynasty (*circa* 2700 B.C.), Egypt and Nubia were culturally (and, as is shown in vol. ii. of this report, racially also) one territory; but, from the time roughly corresponding to the beginning of the period of the Pyramid-builders in Egypt, the histories of the two countries began to diverge the one from the other, Egypt advancing by rapid strides towards national greatness and the attainment of her highest artistic and architectural triumphs; while Nubia was not able even to maintain the old standard of archaic culture, for her people lost their cunning at the same time that their racial purity became tainted with negro blood.

In the time of the Middle Kingdom (*circa* 2000 B.C.), when Egypt for a second time was raised on the crest of a wave of prosperity, Nubia also felt the same influence, and began to exhibit marked signs of progress and the attainment of a distinct individuality; then for the first time her people began to manufacture wares that were not merely inspired by Egypt or imitations of Egyptian workmanship, but deserve to be called Nubian. And if it be admitted that the Nubian arts and crafts show obvious traces of their derivation from the archaic Egyptian, it is also clear that they were developed in a manner strikingly different from those found in Egypt in dynastic times. In the first products of these distinctively Nubian arts we can detect, as also in the remains of the people who made them, an underlying stratum of predynastic Egyptian influence, modified by negro admixture, but evolved in a manner quite distinctive of and confined to Nubia.

Egypt and Nubia each went its own way and evolved along the distinctive lines they had respectively chosen, until a time shortly before the inauguration of the New Empire in Egypt. The passing of Egypt under the sway of the Asiatic Hyksos domination had the effect of driving many Egyptians into voluntary exile in Nubia; this led to a displacement of the Nubian population southwards; characteristic Egyptian graves, containing Egyptian wares and the remains of Egyptian people, made their appearance in Nubia at this time; and evidences of Egyptian occupation of the country were abundant throughout the period of the New Empire.

But when Egyptian power began to wane, the Nubians came into their own once more; but as they returned from the south strangers accompanied them, and, ever after this event, from time to time there were incursions of aliens into Nubia; sometimes tall, Dinka-like negroid warriors, with their own distinctive burial customs; later still, Egyptians of the Ptolemaic and Roman periods occupied Nubia and left the characteristic evidence of their stay in the country, as well as the bodies of criminals of non-Nubian type—perhaps the notorious Blemmyes of the Eastern desert, the mysterious people to whom the classical writers so often referred—whom they had executed; then again, in the early centuries of the Christian era, but before the introduction of Christianity into Nubia, another group of Negroes came north into Nubia, and in the graves of their dead buried their own distinctive pottery, which is neither Egyptian nor Nubian; and in Christian times aliens from Syria and western Asia took refuge beyond the First Cataract.

Nubia was ever a poverty-stricken land; to add to her natural disabilities, her geographical position rendered her liable to be overrun by all these alien hordes, and made her the meeting-place of Egyptians and Negroes and the cockpit where they fought.

[1] "The Archæological Survey of Nubia. Report for 1907–8." Vol i., Archæological Report. By Prof. G. A. Reisner. Pp. v+373+330 text-figures. Plates and plans to accompany vol. i. Pp. 24+73 plates+xxx plans. (Cairo: National Printing Department, 1910.) Price 2 l.e.

This distressful country well earned her ancient title, "wretched Nubia."

In the report of the archæological survey of Nubia there is presented a complete and impartial description of all the historical material thus rescued from the soil, critically sifted, arranged in chronological order, tested by Egyptian criteria, and explained and interpreted.

But in this volume Dr. Reisner has done something more than recover the lost history of Nubia, wonderful as is such an achievement in one short season's work, for he has also given the first adequate and trustworthy account of the earliest stages in the evolution of Egyptian civilisation. It is true that this has often been attempted by other writers: but in all cases fact has been so interwoven with fancy that the pictures painted have been more or less distorted travesties of the truth. Dr. Reisner's report will ever bring the work to the triumphant issue presented in this report. This is no mere idle compliment to Dr. George A. Reisner, assistant professor of Harvard University, who was chosen for this work; for he had a far more exact and intimate knowledge and experience of digging in Egypt such sites as were of crucial importance in Nubia, and had learnt thereby to appreciate the fine distinctions that enabled him to discriminate between archaic burials closely related in time, the one to the other, and to realise the early stages in the divergence between Egyptian and Nubian burial customs before they became obtrusive. It was the possession of this special knowledge that determined the issue in Nubia; and no impartial observer can deny that Dr. Reisner was the man most highly qualified to undertake this work.

No one who was privileged to witness the excavation of the first site dug in the course of this survey

FIG. 1.—The aspect of Nubia near Dabod during the inundation by water held up by the Aswan Dam. From "The Archæological Survey of Nubia."

remain a storehouse of accurate information concerning the springs of Egyptian civilisation, and a work of fundamental importance to all students of the beginnings of culture in other lands.

In the preface to this volume Captain H. G. Lyons, F.R.S., formerly director-general of the Egyptian Survey Department, now lecturer in geography at Glasgow University, explains why this survey was undertaken, and describes the measures adopted to make it as thorough and searching as possible; but he does not tell the reader that to him belongs the credit of initiating and organising the excellent plan of campaign in Nubia.

When Captain Lyons was entrusted with the task of arranging for carrying out the proposed survey, he was singularly fortunate in securing probably the only archæologist competent (in the sense that his training and experience specially fitted him to cope successfully with the tangled problems of Nubia) to (see chapter iv.) can fail to realise the enormous difficulties that had to be overcome before even the alphabet of Nubia's history could be read, and that these difficulties were eventually resolved only by the employment of the most rigorous scientific methods and painstaking analysis of a complicated mass of data, and by the command of an exceptional knowledge and experience to explain them.

In the vast plain surrounding the southern terminus of the Egyptian railroad at Shellal there had been buried the remains of people who had died at every historic period during the last fifty centuries, not only in graves of known Egyptian forms, but in a variety of then unknown Nubian and Sudanese types. Every kind of confusing element was present to complicate the problem: cemeteries of one period intruded in those of earlier date, so that graves of the most varied periods and peoples were apparently inextricably intermingled; the results of the plunder-

ing of graves, both in ancient and modern times, added to the confusion; and the denudation of the plain by the forces of nature in ancient times had destroyed many, and seriously damaged still more, of the graves. The failure to reduce this chaos to order would have gone far to sterilise the essential work of the survey. The results obtained at Shellal gave Dr. Reisner at the outset the whole history of Nubia in epitome; and all the work since accomplished farther south during the last three years has confirmed the accuracy of the conclusions drawn from the study of "Cemetery vii.," while filling in the details of the story that it summarised.

One of the factors that greatly enhances the significance of this report cannot be appreciated without some reference to Dr. Reisner's work before the Nubian survey began. After acquiring a knowledge of Oriental work in Harvard University, he had studied Babylonian and Egyptian philology and archæology, and contributed to the work of cataloguing the collections in the Berlin and Cairo Museums; then in 1899 he began excavating in Upper Egypt as head of the Hearst Expedition of the University of California, and in 1903 at the Giza Pyramids, at first for California, but later, from 1905 onward, for the Harvard University and the Boston Museum of Fine Arts.

During these years, 1899-1907, he and his collaborators, Messrs. Lythgoe and Mace, had devoted the whole of their time and energies to the detailed and critical study of remarkably complete series of burials of the predynastic and early dynastic epochs, in the course of which they were able to sweep away a lot of myths concerning the practices of the early Egyptians, which the fertile imaginations of other explorers had created, and to piece together, bit by bit, the accurate information they themselves laboriously gathered. Unfortunately this expedition was so busily engaged in collecting information that its members found time to impart only a very small fraction of their rich harvest to the public ("The Early Dynastic Cemeteries of Naga-ed-dêr, I.," by Reisner, 1908, and "II.," by Mace, 1910). It is this fact that renders the Nubian report of such importance, for in the remarkable chapter vii., Dr. Reisner draws aside the veil from his vast storehouse of knowledge of Egypt's archaic civilisation, and gives us more exact and detailed information of the pre- and protodynastic periods in the Nile Valley than has hitherto been published.

Another important factor that contributed in no small degree to the success of the Nubian excavations was the systematic training which Dr. Reisner's native workmen had received during their nine years' association with him in Egypt; each man had learned to do his allotted task as a matter of habit, and each became a specialist in some branch of the work, such as prospecting for sites, excavating, cleaning graves without touching or disturbing their contents, and doing all the routine work of making a complete photographic record of every stage of the survey. In chapter ii. Dr. Reisner describes these methods, and in the magnificent volume of plates—in itself one of the completest records of archæological research ever issued—will be found ample evidence of the skill displayed by these illiterate Egyptian boys in the practice of the art of photography and the no less difficult task of systematic scientific excavation.

FIG. 2.—The earliest distinctively Nubian pottery. From "The Archæological Survey of Nubia."

In the work of excavation and the examination and recording of the results, Dr. Reisner was assisted by Mr. Cecil M. Firth and Mr. A. M. Blackman. The major portion of this report consists of their detailed and impartial record of every fact brought to light in the course of their work, illustrated by an exceptionally complete series of photographs and hundreds of text-figures. These results are presented in such a form that anyone who wants to draw his own inferences has all the facts presented to him without bias.

In the last three chapters there is a masterly summary of all the evidence acquired during the first season's work in Nubia, arranged and classified, and

compared with the collateral data obtained in the course of Dr. Reisner's work in Egypt.

In an appendix Mr. W. H. Crosthwaite describes the topographical work carried on by himself, Mr. T. D. Scott, and Mr. G. W. Murray, and their maps, printed in the Survey Department, appear in the volume of plates.

There are complete lists of cemeteries excavated, graves, objects found, and an index.

This report deals only with the first season's work. During the second season Dr. Reisner had to relinquish work in Nubia in order to take charge of excavations in Samaria and at the Giza Pyramids; but the first winter's work proved to be so illuminating that Dr. Reisner was able to hand over to Mr. Firth, who succeeded him, a knowledge of the history of Nubia, which has amply been confirmed at each new site. This winter the survey will reach Korosko and be brought to a conclusion.

When the final results are published the Egyptian Government may congratulate itself on having provided the means for completing the most thorough archæological examination of such an extensive tract of territory, as Lower Nubia is, that has ever been undertaken.

It only remains to express the hope that the unique collection of antiquities collected with such infinite care and skill, and constituting a tangible record of the history of Nubia, will receive the treatment they deserve.

G. Elliot Smith.

GERMANY AND THE PROTECTION OF NATURE.

THE German intellect has a wonderful turn for organic science. Its achievements in this sphere are admittedly unrivalled, and the workers may be counted by the thousand. Such names as Hofmeister, Haeckel, Virchow, Weismann, Sachs, Pfeffer, and Verworn are only a fraction of one per cent. of the list. Consider, for instance, the contributions to a single department, as shown annually in Just's "Botanische Jahresberichte." The typical English attitude, on the other hand, to nature, and especially to organic life, is hardly that of sympathetic study. It may rather be described as amused, or patient, condescension. This patronising habit receives its only modification in the case of "sporting" animals, or the more spectacular birds and mammals; and these are but the materials for a "show," *pour passer le temps.* The Press pours out a flood of "nature books," as the factories pour out toys, to amuse the children. Popularisation is the curse of the age. An up-to-date book on any branch of organic science is not to be found. Instead of a regular issue of sane, scientific accounts of progress, we have outlines for the use of schools, or productions the aim of which is the titillation or excitement of the unintelligent by means of the illustrations, if it cannot be done by the text. Work that does count appears not more often than once in a decade. It is consequently soon out of date. Such books, moreover, are generally too encyclopædic, and their allocation to different departments is far from being scientifically impartial. The various meanings of the term "nature" supply a most interesting study: a corollary may be found in the meanings of the term "natural history." If so vague and obsolete a term is still to be used it should connote the science of all nature, as did the good old phrase "natural philosophy."

The practical English instinct also wastes much energy in exploiting the principle of "design" in nature, and in exercising the habit of "drawing a moral." But it is really far more practical to confine the attention to the mechanism of the phenomena, and to leave teleology to metaphysics. Here, and in other matters relating to the study of nature and to the practical application of science, the German intellectual habit can give us a lesson.

It is refreshing to see a great scientific, and veritably practical, movement carried on without any pandering to amusement, pedagogy, or sentimentalism about "nature." This is distinctly the character of the scheme, the progress of which has frequently been noted in these columns, to preserve the natural monuments of Germany. The term comprises the humblest lichen no less than human monuments, such as the Porta Westfalica.

In Prussia the scheme is highly organised and is a State department. Here we see the cooperation of what we should call municipal and district and county councils with, practically, every man of science in the province, and every voluntary society or association. The German Emperor is patron of the committee for the Hohenzollern district. Every square mile of the country is investigated; when anything approaching a "centre," whether geological or ecological, or even for one characteristic species of animal or plant, is found, that centre receives State protection. The protection, it is well to note, is efficient. The maps printed in the first volume of the "Beiträge" show a remarkable list of such centres reclaimed for nature from man.

This volume of 500 pages records the work done in Prussia during the last five years. The editor, Dr. H. Conwentz, has from the commencement been the moving spirit of the scheme, and he is to be congratulated on a remarkable record of success. But, as we have tried to show, the ultimate factor in this success is the German scientific spirit, which here has the advantage of cooperating with patriotism. It will deserve still more of humanity if its example in this matter is able to inspire other countries.

A large proportion of the volume is occupied by reports, now collected, which were noticed in Nature on their first appearance. The most noteworthy of the new matter is a long and very interesting account of the parallel movement in Denmark, with which the distinguished botanist, Prof. E. Warming, has had much to do. Even a country like Denmark is full of interesting centres of wild nature. The protected colony of *Sterna anglica* is particularly noticeable. The lengthy report of the second conference for *Naturdenkmalpflege* in Prussia, held at the end of 1909, reveals a remarkable combination of enthusiasm and organisation. What especially appeals to us in the whole scheme is its thoroughness and comprehensiveness. We read of a score of "bird reservations," and we find that the protection is more than a mere name. We also read—and to the English mind it reads very strangely—of State-protected wild flowers. Of protected landscapes, "beauty spots," Prussia has about forty: bits of geological interest number, so far, about thirty. What are significantly styled the "remains" of the plant-world and the animal-world are fairly numerous, but we should suppose the lists to be capable of considerable extension. The foreign reader may desiderate the Latin name in every zoological and botanical species cited. This is not always given, and the disentangling of identity from popular German terms is not easy.

[1] "Beiträge zur Naturdenkmalpflege." Edited by Prof. H. Conwentz. Erster Band. Pp. xi+510. (Berlin: Gebruder Borntraeger, 1910.) Price 10 marks.

A very precarious but highly interesting operation is that of assisting the development and propagation of wild creatures and wild plants in their natural homes. Some observations have been made on the subject now and again, and a few isolated experiments are on record, already suggestive of remarkable correlations between development and environment. The principles behind such correlations are wide reaching, and, as ecology has begun to show, of great practical importance. In due course, no doubt, the German scheme will include such experiments, care being taken to prevent that very easily obtained result, the absolute extinction of a species.

A. E. CRAWLEY.

THOMAS RUPERT JONES, F.R.S.

BORN in Wood Street, Cheapside, on October 1, 1819, Rupert Jones, after a long and eminently useful geological career, passed away in his quiet retreat at Chesham Bois on April 13, in his ninety-second year. His father, a silk merchant and throwster, had business premises in Taunton as well as in London, and Rupert Jones spent his early years in Somerset, receiving school education at Taunton and Ilminster. There the fossiliferous beds of the Lias attracted his attention, and the bent of his mind was directed towards science rather than commerce. In 1835 he was apprenticed to a surgeon at Taunton, and he completed his service at Newbury. Geology absorbed all his spare time, and many of his early observations in the neighbourhood of that Berkshire town were published in a pamphlet in 1854. After 1842 Rupert Jones was engaged for some years, chiefly in London, in medical practice. Familiar with the use of the microscope, he applied it with signal success to the study of fossil microzoa. His researches now brought him into contact with William Harris, of Charing, who had gathered a fine collection of Chalk fossils, including the minuter organisms. That geologist also possessed a daughter who became the first wife of Rupert Jones.

In 1849 his monograph of the Entomostraca of the Cretaceous formation of England, his earliest important work, was published by the Palæontographical Society. In the following year he was appointed assistant secretary to the Geological Society of London at Somerset House, where his ability and precision were shown in the editing of the society's quarterly journal. Ever busy, he edited during the years 1854–58 the last editions of Mantell's "Geological Excursions round the Isle of Wight," "Medals of Creation," and "Wonders of Geology." He likewise prepared for the Palæontographical Society further important monographs on the Tertiary Entomostraca (1856), and on Fossil Estheriæ (1862). In 1858 Rupert Jones was appointed lecturer on geology at the Royal Military College, Sandhurst, and four years later professor, when he resigned his post at the Geological Society, and removed to Farnborough, in Hampshire. In association with Dr. Henry Woodward he edited the first two volumes of *The Geological Magazine* in 1864–65, and among other works edited the "Reliquiæ Aquitanicæ" of E. Lartet and H. Christy (1875), and the second edition of "Dixon's Geology of Sussex" (1878).

His special studies were not neglected. He contributed to scientific societies and journals numerous original articles on recent and fossil Foraminifera, and Entomostraca (Ostracoda and Phyllopoda), subjects on which he came to be recognised as the leading authority in this country. Much work, moreover, was done in conjunction with his friends, W. K. Parker, H. B. and G. S. Brady, Henry Woodward, J. W. Kirkby, and others. Thus he received aid in the preparation of the monographs on the Foraminifera of the Crag (1866–97), and on British Carboniferous Entomostraca (1874–84). In 1880 Prof. Jones retired to London as the special teaching of geology at Sandhurst was then abandoned by the military authorities.

His interests extended over a wide geological field, and he had a profound knowledge of the literature. South African geology especially attracted him. In later years he gave much attention to the antiquity of man, and wrote on the plateau implements in 1894. Of sturdy build, though below the average height, he was of a cheery disposition, prone to jocularity, but ever ready to give earnest help to others. Proof-correcting he regarded as one of his recreations. Prof. Jones was elected F.R.S. in 1872, and the Lyell medal was awarded to him in 1890, by the council of the Geological Society. He was president of the Geologists' Association in 1879–81, and president of the Geological Section of the British Association at Cardiff in 1891.

H. B. W.

NOTES.

A MOST important discovery in regard to the existence of man in early Pleistocene or Pliocene strata has been made by the Marquis of Cerralbo in Spain. In the alluvial deposits of the River Jalon, which is an affluent of the Guadalquiver, he has discovered very abundant remains of undoubted *Elephas meridionalis* in contact with well-characterised implements of human workmanship of the proto-Chellean type. Photographs of the specimens and of the cuttings in which they occur have been received from the Marquis in Paris, and Prof. Marcelin Boule left Paris in Easter week in order to examine the site and the specimens. It is possible that *E. meridionalis* may have survived in the south of Europe from Pliocene into early Pleistocene times, but the association of implements of human workmanship with this early species of elephant is altogether new. This discovery tends to confirm the truth of Mr. Moir's contention that the admitted proto-Chellean flint implements discovered last year by him in Suffolk, and exhibited at the Geological Society in the autumn, are really anterior to the Red Crag deposit beneath which they occur. It is to be hoped that Mr. Moir will soon publish an illustrated account of his discovery.

A VERY interesting expedition is about to visit the neighbourhood of Astrakhan. It consists of a party of trained medical observers, provided with all appliances for research, organised in Paris, and under the personal direction of Prof. Elie Metchnikoff. The object of the expedition is two-fold. It will study the history of the endemic foci of plague in the neighbourhood of Astrakhan. The cause of the repeated outbreak of plague in this region, which although usually on a small scale is of almost regularly annual occurrence, will be investigated in the light of our present knowledge of the relation of rat-like animals and fleas to plague. A second object is to investigate the causes of the singular difference of susceptibility to phthisis presented by the Calmuck Tartars and the Russian town population. It appears that the Calmucks when living their usual nomadic life in tents are free from phthisis, yet when young Calmucks (semi-adult) are brought into the towns to be "educated," they invariably contract phthisis and die. What is the reason of the less susceptibility of the Russian town population? Is it due to immunity conferred by other microbes than that of tuberculosis which have escaped detection hitherto, and

are not present in the Calmuck communities, though regularly infecting and "immunising" the Russian town-dwellers in childhood?

The death is announced of Dr. A. J. M. Bentley, distinguished by his knowledge of tropical diseases and as the author of "Beri Beri, Its Etiology, Symptoms, Pathology, and Treatment."

The death is announced, at sixty-six years of age, of Dr. B. S. Ringer, formerly medical officer to H.B.M. Consulate-General and the Chinese I.M. Customs, Canton, China, and the discoverer in Formosa of a parasitic worm known as *Distoma ringeri*.

The Astronomical Society of France has just elected the following officers:—President, M. P. Puiseux, astronomer to the Paris Observatory; vice-president, Prince Roland Bonaparte; general secretary, M. Camille Flammarion; secretary, M. Jean Mascart; and treasurer, M. Maurice Ballot.

The Christiania correspondent of *The Times* states that on April 20 a Bill was brought forward providing for the necessary grant for wireless telegraphy stations at Hammerfest and Spitsbergen. The Spitsbergen station will be kept open all the year round, and will be in charge of three or four men. The distance from the Hammerfest station is 750 miles.

A fund has been opened for the purpose of presenting a testimonial to Mr. Henry Keeping, who has been for fifty years curator of the Geological Museum, Cambridge, and is now retiring from active work. There are probably many who will welcome this opportunity for expressing their appreciation of Mr. Keeping's long service in the cause of geology. Subscriptions should be sent to Mr. F. R. Cowper Reed, Sedgwick Museum, Cambridge.

A new system of wireless inductive telephony was inaugurated at Stratford-on-Avon on Thursday last, when Mr. H. von Kramer's "railophone" was tested on a train belonging to the Stratford-on-Avon and Midland Junction Railway. Two large frames—or coils—of wires are attached to the carriages, one being used for despatching messages and the other for receiving same. By means of induction between these coils and a wire running along by the side of the metals, but some distance away, and connected to instruments in the signal-cabins, messages can be received and despatched whilst the trains are in motion or standing. The test was successfully carried out, and a party of journalists and others were conveyed in the train for several miles, receiving or sending messages whilst *en route*. Eventually it is proposed to connect up the signal-cabins with the general telephone and telegraphic systems, thus making it possible to send and receive messages and telegrams to or from places far away from the railway whilst still in the train.

News of Captain Amundsen's Antarctic Expedition has been brought by Captain Nilsen, commanding the *Fram*, which arrived at Buenos Ayres a few days ago. It appears from a Reuter message that Captain Amundsen arrived in Antarctic regions on January 14, and the ship dropped anchor safely close to a comparatively elevated coast. Camp was established on a hill near where the *Fram* was moored, and preparations were begun for a journey to the Pole. The *Fram* sailed on February 14, before Captain Amundsen had started for the south. In a few weeks the vessel will leave Buenos Ayres for scientific work during a voyage between Africa and South America, and will then return to Buenos Ayres to renew her stores. Captain Nilsen expects to be able to leave Buenos Ayres on October 1 in search of Captain Amundsen and his party.

The death is announced of M. Edouard Dupont, director of the Royal Museum of Natural History in Brussels, and well known for his researches in many departments of geology. An appreciative notice by M. Cornet appears in *Le Mouvement Géographique* for April 9. M. Dupont was born at Dinant on January 31, 1841, and died at Cannes on March 31 of the present year at the age of seventy. His work in connection with the preparation of a geological map of Belgium is well known in the British Isles, and the complete skeletons of Iguanodon, discovered in the clays of Bernissart, were set up in the museum in Brussels under his care. While the palæontological collections were extended through his personal studies, he paid attention also to the stratigraphical conditions under which the rocks of Belgium were laid down. His researches were especially directed to the Carboniferous Limestone, in which he recognised a coral-reef type and also calcareous fragmental deposits of a pelagic character. In 1887 he made an expedition at his own expense to the Congo territory, the results being published in a book entitled "Lettres sur le Congo," in which geological, botanical, and anthropological observations were happily combined.

The experiments of Mr. Glen Curtiss with his hydro-aëroplane have culminated in the production of a machine capable of running over land and travelling on the water with the same facility with which it rises from either of these elements into the air. His original model was fitted with two floats, a water-shield, and a large pontoon, but in his latest production only a single pontoon is used. This pontoon is rectangular in plan, 12 feet long, 2 feet wide, 1 foot deep, and 50lb. in weight. Its under surface curves up to meet the upper surface 3 feet from the front edge; similarly, its upper surface curves down to meet the under surface 3 feet from its rear edge. The aëroplane itself is of the usual type of Curtiss biplane, and carries under each extremity of the lower plane a skid, 4 feet long, to prevent the plane tips touching the water when turning upon it. Wheels are fitted in front and behind the pontoon. The aëroplane has made many successful flights at San Diego Bay (Cal.), rising easily into the air, and after flights gliding down to water, upon which it alighted without a splash. The diminution of speed caused by the head-resistance of the pontoon, which, as will be understood, does not possess the stream-line form, is said to be about five miles an hour.

Dr. Petrie's discovery, which is reported in *The Times* of April 15, that the marmot is the host of fleas of very large size, may prove of considerable importance in connection with the study of the epidemiology of plague in Manchuria. Although it appears highly improbable that an epizootic has played any part in the outbreak in Manchuria proper, there is ample confirmation for the hypothesis that, in regions further west, the epidemic is derived from marmots. These animals, locally known as "tarbagans," are hunted for their skins. The occurrence of plague epizootics among them has been recognised for some years, but it is not known what form the disease takes, nor how it may be transmitted to the hunters. This demonstration of the existence of the marmot flea indicates a possible link in the chain of infection, and it is not improbable that future investigations will show that, in Manchuria, the marmot flea may to some extent play the same part as the rat flea in India. In the meantime, it cannot be said that this discovery brings us much nearer

to an explanation of the epidemic in Manchuria. No adequate reason has yet been found for the wide dissemination of the disease, at a season when few fleas of any kind are to be encountered. The appearance of the disease in a pneumonic form of exceptionally high virulence affords also a problem which still requires an answer. Although the Chinese epidemic has attracted so much attention, it becomes almost insignificant when compared with the ravages of the disease in India. Prof. Simpson, in a letter to *The Times* of April 17, directs attention to the enormous plague mortality in the United Provinces of Agra and Oudh, districts of which the joint population is little greater than that of the British Isles. Upwards of 72,000 persons died of plague in these provinces during March, and in the week ending March 25 the number of deaths reached the appalling figure of 22,000.

The number of Easter vacation workers at the Port Erin Biological Station has this year, for the first time, exceeded fifty. The universities and university colleges of Birmingham, Cambridge, Cork, Liverpool, Manchester, and Reading are represented by members of their biological staff or by senior students; and the researchers include:—Prof. B. Moore and Mr. E. Whitley (bio-chemistry), Mr. Walter Tattersall, and Mr. E. W. Shann from Manchester, Prof. Cole from Reading, Mr. Douglas Laurie from Liverpool, a group of botanists—Prof. Harvey Gibson (Liverpool), Mr. J. C. Johnson (Cork), and Mr. R. H. Compton and Mr. S. Mangham (Cambridge)—working at algæ, a group of planktologists from Liverpool, including Mr. W. Riddell, Dr. W. J. Dakin, Prof. Herdman, and others. The new wing of the Biological Station, which was erected last winter, is now fully occupied by the researchers, and the larger laboratory is crowded with senior students. If numbers continue to increase, a further extension in the near future will certainly be required. The fish hatching is proceeding as usual. The first fertilised eggs of the plaice appeared in the spawning pond this year on February 13, but after that the cold, tempestuous weather seemed to delay the spawning, as the total numbers passed through the hatching-boxes up to date (April 20) are behind those of last year. The number of visitors to the aquarium of the institution is, however, considerably in advance of last year. Periodic observations on the plankton at sea are being taken from Prof. Herdman's yacht *Runa*, and the outstanding fact in this season's work, so far, is that the diatoms are unusually scarce and late. The vernal phytoplankton maximum has not yet arrived.

In the Australian monthly, *The Lone Hand*, for February, Prof. J. Macmillan Brown discusses the question of the White Gods of Ancient America. He points to the singular fact that among the races of the Isthmus there is a large sprinkling of blonde-haired, blue-eyed, European-like men and women, whose origin is not to be explained by the theory of descent from the white emigrants of later historical times, this more recent European type being rapidly modified by environment and miscegenation, and quickly disappearing. He also refers to legends of the arrival in America of bearded white strangers, like Manco Capac. These stories, like the stone culture, are mainly confined to the Pacific littoral and the neighbouring mountain ranges. To explain these facts Prof. Brown postulates a Polynesian, that is to say, ultimately a Caucasian, immigration which passed northwards from Peru, from which direction he assumes that the culture represented by the Palenque ruins and that of the Astecs had its origin. It can scarcely be said that the facts which he has collected prove his theory; but the problems of the origin of Central American civilisation are so perplexing that this suggestion deserves consideration.

Hitherto it has been generally believed that the paper read before the Society of Antiquaries in February, 1785, by W. Marsden, entitled "Observations on the Language of the People commonly called Gypsies," in which, from materials collected in 1783–4, he announced the similarity of Romani to some Indian dialects, was the first publication of the fact in this country, though it had been anticipated on the Continent by Rüdiger and Grillman. In *The Gypsy-Lore Journal* for January, Mr. J. Sampson advocates the prior claims to this discovery of Jacob Bryant, the author of that fantastic and now wholly useless treatise on mythology, "The New System, or an Analysis of Ancient Mythology." At the meeting of the Society of Antiquaries in the April following the receipt of Marsden's communication, that of Bryant, "Collections on the Zingara Gypsey Language," was read. The glossary of Bryant has now little value, and abounds in curious mistakes; but Mr. Sampson proves that the material was collected at least as early as 1776; and, if this be so, Bryant has the honour of having anticipated not only Marsden, but also the Continental philologists in this remarkable discovery.

In the January number of *The Gypsy-Lore Journal*, Mr. D. F. de l'Hoste Ranking begins a useful analysis of the account of the beliefs and sociology of the Gypsies of Central Russia recently collected by Mr. V. N. Dobrovolski. This branch of the Gypsy race strongly insists on its Egyptian origin, and even assigns to Pharaoh the useful invention of the "jemmy," which enables them to tackle modern locks. They are on a much higher plane, as regards intelligence and culture, than the peasantry among whom they live. They possess, for instance, an elaborate system of defining time by the motions of the stars, a survival of their primitive nomadic life. Their most cherished possession is the whip, and the association of it with the marriage customs of the tribe, which Mr. Ranking suggests to be connected with marriage by capture, is more probably intended to expel the evil spirits which beset the bride and bridegroom at this crisis of their lives. The use of the doll in the betrothal rites seems to be based on a mimetic fertility charm. Their polytheism has now widely absorbed the national reverence for the ikons; and another form of magic includes the use by thieves of a candle made of a dead man's fat, the "Hand of Glory" of the "Ingoldsby Legends." Mr. Ranking suggests that the *provenance* of this last superstition may form an important link in the chain of evidence which may solve the problem of Gypsy origins, and he pleads for special inquiries regarding this belief.

Messrs. E. Leitz have issued a very useful pamphlet on the microscope and how to use it. The path of the rays, the meaning of aperture, resolving power, illumination, eye-pieces, and focussing are all briefly but fully explained, the text being illustrated with many excellent diagrams.

The Eugenics Review for April (iii., No. 1) contains an interesting and suggestive article, by J. H. Kohlbrugge (translated from the German by J. H. Koeppern), on the influence of a tropical climate on Europeans. It is pointed out that no white race has been able to survive in the tropics unless race-mixture has taken place, and as the white races cannot become really acclimatised, and as it is doubtful whether we can achieve satisfactory results by race blending, it is concluded that we can neither take the place of the native nor do without him

Miss Chick and Dr. Martin give an interesting summary, with new experiments, on the readiness with which various rat fleas bite man (*Journ. of Hygiene*, xi., 1911, No. 1). The matter is of importance with reference to the spread of plague. They find that the common rat flea of temperate regions (*Ceratophyllus fasciatus*) readily bites man. Two more specimens of *Xenopsylla cheopis*, the common rat flea of India and other parts of the tropics, have been captured by Dr. Boycott at Guy's Hospital. Only one specimen of this flea has hitherto been recorded in England. The destruction of fleas by exposure to the sun is dealt with by Captain Cunningham, I.M.S., in No. 40 of the Scientific Memoirs of the Government of India. It is found that in the hot sun of India fleas die in about forty-five minutes, the result being chiefly due to the heat rays.

To Mr. F. L. Dames, of Berlin, we are indebted for a copy of "Bibliotheca Entomologica," a classified catalogue of entomological works and papers for sale at his establishment, containing, in this instance, 7633 items.

We have to acknowledge the receipt of a copy of the second number of *The Nature Photographer*, the official organ of the Nature Photographic Society. The feature of this issue is a portrait of a grey wagtail, which is a superb example of live-bird photography.

In our last week's number reference was made to a notice in the *Aarsberetning* of the Bergen Museum, of the recent scientific cruise of the *Michael Sars* in the Atlantic. A fuller and well-illustrated article on the same subject, by Dr. Johan Hjort, appears in *Naturen* for March and April. After an introductory notice of the object and extent of the cruise, attention is directed to the hydrographical results, which include observations on temperature and salinity taken at 110 stations, these being illustrated by maps and diagrams. After a short notice of the plankton, and another of pelagic animals, the deep-sea fishes taken during the cruise receive fuller attention, special interest attaching to the maps illustrating the localities where specimens of Cyclothone, Gonostoma, and Chauliodus were respectively taken.

Writing in his usual picturesque and attractive style, Sir Harry Johnston, in the April number of *The Quarterly Review*, pleads for the preservation of the fauna and flora, not only of the British Empire, but of the world at large. For he recognises that if effective measures are to be taken with this end in view, they ought to be taken without delay, "lest, before we can put in force regulations to save from destruction the rarer and more wonderful and beautiful of living forms on the earth's surface, they may be swept away for ever to gratify the whim or the taste of the uneducated many." Sir Harry puts the case in a very temperate manner, freely admitting that in many districts, East Africa for example, the claims of agriculture must be paramount, and that the wild fauna should be mainly restricted to reserves. In urging that such reserves should not be opened even to personages of the most exalted rank, the author has our full sympathy. Whether he is justified in his belief that the Lado white rhinoceros is even now in peril of extinction, may perhaps be doubtful; but we are in full accord with him in regarding a recent much-advertised slaughter of the species as altogether unjustifiable. That we ourselves are by no means blameless in such matters, is, however, proved by the evidence quoted as to the recent enormous destruction of sea-elephants in South Georgia.

In the February number of *The Cairo Scientific Journal*, Mr. F. Hughes discusses the amount of silt carried by the Nile during the floods of 1908 and 1910. Observations were made near Cairo and at points on the Rosetta branch of the river, and results in parts per million of from 1200 to 2000 were obtained. Some examples were collected from canals of various dimensions, and the reduction of coarser suspended matter in some cases in subsidiary canals was very marked after a short distance.

The Dutch Meteorological Institute publishes a series of observations obtained by means of kites on board ship in tropical latitudes. Forty-one ascents are given, 2360 metres being reached in one case. Naturally the sets of observations at any one place are few, but the material will be of value in connection with such other information as accumulates in these little investigated regions. Pressure, temperature, humidity, and wind force and direction are given.

In the April number of *The Geographical Journal* the positions of nineteen geodetic positions of stations of the Uganda are given. The War Office intend to publish a full account of the operations and calculations connected with this work, and in a second part to discuss the local attraction, based on a comparison between the above positions, and the astronomical latitudes now being computed by the Belgian astronomer, M. Dehalu. The same number contains a reference to Dr. K. Peucker's proposals for the colouring of relief maps, for which aërial locomotion has produced demand. His method is based on the teachings of physiological optics, and there is certainly room for a more scientific and less empirical study of cartography in this country than has hitherto obtained.

A geographical report on the Franz Josef Glacier has been published by the New Zealand Department of Mines. Mr. J. M. Bell, the director, examined the area in 1908 and 1909, a topographical survey of the glacier and its tributaries being made with theodolite and phototheodolite. A number of points were fixed and marked for future reference, for the frontal face of the main glacier is ever changing and it is difficult to determine its general direction of movement; on the whole, it seems to have retreated in recent times, and now stands at a point 692 feet above sea-level. Measurements of a series of points on the glacier surface gave rates of movement of from a foot a day near the side to about double this amount near the centre.

In "Extracts from Narrative Reports, 1907–8," of the Survey of India, are given more detailed results than can be included in the annual report. The diurnal variation of horizontal magnetic force was determined at Trichinopoly, in southern India; and a comparison of the magnetic instruments at Dehra Dun with those which Mr. D. C. Sowers, of the Carnegie Institute, had used while travelling overland from Pekin to Srinagar, was made. Full details of the secular change values for each month are given at each of the four magnetic observatories of Dehra Dun, Barrackpore, Toungoo, and Kodiakánal, as well as hourly means of declination and horizontal force. The section dealing with tidal and levelling operations gives the values of the tidal constants for the eight stations in operation. Binocular American precise levels were used by one party, and were to be used by all parties in the following season, by which change an appreciable increase in the rate of work was attained. In the work of the pendulum party the changes in the times of vibration of each of the four pendulums from 1904 to 1909 are given and discussed.

The Seismological Society of America, which owes its foundation to the interest aroused by the Californian earthquake of 1906, has recently issued the first number of its quarterly Bulletin. Most of the short papers which it contains are devoted to the study of seismology in the United States, to the difficulties under which its prosecution labours, and to suggestions for organised work in the future. Among the papers of permanent interest may be mentioned Mr. H. F. Reid's account of the earthquakes felt in Central New Mexico in 1906 and 1907, and the list of seismographs known to be at work on the American continent, a list which includes no fewer than thirty-five Wiechert pendulums, twenty-nine Bosch-Omori pendulums, and nine Milne seismographs. Prof. Branner, in discussing the relations between earthquakes and the growth of faults, suggests the need for distinguishing between faults which are now active and others which have apparently reached a condition of stability, and he points out the useful work which might be carried out in this direction by the organised study of Californian earthquakes.

The daily and yearly period of rainfall at Trieste is discussed by Dr. E. A. Kielhauser in an interesting paper laid before the Vienna Academy of Sciences in November last, based on eleven years' readings of the self-recording rain-gauge at the observatory (1896–1906). Among the many points referred to we may mention that the rain-curve of the amounts for separate hours shows that it is made up of a large number of waves of short periods. In addition to the most prominent extremes of the absolute maximum (11h.–12h. p.m.) and the absolute minimum (11h.–12h. a.m.), fifteen relative maxima and minima are exhibited. In spring and winter, the hours of 5 a.m. to 1 p.m. are relatively dry, while in summer and autumn they are relatively wet; for the other hours the reverse naturally obtains. At all seasons of the year the duration of rainfall is greatest at night-time. The annual rainfall is 39·7 inches (mean of sixty years, 42·8 inches). The driest months are February, April, December, and especially January; the wettest months are May, June, November, and especially September and October. The driest month of the eleven-year period was February, 1896 (0·07 inch), the wettest, October of the same year (10·7 inches).

The April number of the Journal of the Röntgen Society contains a paper by Dr. W. Salomonson, of Amsterdam, on the induction coil, considered mainly from the point of view of the Röntgen-ray photographer. It is well illustrated by reproductions of photographs of the spark and of the primary current taken with a string galvanometer or an oscillograph. These show clearly that, as the capacity of the condenser in the primary is increased from a very small value, the time taken for the primary current to fall to zero at first decreases, then increases, in agreement with the theory of Mizuno. With an interrupter working in hydrogen or coal gas, the time of fall of the primary current may be reduced to 0·0002 second. Experiments with a new coil, by means of which photographs of the heart and lungs can be taken in 0·01 second, show that the spark is shaped like a corkscrew, and that it passes before the magnetic field due to the current in the primary has disappeared.

To those who are so unfortunate as to have to deal with electrical apparatus which has been flooded, the account of the steps taken by the railway and other companies to clean and dry the apparatus submerged during the Paris floods of 1910, published in *The Electrical Review* for April 14, will prove useful. It is compiled from the report of the Société des Electriciens, which relates to more than a thousand pieces of apparatus which were dried satisfactorily. The apparatus was first washed either with water, or, if battery acid had attacked it, with dilute acid, then water, then weak alkali, then water. If oil had got into the apparatus it was first washed with benzoline. Any method of drying, if properly applied, was found effective. Fixed machinery was dried either by an air blast or by fires underneath, in the first instance, and the process completed electrically. Portable machinery was treated in ovens gas or steam-heated to 120° C. at atmospheric, or to 70° C. at reduced pressure. A 60-kilowatt direct-current generator gave up two gallons of water in the drying process. Storage cells appear to have come through the floods with very little deterioration.

Messrs. Carl Zeiss (London), Ltd., have recently introduced the following novelties in optical instruments:—Mayer's new dissecting microscope has a characteristic form of exceptionally large stage, and can be fitted with either monocular or binocular observing systems. It can also take a stereocamera and drawing apparatus. Zeiss's field-glasses are made in a new form, possessing increased light-transmitting power combined with exceptionally large field. Strict alignment of the lenses is secured by casting the hinges and body in one piece. Telescope spectacles are for extreme myopia (10–20 dioptres), and give a field of more than 40°. For astigmatism a special form is provided. A new level is of small dimensions but of extreme sensitiveness. The bubble is observed by a reflecting prisma, which shows images of the semicircular ends of the bubble. In adjusting the instrument, these semicircles are brought into contact along their diameters. All axes are truly cylindrical. The telescope is hermetically sealed up, and by means of a transferable eye-piece can be read from either end. The instrument is packed in a case about 8 inches by 5 inches by 2½ inches, and the accuracy equals that of a 12-inch or 14-inch level of ordinary type. The Cardioid condenser is for dark-ground microscopical illumination, and is chiefly for studying colloidal matters. It gives a narrow extreme annular illumination the rays of which reunite in the plane of the object. Colloidal gold particles of less than 10 $\mu\mu$ can be seen moving rapidly in a field illuminated with this device. The oral illuminator contains a special arc lamp of 5 amperes fitted with a condensing arrangement for dental and mouth illumination. It is also fitted with a special tinted glass for bleaching the teeth. A new illuminating device for operating theatres consists of a powerful automatic-feeding arc lamp of 30 amperes, throwing a strong beam of light upon a large collecting lens. A system of mirrors breaks up and recollects the light so as to concentrate it free from shadows upon the operating table. The arrangement is, naturally, chiefly useful when surgical operations are performed at night.

In an article on the central buffer-coupling appearing in *Engineering* for April 21, it is stated that there is a distinct tendency towards its adoption in countries where the 5-foot 6-inch gauge is the standard. In India, where there are some 16,300 miles of 5-foot 6-inch gauge line, the standard coupling is causing ever-increasing trouble. On one line, the renewals necessary to replace one year's breakages necessitated the placing of orders recently for 10,000 screw-couplings. As the present standards give a coupling of about the maximum weight which can be handled conveniently by the native staff, it is apparent that relief must be sought either by making use of much more costly material or in making a change in the type of draw-gear. The present trouble arises from the greater hauling capacity of modern locomotives, the extending use of high-

capacity wagons, and the more general application of automatic brakes. It is of interest to note that the central-buffer coupling produces less waste of energy in trains travelling on a curve. Tests carried out in India on a 5-foot 6-inch line showed that the side-buffered stock required an increase of power of 5·82 per cent. on a 40-chain curve as compared with similar stock, but fitted with central-buffer couplings.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR MAY:—

May 1. 1h. 11m. Venus in conjunction with the Moon (Venus 1° 29′ S.).
4. 11h. Uranus stationary.
5. 6h. Mercury in Inferior conjunction with the Sun.
11. 16h. 53m. Jupiter in conjunction with the Moon (Jupiter 1° 19′ N.).
12. 17h. 57m. Moon eclipsed, partly visible at Greenwich.
18. 9h. 16m. Uranus in conjunction with the Moon (Uranus 4° 43′ N.).
22. 13h. 54m. Mars in conjunction with the Moon (Mars 2° 19′ N.).
26. 7h. 15m. Saturn in conjunction with the Moon (Saturn 2° 38′ S.).
28. 14h. 28m. Mercury in conjunction with Saturn (Mercury 1° 35′ S.).
29. 14h. 51m. Venus in conjunction with Neptune (Venus 2° 59′ N).
30. 14h. 57m. Neptune in conjunction with the Moon (Neptune 5° 32′ S.).
30. 16h. 50m. Venus in conjunction with the Moon (Venus 2° 35′ S).

COMETS AS MERELY OPTICAL PHENOMENA.—On a plate accompanying No. 4492 of the *Astronomische Nachrichten* there appear reproductions of fifteen photographs, each of which bears a striking resemblance to one or other of the various cometary forms made familiar to us by photographs of comets. But each of these images was produced by passing luminous rays through various lenses in abnormal positions, and the author, Signor Luigi Armellini, of Tarcento, throws out the suggestion that comets may only be optical phenomena produced by the distortion of solar rays passing through lenticular cosmical masses of meteorites. The author does not discuss the spectroscopic side of the question, and the idea is not novel, but the photographs reproduced are so realistic as to make the note of interest.

THE "ASTRONOMISCHEN JAHRESBERICHTS."—Owing to ill-health, Prof. Berberich has been forced to hand over the editorship of the extremely useful *Astronomischen Jahresberichts*, founded by the late Dr. Wislicenus in 1900, to the Astronomische Rechen-Institut of Berlin. In order that the year-book may not suffer by the change, Dr. Fritz Cohn, director of the Rechen-Institut, asks for the cooperation of astronomers who publish any papers during the year. The section on variable and new stars has been undertaken by Dr. Pračka, Observatorium Nižbor, Bohemia, to whom extracts coming under that heading should be sent.

THE INTRINSIC LIGHT AND EFFECTIVE TEMPERATURES OF ALGOL AND ITS SATELLITE.—In a paper recently published in the *Bulletin Astronomique*, Dr. Nordmann discusses the intrinsic brightness and temperatures of Algol and its satellite by a method depending upon a knowledge of these quantities for the sun, and quite independent of his heterochrome photometer method. In the result, he finds that the surface brightness of Algol is about twenty-six times that of the sun per unit area, and that the effective temperature of the star is about 13800°; by the independent photometric method he found 13300° as the temperature.

While the general failure to detect a secondary minimum in the light-curve of Algol suggests that the satellite only emits a negligible quantity of light, Dr. Nordmann's results indicate that the satellite is not the obscure, cool body it is generally supposed to be, but has an effective temperature and a surface brightness of the same order as those of the sun, to which it is about equal in diameter. The temperature found is equal to, or less than, 5730°, and the magnitude is not greater than 5·5. For the sun he obtained a temperature of 5320°, and for γ Cygni, which Lockyer places in the Polarian class, a stage higher than the Arcturian class which includes the sun, he found 5670° by his photometer method, but he concludes that Algol's satellite has a temperature not very superior to that of γ Cygni. Finally, he shows that, alone, the radiation from Algol would probably suffice to maintain the surface of the satellite turned towards the primary in a state of incandescence.

HALLEY'S COMET.—In a letter to *The Observatory* (No. 434, April) Mr. Keeling directs attention to an apparent brightening of Halley's comet early in March. From November, 1910, to February 5, the comet was becoming fainter, from mag. 14½ to mag. 15½, but on March 4 both the visual and the photographic observations at the Helwan Observatory showed it to be much brighter, smaller, and more sharply defined than during the previous four months. Its magnitude, determined from two plates taken on that date, was 14–14½, but it was half a magnitude fainter again on March 8. The Helwan observations show that throughout the long period it has now been observed during this apparition it has been about a magnitude brighter visually than photographically.

At the last meeting of the Royal Astronomical Society Mr. J. H. Reynolds directed attention to the distinct type of tail emanating from the comet on different dates. The Helwan photographs form a very long, connected series, and from them Mr. Reynolds suggests that the type of tail presented depends upon the distance from the sun rather than upon the size of the comet; when near the sun the tail appears as a prolongation of the envelopes around the nucleus, but when distant it takes the form of streamers radiating from a point directly behind the nucleus. Investigations by Mr. Knox Shaw indicate that at distances from 0·4 to 0·7 the tails are of the extended envelope type, from 0·7 to 0·8 they are of an intermediate type, and above 0·8 they are of the radiating type, such as seen in the case of Morehouse's comet.

A continued ephemeris for the comet is published by Dr. Ebell in No. 4492 of the *Astronomische Nachrichten*.

OBSERVATIONS OF JUPITER.—In the April number of *L'Astronomie* M. Antoniadi describes his observations of Jupiter made at the Barbier, the Meudon, and the Juvisy observatories during 1910. Numerous spots, clouds, and disturbances were seen and are described, and it is remarked that the suggestion, made in 1902, that the Red Spot is pushed forward by the great disturbance which overtakes it periodically, was confirmed by the observations made in July; on July 25 the longitude of the Red Spot was 356° instead of 358°. A splendid drawing in colours is reproduced on a plate accompanying the article.

GEOLOGICAL WORK IN BRITISH LANDS.[1]

II.—IN AUSTRALASIA.

THE Geological Survey of Western Australia suffers, like that of India, from the pecuniary attractions offered by mining companies. It thus lost Mr. Brooking at the end of 1909, but hopes to retain other efficient officers. In the Annual Progress Report for that year (issued in 1910), Mr. H. P. Woodward describes an association of albite and tantalite in pegmatite dykes (p. 17) which recalls the famous dyke with rare black minerals at Ytterby. The albite has been removed in one reef and replaced by quartz, furnishing another point of similarity between the Australian example and those of Swedish isles. The Bulletins recently issued rightly devote much attention to mining interests. We are glad to note that Mr. J. Allan Thomson, lately one of the Rhodes scholars from New Zealand, contributes the petrographical matter to No. 33. He provides, among other points, an interesting discussion on uralitic hornblende (p. 132). The mining memoirs, such as this on the Gascoyne and Pilbara Goldfields, and No. 38 (1910), on the Irwin River Coalfield,

[1] The first article appeared in NATURE of February 23, 1911 (vol. lxxxv., p. 553).

are complete in themselves, with colour-printed maps and sections. The responsibility of one officer for each field bulletin probably aids the rapid production of a series in a single year. Mr. Talbot describes in No. 39 (1910) the country traversed on a water-seeking expedition in the interior, between Wiluna, Hall's Creek, and Tanami. We note the occurrence of obsidianites at one point (p. 29). The descriptions and excellent photographs of the country make the bulletin of geographical value (Fig. 1). Four contributors furnish Bulletin 36 (1910), on palæontology, two being English specialists. Dr. G. J. Hinde describes sponge-spicules, the silica of which remains uncrystalline, from a post-Cretaceous rock in the Norseman district. Mr. Newell Arber deals with certain plants, which would determine strata at Mt. Hill and near Mingenew as Jurassic; and Mr. R. Etheridge describes a number of Jurassic marine fossils from the Greenough River district.

FIG. 1.—Jellabra Rock-hole, east of Gardiner Range, on the border of West and South Australia, Devonian Sandstone.

Mr. L. Glauert, of the Western Australian Survey, compares the jaw and teeth of a new diprotodont species, *Sthenurus occidentalis,* found in stalagmite, with the species known to Owen. He then (p. 71) gives a useful systematic list of Western Australian fossils, which must not be overlooked by stratigraphers and students of distribution. He holds (p. 111) that the occurrence of Devonian beds in his State is confirmed by a review of specimens from the Napier Range, submitted to Dr. Henry Woodward.

Mr. H. Y. L. Brown reported to the South Australian Government in 1910 on the country south and east of the Murray River. The observations of geologists have here shown the existence of old river channels in a rock-floor under marine Tertiary beds; the latter receive water inland at their junction with the older rocks, and provide important reservoirs, through which the fresh water percolates gradually to the sea. Bores in the desert region have been successful. Mr. W. Howchin, of the University of Adelaide, describes two very striking moraines of the Permo-Carboniferous Glacial epoch at Rosetta Head and King's Point, South Australia (Trans. Roy. Soc. South Australia, vol. xxiv., 1910). The great boulders of transported granite appear to weather out as if they were of modern origin, just as they do in South Africa, where denudation has attacked the Dwyka beds (Fig. 2).

The Geological Survey of New South Wales has issued a well-illustrated account of the Murrumbidgee River district, where a storage-reservoir is in progress (Records, 1909, price 7*s.* 6*d.*, with large coloured maps and sections). The author, Mr. L. F. Harper, keeps in view the geological history of the country, and is by no means content with mere description. Messrs. R. Etheridge and W. S. Dun furnish a monograph on Eurydesma in New South Wales (Mem. Geol. Surv. New South Wales, 1910, price 7*s.* 6*d.*). This large Permo-Carboniferous lamellibranch is known only from Australia and from the Indian Salt Range. The authors support Morris, to whom the generic name is due, and differ from Stoliczka, by placing Eurydesma near Avicula. They regard Aucella as its nearest fossil, and Meleagrina, the pearl oyster, as its nearest modern representative. Its stratigraphical and local restriction gives it special interest. Mr. A. R. McCulloch has illustrated the genus by appropriately bold and striking plates.

In Victoria, Prof. Skeats describes the gneisses and dacites of Dandenong, twenty-five miles from Melbourne (Quart. Journ. Geol. Soc. London, 1910, p. 450). The interest lies in the conclusion that the gneissic rocks result from dynamic action on dacites, the product being subsequently altered by contact with a mass of granodiorite. Mr. F. Chapman (Proc. Roy. Soc. Victoria, vol. xxii., 1909, p. 263) has investigated the Batesford Limestone, devoting particular attention to the foraminifera and the ostracods. New species are described, and the rock is regarded as of Middle Cainozoic age. Mr. Chapman, by his continuous and patient work, is carrying out ably for Australia the traditions of Prof. T. Rupert Jones. Mr. R. W. Armitage (*Victorian Naturalist*, vol. xxvii., 1910, p. 21) reviews known cases of the inclusion of plant-remains in lavas, and records the discovery of charred wood in Pliocene basalt near Melbourne. The basalt has intruded minutely into the shrinkage-cracks of the timber, "along the medullary rays and around the annual rings." Mr. Armitage has also guided the Field Naturalists' Club of Victoria to West Essendon (*ibid.*, p. 83), and gives an interesting account of Cainozoic sands converted by percolating waters into quartzite. In discussing the literature of similar cases, he would have been aided by a fuller reference to the modern quartzites formed in arid regions of South Africa.

The Geological Survey of Queensland is naturally concerned principally with mines. Mr. L. C. Ball describes the Starcke Goldfield (Publication No. 223), where the reefs are formed through the replacement of the slaty country-rock by quartz and a triclinic felspar, the alteration spreading inward from fissures due to earth-movement. The occurrence of secondary felspars in similar

FIG. 2.—Granite erratic resting on Permo-Carboniferous glacial till, Palæozoic moraine of King's Point, South Australia.

veins elsewhere is referred to (p. 14). Mr. Ball also reports on minerals, including tin, mercury, copper, and coal, in North Queensland (No. 222, 1910). The coals of Cooktown are believed to be of early Mesozoic age; but the author refers (p. 37) those of Mount Mulligan to the Palæozoic, on account of the presence of Glossopteris. Mr. Marks describes the coal-measures of Trias-Jura age in south-east Queensland (No. 225), but does not add anything to their palæontology. A large map has been issued 1910), showing the topography of the mineral fields and coal-fields in east central Queensland, on the scale of one inch to four miles.

The Bulletins of the New Zealand Geological Survey continue to maintain their exceptionally high position. Messrs. Bell and Clarke (No. 8, 1909) make us acquainted with the scenery of the Whangaroa district, in the far north of the long promontory of Auckland. The difficulties so often met with in the palæontology of New Zealand appear to crop up here, and, in view of the scarcity of fossils and the uncertainty of those discovered, it is found impossible to divide the Kaeo series into a Mesozoic and a Cainozoic portion, though both are believed to be present. Greensands and "claystones" are its most extensively developed rocks (p. 49). Igneous rocks of Palæozoic (?) to Cainozoic age occur, and are illustrated by thin sections. Mr. J. H. Adams (No. 9, 1910) describes the Whatatutu subdivision in Raukumara, which is also in the North Island. Here satisfactory fossils enable him to place the whole of his beds, the Whatatutu series, in the Upper Miocene, and to reject a previous grouping into Cretaceous and Lower Cainozoic (pp. 12 and 23). Mr. C. Fraser (No. 10) treats of the Thames Goldfield in Hauraki, Auckland, which has suffered from the usual periods of "boom" and consequent depression. The "sensational development," however, of one mine in 1904 shows how irregular vein-mining may prove to be. One of the features of the district is the Table Mountain, formed by the weathering out of a huge dyke of andesite, which penetrated a plateau of easily eroded rhyolite-tuffs. The gold and silver ores began to be imported into the district in early Cainozoic times, and the vein-material partly fills fissures and partly replaces country-rock (p. 41). The "bonanza" deposits are attributed to waters that had acquired different characters meeting at certain points along intersecting veins, and thus promoting deposition. Mr. E. Webb (No. 11) writes on the country in the north of the Westport Division in Nelson. The faults which lowered the highland that once lay to the west of the New Zealand Alps play a great part in the physiography of this region, and the block-system of mountain-building is shown in the retention of fault-scarps between the highland levels and the lower land stretching to the coastal plain. Copper-ores and molybdenite have directed attention to the district.

G. A. J. C.

THE PHARMACEUTICAL SOCIETY'S SEVENTIETH ANNIVERSARY.

THE seventieth anniversary of the Pharmaceutical Society of Great Britain, which occurs this month, is an event of some considerable interest, which is not wholly confined to those who practise the art of pharmacy. Since its earliest days the society has devoted its attention to improvements in scientific education, and, indeed, before it was a year old, it had instituted courses of lectures in chemistry, materia medica, pharmacy, and botany. Its foundation dates from April 15, 1841, when at a meeting of chemists and druggists held at the Crown and Anchor Tavern, in the Strand, it was resolved to form an association "for the purpose of protecting the permanent interests and increasing the respectability of chemists and druggists."

At that time there were many men who by their training were well equipped for the work of compounding drugs and dispensing medicines, but owing to their lack of cohesion the science of pharmacy was making very slow progress. The rapid advances which the society made in the commencing years of its existence was in a large measure due to the pervading influence of its first president, William Allen, F.R.S., who, in addition to carrying on the business of a chemist in Plough Court, in the City, was a man with very considerable scientific attainments. In 1796 he had with several other young men formed the Askesian Society for practical scientific research, and three years later he helped to form the British Mineralogical Society, while in 1804 he delivered a course of lectures on natural philosophy at the Royal Institution.

With such a man at the head, there is little wonder that the newly formed Pharmaceutical Society became imbued with his scientific spirit, and turned to education as a means of raising pharmacy from the low level at which it stood as a calling in those days. The Royal Charter of Incorporation was obtained in 1843; therein the purpose of the society is set forth as being for the advancement of chemistry and pharmacy and the promotion of a uniform system of education of those who carry on the business of chemists and druggists. As already stated, the School of Pharmacy was soon established, and in 1845 a laboratory was constructed which compared favourably with the laboratories of Germany, including that of Giessen, and most of those in France. Having instituted a sound system of education and examination, the society was in a position to ask the Government for privileges for its members, but it was not until 1852 that an Act was passed restricting the use of the title of pharmaceutical chemist to examined persons. This Act did not restrict the sale of poisons, and the society had to wait another sixteen years before it obtained from Parliament a measure of legislation by which the retail traffic in poisons was placed in the hands of those who had passed the statutory examinations.

To revert to an earlier period and the efforts made to encourage scientific research, a committee was appointed in 1844, on the recommendation of Dr. Pereira, to investigate the then known materia medica. The committee was composed of several officers and members of the society, together with the professors at the school, and did a considerable amount of useful work, the results of which were communicated to meetings of the society. The evening meetings, held once a month in the autumn and winter, have contributed very largely to the advancement of scientific pharmacy, and the great improvements in the methods of preparation and administration of medicinal compounds which have been effected during the last seventy years have been due in a great measure to the discussions at these meetings.

The influence of the Pharmaceutical Society and its members on the British Pharmacopœia has been extremely important, notwithstanding that the society, as such, has no statutory acknowledgment of its work in this connection. In a paper read in 1845, Peter Squire, who subsequently held the office of president, pointed out the evils likely to result from the discrepancies existing in the formulæ of the Pharmacopœias for England, Scotland, and Ireland, but it was not until 1864 that the first British Pharmacopœia was published. When the preparation of this volume was contemplated, the council of the Pharmaceutical Society, at the request of the College of Physicians, appointed a committee to assist in its compilation, and when a few years later the duty of preparing the Pharmacopœia was transferred to the General Medical Council, the society was requested to keep in touch with that body. In the preparation of subsequent editions the services of pharmacists have been invaluable.

The British Pharmaceutical Conference, although in no way part of the society, largely consists of members of the society, and the parent body has never ceased to encourage the conference in the useful work it has accomplished. *The Pharmaceutical Journal* was founded in 184[illegible] by Jacob Bell, and has been the means of recording and distributing the results of work done in connection with pharmacy and allied sciences. The British Pharmaceutical Codex is another of the society's publications which has contributed to the progress of pharmacy. More recently the society has directed its attention to improving its educational system, which seems to justify the belief that the scientific spirit which imbued its founders has been inherited by those who govern its affairs to-day.

AMERICAN HYDROLOGY.[1]

THE investigations of the hydrographical department of the United States Geological Survey have already received notice in these columns, and of the reports under consideration, two belong to a group which has been described at some length. These are papers Nos. 262 and 264, dealing with the conditions of stream and river flow on the South Atlantic coast and the eastern Gulf of

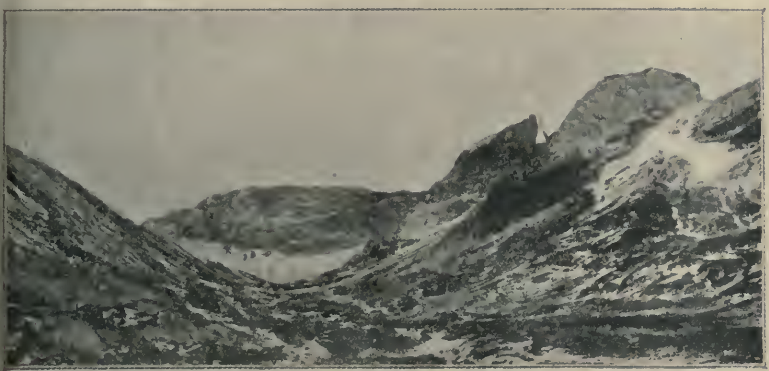

FIG. 1.—Synclinal Valley of Upper Willow Creek, Colorado.

Mexico (M. R. Hall and R. H. Bolster), and on the St. Lawrence basin (C. C. Covert, A. H. Horton, and R. H. Bolster).

The other five reports are of more distinctive character, and call for individual notice.

Paper No. 260 is a preliminary report on the ground waters of the Estancia Valley, New Mexico (Oscar E. Meinger). It is an investigation of the conditions affecting the irrigation of a valley in the centre of New Mexico, which is a depression 2000 square miles in area, without any drainage outlet. Insufficient rainfalls have been the cause of several crop failures. The proposal is to utilise wells for the supply of water, and, except perhaps in the central portion, where the presence of alkali threatens to impair seriously their quality, the prospect, on the whole, is favourable to a development of these subterranean supplies.

Paper No. 240 deals with the geology and water resources of the San Luis Valley, Colorado (C. E. Siebenthal). This valley lies in the south central part of the State of California, and has a length from north to south of 150 miles, and a maximum breadth of 50 miles. The area is drained by the Rio Grande, with a number of tributary streams, notably the Conejos River and La Jara, Alamosa, and Saguache Creeks. The geology of the district is summed up as a "Miocene deposition, unconformable below, of a series of sands, gravels, and interbedded lavas and tuffs, followed by orographic movements and additional volcanic activity, succeeded by quiet deposition of sands and clays in fresh-water lakes, passing without stratigraphic break into Pleistocene and Recent deposits." As regards its water resources, the San Luis Valley is an "almost ideal example of the artesian basin." Water occurs in beds of fine blue to grey sand, varying from 1 to 20 feet or more in thickness, separated from one another by beds of blue clay ranging from a foot to several hundred feet in thickness. The source of supply is the mountain streams which flow down from the higher levels and disappear as soon as they reach the alluvial slope. The Rio Grande itself in one section of 15 miles loses no fewer than 75 cubic feet per second by seepage. The report records the existence, by actual count, of 3234 wells capable of irrigating from 20,000 to 25,000 acres.

Paper No. 254 is of a similar character, treating of the underground waters of north central Indiana (S. R. Capps and R. B. Dole). The area covered is one of 7611 square miles, comprising nineteen counties. About two-thirds of it is covered with drift to a depth of more than 100 feet. This drift furnishes the water to by far the greater number of wells within its region, and there are few places where sufficient water for domestic needs cannot be obtained at moderate depths. For public supplies and manufacturing purposes, however, the source is inadequate. The report gives detailed particulars relating to the wells of the different localities, together with a comprehensive survey of the geological conditions. There is also included a section on the chemical character of the water and the means to be adopted to render it suitable for domestic and industrial uses.

Paper No. 253 is on the water powers of the Cascade Range; part i., southern Washington (Jno. C. Stevens). The Cascade Range runs through the States of Washington and Oregon with a general summit elevation of 6000 to 8000 feet. The higher peaks include Mount Shasta (14,380 feet), Mount Ranier (14,363 feet), and five or six others above 10,000 feet. The range is characterised by steep slopes and its streams by rapid flow. Add to this that there is an abundant and fairly uniform supply of water, fed during the summer by the snow banks and glaciers of the upper regions, and it will be seen that the district presents many interesting features from a hydrographical point of view, and is a very favourable locality for the development of water power. The area dealt with in the report comprises the drainage basins of the Klickitat, White Salmon, Little White Salmon, Lewis, and South Rivers flowing through the southern portion of the district and situated in Washington. Of these streams, the Klickitat is the most important, having a range of elevation of 3255 feet through the course of 73 miles surveyed, and being capable of developing some 150,000 horse-power under conditions of average minimum discharge. Altogether the potential horse-power of the district aggregates some 425,000.

The last report to be noticed is that, perhaps, which presents most features of interest to the general reader, as apart from the specialist. The paper on underground

FIG. 2.—Artesian Well on the Navin Ranch, San Luis Valley, Colorado.

waters for farm use (Myron L. Fuller) is a particularly valuable little manual affording a considerable fund of information within small compass on matters of vital importance to the community at large, and especially to the pioneer agriculturist—information which is very often regrettably outside the range of his ken. To commence with, there is a brief, general, and lucid account of the manner in which water occurs in the various geological strata, illustrated by some excellent photographs, with a statement of the relative safety of the different materials. The common sources of water supply are then discussed,

[1] Surface Water Supply of the United States, Papers 240, 253, 254, 255 260, 262 and 264. (Washington: Government Printing Office, 1910).

including lakes and ponds, streams, springs, wells, and cisterns, and the opinion is expressed that, of all these sources of supply, ground water is the most satisfactory for farm use, because it is least liable to pollution, and that streams and ponds are least trustworthy, because of the ease and frequency with which they are contaminated. Next follows a general description of underground waters and of the means to be adopted for their protection. The information on the subject of wells is detailed and complete, and includes some useful statistics of the cost of the various types, and a tabular statement of their advantages and disadvantages. The "safety distance" from possible sources of pollution is discussed, and that recommended ranges from 100 feet in clay and shale to 200 feet and more in sand and gravel. Boring tools and appliances and the methods of sinking wells are illustrated by diagrams and photographs. Altogether, the manual is one to be cordially commended for careful perusal and study by those dependent for water supply on local and adventitious sources.

It is interesting to note the author's remarks on the use of the "divining rod" for detecting the presence of underground water. He is of opinion that the alleged automatic deflection of the rod can only be attributable to unconscious muscular action, and that, however honestly the operator may believe in the reality of his powers, the irregularity of the results obtained and the numerous instances of failure recorded indicate that the system is crude, merely experimental, and quite untrustworthy.

B. C.

SCHOOL MEDICAL SERVICE.[1]

Only to those familiar with the origins of the medical inspection movement is it credible that, in little more than four years, a system should have developed that needs a Blue-book of upwards of 200 pages even for a brief summary of the work. The second report of Sir George Newman, chief medical officer to the Board of Education, shows that the system of medical inspection is now a fully organised service, producing its multitudes of new facts and propounding innumerable problems of detail.

Section I. deals with administration. The statement of policy is unambiguous. "From the outset the Board took the view that the Medical Inspection of School Children was but one of a number of activities comprised in School Hygiene, and the science and art of School Hygiene itself could not be regarded as an independent science and art which could be pursued in detachment from other studies, but was, in fact, an integral and vital part of that science which, under the name of Public Health, deals with all questions affecting the health and physical condition of the nation" (p. 3). Time alone can fully justify this statement; but, from the beginning, it appealed to the administrative mind. The creation of rival services for inseparable departments of health would have meant that one service would ultimately be superseded. The return of the public health officers into touch with the individual children has undoubtedly restored to that service a unity of purpose that it should never have lost. Preventive medicine includes personal as well as environmental hygiene.

This report contains much material to justify the Board's policy. Of the schedule used, it is important to record that "it is not, and never was, intended to be merely a means of collecting statistics. . . . The intention of Parliament was clearly that Medical Inspection should be of a practical character, and have practical rather than academic results" (p. 8). This is a timely warning against the danger of statistics heaped up without any synthetic idea. Nothing more disconcerts the man of practice, who, in this question, is more important as yet than the man of theory. On the whole, this year's reports come well out of the test. The medical men engaged in the medical school service number approximately 986; there are 73 women doctors and 289 nurses.

Section II. deals with the physical condition of the children as revealed by medical inspection. There are many interesting percentages as to cleanliness. Pediculosis is all too common, but the systematic schemes of cleansing have effected immense improvements. Incidentally, such schemes will help in the control of less easily perceptible parasites. There is abundant evidence that lavatory accommodation and spray baths are on the increase. But it is certainly disappointing to have to read that here 26 per cent., there 15 per cent., elsewhere 21 per cent., should suffer from vermin. It is, on the other hand, gratifying to find that, in one case, the 26 per cent. of one examination fell to 9 per cent. on the second examination, and this over a total of more than 3000 children. Obviously the activity of the parents has been stimulated by the concentration of attention on the parasitic state. Ring-worm is extremely common. This troublesome and wearisome ailment ought to be extinguished, but its extinction will be difficult. In some counties the cases amount to 1 in 73, in others to 1 in 45. In one town the cases were 1 in 67, in another 1 in 1000. Adenoids and enlarged tonsils and glands have contributed largely to the recorded ailments. So have defective hearing and defective vision. It is impossible to summarise the masses of facts and methods here detailed, but the special attention directed to the respiratory passages may be expected, in the long run, to reduce malnutrition and early tuberculosis. Heart disease should also profit by the inspection. One school medical officer reports "1·7 per cent. of heart disease among all children examined at five and thirteen years," but he adds that "three times as many suffer from hypertrophy or dilatation" (p. 61). Another found 2·3 per cent. among five-year-old children and 1·2 per cent. among twelve-year-old children. The association of heart disease with rheumatism has been carefully studied by some medical officers. Factors in the production of "dilated heart are anæmia, over-strain, work out of school hours, and cigarette smoking" (p. 62). Of seventy-six boys examined for "heart strain due to double digging undertaken in connection with the garden classes," nine showed signs of rheumatic heart disease, and "in eighteen other cases signs of heart strain were discovered" (p. 61). These facts are of fundamental importance in physical education. The whole question of the "rheumatism of children and adolescents" demands careful investigation.

The section on tuberculosis contains many facts of great importance. "It is interesting to observe that the percentage of tuberculosis among the routine cases is found to be 0·75 in 1909 as against 1·02 in 1908, and among the routine and special cases 1·22 in 1909 as against 1·31 in 1908. Among the special cases, the percentage shows a slight rise—2·02 in 1909 as compared with 1·97 in 1908" (p. 63). These figures refer to 683,715 children examined in 1909, as compared with 245,000 in 1908. It is not indicated whether any special reaction methods have been used in diagnosis. The amount of tuberculosis discovered in different localities varies enormously; but the results, if based simply on ordinary clinical inspection, cannot be accepted as indicating the full extent of tubercular prevalence. "The prevalence of phthisis among school children is still a matter upon which great differences exist among school medical officers, and this will continue to be the case until definite standards of diagnosis are introduced" (p. 66). The results recorded abroad from von Pirquet's reaction are in entire discord with the facts recorded here. It is obvious that the whole question of the prevalence of tuberculosis needs investigation *de novo*. It is a question of primary importance, not merely for practice, but for correct inferences as to heredity. If, as one observer (Dr. Herford, of Altona) finds, that, in an examination of 2594 school children, "63 per cent. reacted, 50 per cent. of the five-year-old groups, and 94 per cent. of those about to leave school" (p. 66), and if these results be verified, we must suspend judgment on the whole question of prevalence. If those results are correct masses of statements about "tubercular diathesis" and "intensity of inheritance" fall to the ground. The increase of open-air schools is a gratifying practical result.

Section III., on "following up," contains a good deal of important practice. Section IV. indicates the range of "medical treatment," including the improvement of school arrangements, sanitation, physical exercises, open-air classes, powers under special Acts for blind, deaf, defec

[1] Annual Report for 1909 of the Chief Medical Officer of the Board of Education Pp. 213. (London: H.M. Stationery Office, 1910.) Price 11*d*.

tive, epileptic, cooperation with the sanitary authorities as to infectious disease, directions to the parents, school nursing, contributions to hospitals, and establishment of school clinics (p. 94).

Section V. deals with dental disease and dental treatment. Section VI. discusses the problem of special schools for physically defective and epileptic children. Section VII. deals with feeble-minded children; Section VIII. with physical training. There are important appendices on practical questions.

Altogether, the Board of Education and its chief medical officer are to be congratulated on this conspectus of the school medical service, which is rapidly becoming the most important medical service in the country.

OPTICALLY ACTIVE PHOSPHORUS-COMPOUNDS.

ONE of the most fascinating problems of organic chemistry consists in the attempt to prepare compounds the molecules of which are devoid of planes of symmetry, and are therefore capable (like a screw or a glove) of existing in two forms, usually distinguished as left-handed and right-handed; these have the property of rotating the plane of polarisation of a beam of light to equal extents in opposite directions. Such compounds usually contain an "asymmetric" atom linked to four or five radicles all differing from one another; but compounds have recently been prepared in which the asymmetry cannot be attributed to any single atom, but is a property of the whole molecule (see NATURE, vol. lxxxii., p. 266, December, 1909; this vol., p. 93, March 16). In addition to carbon (linked to four different radicles), asymmetry has been traced by Pope and his colleagues to atoms of pentavalent nitrogen and of tetravalent tin, sulphur, and selenium, whilst Kipping has added tetravalent silicon to the list. The latest addition, that of pentavalent phosphorus, forms the subject of a recent paper by Prof. Meisenheimer in the Berlin *Berichte.* Two or three years ago this author described a new type of isomerism in the case of nitrogen, the chief characteristic of which was the presence of only four different radicles attached to the pentavalent atom instead of the five that had usually been thought necessary to give rise to optical activity. The conclusions then arrived at have been confirmed by the recent preparation of methylethylaniline oxide,

$$\left.\begin{array}{l}CH_3\\C_2H_5\\C_6H_5\end{array}\right\rangle N=O$$

in pure crystals, which displayed a large optical activity when dissolved in dry benzene, both the dextro and the lævo forms of the oxide having been separated and examined. The new phosphorus compound is of precisely similar composition, having the formula

$$\left.\begin{array}{l}CH_3\\C_2H_5\\C_6H_5\end{array}\right\rangle P=O$$

It was prepared by combining diphenylethylphosphine, $(C_6H_5)_2P(C_2H_5)$, with methyl iodide, liberating the base by means of silver oxide, and decomposing it by boiling with water, as indicated by the equation

$$(C_6H_5)_2(C_2H_5)(CH_3)POH = C_6H_6 + (C_6H_5)(C_2H_5)(CH_3)PO.$$

The inactive base was resolved by combining it with bromocamphorsulphonic acid—the same agent that was employed twelve years ago by Pope and Peachey in preparing the first active derivatives of asymmetric nitrogen—and was separated again from this acid by passing ammonia gas into a solution of the salt in benzene. The ammonium salt was filtered off, and the base separated in needle-shaped crystals of undoubted purity. When redissolved in benzene, the base showed the highly satisfactory rotatory power $[\alpha]_D + 33 \cdot 8°$ $[M]_D + 57°$.

The experiments now described provide a completed solution of a problem which had already been solved partially by Kipping and Luff (Proc. Chem. Soc., 1909, p. 203). These authors succeeded in isolating two isomeric hydrindamides of the formula

$$O=P\left\langle\begin{array}{l}OC_6H_5\\OC_7H_7\\NH\cdot C_9H_9\end{array}\right.$$

which differed from one another in optical rotatory power, and almost certainly contained the dextro- and lævo-rotatory forms of the phosphoric radicle; unfortunately, it was not found possible to separate this radicle from the active hydrindamine which had been used in resolving it, and the final proof of the activity of the phosphoric radicle could not be given.

METEOROLOGICAL REPORTS AND SUMMARIES.

MANILA WEATHER BUREAU (1906).—The meteorological observations at the secondary stations have now been published, and form part ii. of the annual report (part i., referring to the central observatory, appeared some time ago). It extends to 404 quarto pages, and includes daily observations and monthly means at the stations which at that time constituted the meteorological service of the Philippines. The observations are carefully collated and examined at the central observatory; some of the stations extend to the Ladrone and Western Caroline Islands, and are of the utmost importance in connection with the origin and premonition of the destructive typhoons that frequently advance from that part of the Pacific Ocean. They are also used in the preparation of the valuable monthly weather bulletins of the bureau, to which we have often had occasion to refer.

Toronto Observatory (1908).—During the year covered by this report, the building used since 1855 was replaced by a new Canadian Meteorological Office and Observatory. The following values are taken from the useful summary of results given for each month and the year, with differences from the average of the past sixty-nine years. The extremes of temperature are taken from the maximum and minimum thermometers in the Stevenson screen. Highest temperature (July 30), 91·5°; lowest (February 4), −17·4°; highest on record, 99·2°; lowest, −26·5°. Mean of highest readings in 1908, 55·8°; of lowest, 37·7°. Mean from max. and min., 46·7°, being 2·7° above the average. Highest solar radiation (August 4), 128·3°; lowest night radiation (February 4), −21·0°. Rainfall, 21·72 inches; depth of snowfall, 77·8 inches. Percentage of possible sunshine, 47, the average for the past twenty-seven years being 42 per cent. The mean W. declination was 5° 54·1′; dip, 74° 36·9′.

Korea Meteorological Observations (1908–9).—These valuable observations and results are in continuation of those referred to in our issue of May 19 last. The following statistics refer to Chemulpo Observatory (lat. 37° 29′ N., long. 126° 32′ E.) for 1909. Temperature:—mean maximum, 58·5°; absolute, 93·2° (in August); mean minimum, 44·1°; absolute, 8·1° (in December); annual mean, 50·7° (normal, 51·1°); rainfall, 25 inches (normal, 37·7 inches), days, 96; sunshine, 2746 hours (62 per cent. of possible amount). The instruments and methods are the same as those at Japanese stations.

Odessa Observatory (1909).—We are glad to see that Prof. Stankevitsch proposes to cooperate regularly in the international researches of the upper air. Two kite ascents were made in December, but only moderate altitudes were reached. At present this important work can only be carried out under difficulties, as the director and his principal observers are engaged at the University. The annual summary shows that the mean temperature was 50·7°; January, 21·2°; July, 74·3°; absolute maximum, 94·8° (in July), minimum, −7·2° (in January). Rainfall, 14½ inches, on 98 days; fog, 58 days; frost, 95 days. Appendices give the normal values for a number of years (see NATURE, February 16), also rainfall and thunderstorms, at stations in south-west Russia.

India Weather Review, Annual Summary (1909).—The greater part of this work is taken up by the calculation of the monthly and annual departures of each element from the normal values, and a useful discussion of the results under four seasons: cold-weather period (January and February), hot-weather period (March–May), south-west monsoon period (June–September), period of the retreating south-west monsoon (October–December). These are followed by abstracts of the observations made in India and a few extra stations, and by maps relating to rainfall, and the tracks of cyclonic storms formed in the

Indian seas. The temperature in 1909, as in the two preceding years, was slightly colder than usual. The lowness occurred almost entirely in northern and central India, owing chiefly to a defect of day temperature; the largest deficiency occurred in April and June. The total rainfall, on the average of the whole of the plains, was 2·1 inches (5 per cent.) above the normal, which is the largest excess since 1894. In the Indian Ocean it was very irregularly distributed, being 25 per cent. below the normal at Seychelles, nearly normal at Mauritius, and 43 per cent. above the average at Zanzibar.

Deutsche Seewarte, Hamburg (1909–10).—The observations and results for stations under the control of the Seewarte are published in its *Jahrbuch* for 1909 in the usual form (Nature, May 19, 1910). The present volume, the thirty-second of this valuable series, includes ten stations of the second order (for four of which hourly readings are also given) and extracts relating to storms from registers kept at fifty-seven signal stations. The following values are quoted from the annual summary for Hamburg:—temperature: mean maximum, 52·2°; mean minimum, 41·4°; mean, 46·4°; absolute maximum, 81·7° (May); minimum, 9·3° (January and February); rainfall, 27·8 inches, 164 days. Fog, 64 days; the only months free from it were April–June.

Like its predecessors, the thirty-third annual report of the work of the Deutsche Seewarte, for 1910, contains full details of the staff, observers, and of the duties performed in various departments. In the branch of ocean meteorology, one is struck by the increasing number of observers, now numbering about 1075, and at the amount of data relating to the sea, about 4228 months' observations during the year in question. This branch is actively promoted by agencies at twenty-three ports, which, in addition to other duties, undertake the verification of instruments. The observations are utilised in monthly meteorological charts and daily synoptic weather charts of the North Atlantic Ocean, and many other useful publications. The department dealing with weather telegraphy and storm warnings also shows great activity. An exchange of telegraphic observations is kept up with foreign services, and is supplemented by daily kite observations and reports from mountain stations. We have before mentioned the useful experiments of issuing storm warnings to the North Sea and Baltic deep-sea fisheries, &c., by wireless telegraphy. Several other departments are engaged in valuable work, including the issue of handbooks and other publications, to some of which we have frequently had occasion to refer.

Stonyhurst College Observatory (1910).—The results of the meteorological observations show that the mean temperature of the year, 47·2°, was 0·4° in excess of the average. The warmest month was August, 57·2°, and the coldest January, 37·0°; June had the greatest number of high readings: above 70° on nine days. The absolute maximum was 78·0°, in June and July; minimum, 13·5°, in January. The annual rainfall was 53·29 inches, being 6·26 inches above the normal. The amount of bright sunshine was only 28·3 per cent. of the possible quantity. Terrestrial magnetism forms an important part of the work of the observatory; the yearly mean values were:—declination, 17° 20′ W.; inclination, 68° 42·2′; horizontal force, 0·17407 C.G.S. units. Data relating to magnetic storms are supplied to the International Committee on Terrestrial Magnetism and to Potsdam Observatory. The solar surface was observed on 166 days; on 40 days the surface was found quite free from spots. The principal meteorological means, &c., are compared with the averages of 63 years; this long period greatly enhances the value of the data.

MUSEUM CONFERENCE AT HALIFAX.

A CONFERENCE of members of the Museums Association and other persons interested in museum work was held at Halifax on April 8. Halifax is peculiar in the organisation of its two public museums, which are directed by honorary curators, under the control of the Education Committee of the borough, and it was by these authorities that the conference was summoned. About sixty persons attended, including representatives from Liverpool, Manchester, Sheffield, Salford, Hull, Bolton, Warrington, and other museums in Lancashire and Yorkshire. After the Natural History Museum (Belle Vue) and the Museum of Anthropology and Arts (Bankfield) had been inspected, and tea taken on the invitation of the Mayor of Halifax, the chair was taken by Mr. Howard Clay, chairman of the Education Committee.

Mr. W. B. Crump, Halifax Museums, read a paper "On a New Method of illustrating British Vegetation in Museums," in which he described the exhibition of common British trees at the Halifax (Belle Vue) Museum, where it is carried out from the nature-study point of view, so as to direct attention to the features in the life-history which are readily observable in the woods, and proceeded to advocate the arrangement of botanical specimens in popular museums on a geographical basis instead of the usual systematic plan. A Pennine moor, an oak wood, a salt-marsh, the vegetation of a pond, may, by careful selection of material and the free use of photographs, be effectively illustrated in a museum.

Mr. H. Ling Roth, Halifax Museums, in a paper "On the Use and Display of Anthropological Collections in Museums," compared the two methods, the geographical or ethnographical and the Pitt-Rivers or topical method, in which latter the evolution of articles for some definite use is exhibited. By the study of unrisen peoples we may learn a great deal about our own gradual progress. Specimens should be accompanied by illustrations of the people who make and use them, and collections should be formed to show how things are made. All the points were demonstrated by reference to the exhibits in the Bankfield Museum. Mr. T. Sheppard, Hull Museum, spoke of the advantages following the publication of guides to the museum, and gave particulars of ways and means. Mr. H. P. Kendall made an appeal for the more systematic collection in museums of prints and other illustrations of local antiquarian interest.

SOME RECENT FISH LITERATURE.

TO the Philippine Journal of Science for October, 1910, Mr. Alvert Seale contributes an account of a collection of Bornean fishes; this includes 117 species, of which ninety-one are common to the Philippines. Among the five species described as new, mention may be made of a shark, *Carcharias borneensis*, allied to *C. dussumieri*, but differing in the position of the fins and the form of the teeth.

The Japanese representatives of the families Sciænidæ, Lobotidæ, and Lutianidæ form the subject of two papers by Messrs. D. S. Jordan and W. F. Thompson in the Proceedings of the U.S. National Museum, Nos. 1787 and 1792. Of the first family Japan possesses few species, all referable to the typical subfamily, and allied to Chinese and Indian types; there is but one representative of the second family, and the species of the third are not numerous, although two are sufficiently common to be of commercial value. It may be noted that in the second paper a new generic name is proposed for a Hawaiian fish. In No. 1782 of the same publication Mr. T. Gill discusses the structure, affinity, and habits of the wolf-fishes. From peculiarities in the structure of the scapular arch and the actinosts of the fins, coupled with the absence of ventral fins, the author supports the views that these fishes should be separated from the Blenniidæ to form a family by themselves—the Anarrhichadidæ. Examination of the skeleton demonstrates that the current classification of the genera requires radical amendment.

The generic and, in some degree, the specific name of the typical wolf-fish (*Anarrhichas lupus*) is based on a misconception, the former term signifying a climber, from a legend that these fishes occasionally leave the water and clamber on to the rocks, while the latter seems to have been given from an idea that they prey on other fishes. It has, however, long been known that they feed almost exclusively on molluscs, crabs, and sea-urchins, for seizing and crushing which their powerful dentition is specially adapted. Most of the species are normally inhabitants of depths where perpetual darkness reigns; and when the typical wolf-fish visits shallow water for spawning, it is active only at night. In spite of the prejudice against the wolf-fish on account of its hideous head and formidable teeth, the flesh is stated to be excellent for the table.

To the Proceedings of the Academy of Sciences of Philadelphia for October, 1910, Dr. H. W. Fowler contributes notes on little-known New Jersey fishes, and likewise notes on various chimæroids and ganoids. In the latter a new chimæra is described from New Zealand, and two new species of Cylindrosteus are likewise named.

In the same serial for December, 1910, Mr. Burnett Smith describes certain fish-remains from the Devonian of New York. Most of these are species pertaining to the European genus, Machæracanthus; but the author was fortunate enough to obtain part of the armour of a small arthrodire, which is provisionally regarded as referable to the plastron of a species of Dinichthys. Assuming this to be the case, he points out that the generally received determination of the bony elements of this part of the exoskeleton is incorrect.

In *Science Progress* for January, Dr. H. H. Swinnerton gives reasons to show that the ordinary view as to the respective functions of the median and paired fins of fishes require revision. These views are based, at any rate to a considerable extent, on the movements of fishes which have been deprived of one or more of their fins; but the author points out that operations of such severity must have caused very serious shock to the patients, and thus induced "wobbling" and other eccentric movements. As regards the hind dorsal and the ventral fin, the author is of opinion that their function is connected with the tail-fin, which is the sole propelling organ of the fish. The anterior dorsal fin, on the other hand, appears to serve as the chief agent in the rapid turning movements which are essential to the safety of a fish living in swiftly flowing waters. As regards the functions of the paired fins, these appear to have changed *pari passu* with the modification in the structure and orientation of these appendages which has taken place as we pass from ancient generalised to modern specialised types. To follow the author in tracing these out would, however, occupy too much space on the present occasion, and it must suffice to state that whereas in the primitive fossil shark Cladoselache the paired fins were little more than broad-based lobes on the sides of the body, with their expanded surfaces in the plane of the latter, in modern teleost fishes they are narrow-based fan-like structures, with their broad surfaces capable of being extended at right angles to the axis of the body. And the author has found that "it is possible to recognise a complete sequence from the broad-based fin acting as a keel, through the narrow-based fin with limited freedom acting as a lateral rudder, to the narrow-based fin with great freedom of movement which enables it to be used either as a keel, a lateral rudder, or a break."

In the April number of *The Zoologist* Colonel C. E. Shepherd continues his account of the pharyngeal teeth of fishes, dealing in this instance with the members of the cod family (Gadidæ) and the Carangidæ. R. L.

TECHNICAL TRAINING AND THE OPTICAL INDUSTRY.

THE scheme for the establishment of an Institute of Technical Optics in London was described in a short article in the issue of NATURE for March 16. In that article reference was made to two elaborate reports, covering nearly forty pages of foolscap print, and signed, respectively, by the education officer of the London County Council, Mr. R. Blair, and the Council's educational adviser, Dr. Garnett. The contents of Mr. Blair's report provide much information as to the provision made in this and other countries for higher work in technical optics, and we here reprint extracts from this report as showing the need for the action of the London County Council.

Introduction.—Although the United Kingdom is no longer in the forefront of the optical industry, the science of optics stood on a high level in this country for about 140 years after the publication of Newton's "Treatise on Optics" in 1704. Since 1850, however, the study of geometrical optics has progressed rapidly in Germany, but has been practically at a standstill in England. The trade conditions in both countries have kept pace with the state of optical knowledge. At one time the United Kingdom made most of the best optical instruments in the world and produced a large proportion of optical inventions. But latterly, inventions, presumably owing to more improved facilities for study and practical training, have been more numerous in Germany than in the United Kingdom. The great increase in the German production and export has also been assisted by many other factors, amongst which may be mentioned the help afforded by the Imperial Physical-Technical Institute at Charlottenburg (which should not be confused with the Technical University at the same town), the efforts of the Association of Instrument Makers, and the perfection to which the production of the special glass required has been brought at Jena. During the last fifteen years it has been gradually recognised in England that if the lost ground is to be regained, either wholly or partially, adequate provision must be made for optical instruction in all its branches.

A large amount of valuable information had been gradually gathered together, but, in view of the considerable expenditure suggested in aid of technical training for the optical industry, the presentation of this report was postponed until all available sources of information could be consulted. The inquiries include information regarding the extent of the trade in London and the provinces; the amount of capital invested and the number of workmen employed; the amount of imports and exports; any pecuniary support likely to be forthcoming from the trade or other sources, and the extent to which the trade would cooperate both in giving facilities to employees to attend the proposed institute, and in other ways; the question as to what branches of the optical industry should be included in the scheme, and the nature and extent of the institute as regards accommodation, equipment, and staff. It has also been necessary to study carefully the conditions of optical instruction and trade in Germany, and to investigate the statements and representations on behalf of their interests made by persons and bodies interested in the science of optics and the manufacture of optical instruments in England.

The final results of the investigations made and the conclusions which may reasonably be drawn from them, taken as a whole, point to the necessity for the establishment of the proposed institute for industrial, scientific, and national reasons—industrial because of the lack of progress in the British optical industry compared with the rapid progress made in Germany, and the fact that the value of an optical instrument lies almost wholly in the scientific knowledge and skilled labour applied to its making; scientific because of the necessity to the scientific worker of the production on the spot of the best and most suitable instruments for the purposes of pure and applied science; national because of the necessity of the home production of instruments for various branches of the public service.

COMPARISON BETWEEN THE PROVISION OF OPTICAL INSTRUCTION IN ENGLAND AND GERMANY.

It appears beyond doubt that instruction in pure and applied optics and in fine instrument making is much more developed in Germany than in England. At most German universities, especially the technical universities, the importance of optics and its practical applications are recognised to a greater extent than in England; in some cases attention is even devoted to the practice of instrument making. At English universities optics are either practically neglected or are taught as a branch of physics together with sound, heat, and electricity. When attention is devoted to optics, the practical application of optical principles to the designing of instruments is almost entirely disregarded.

With regard to special technical schools for instrument making, Germany possesses four, England only a department of an institute. Moreover, the German schools are generally housed in proper buildings and well equipped for theoretical and practical work, whilst the building and equipment of the Northampton Department of Optics are quite inadequate.

The attention devoted to the German schools is reflected in the attendance of full-time day pupils:—Schwenningen, for example, has seventy-two, Göttingen eighty-eight, of whom a large number are engaged in technical optics. The department at the Northampton Institute has twenty

students, most of whom are engaged in sight testing and spectacle making and not in optical instrument making. The liberal funds available for the German schools enable them to charge only about 30s. per annum for full-time instruction. The Northampton Institute is compelled to charge 15*l*. per annum, a fee which many students must find it impossible to pay.

It is of some importance to observe that the four German schools, as their names imply, are organised for the teaching of fine instrument making generally, whereas the Northampton department is principally concerned with optical instruments.

Finally, it may be noted that the German schools have been established by the municipalities concerned, generally as a result of action taken by the local trades. They receive, however, maintenance grants from the States concerned and appear to be in close touch with the authorities.

The single courses given in fine instrument making at various German trade schools are at least equal in organisation and quality to the one or two courses at technical colleges in England and are greater in number. The work of the Munich course has been developed to that of a department of technical optics; 201 pupils receive eight to nine hours' instruction per week.

The more numerous and superior opportunities for optical instruction in Germany have made themselves felt in all directions. Formerly a large number of optical inventions were made in England. Latterly, they have been more frequent in Germany, and the resulting trade has gone to that country. The records of the Patent Office are conclusive in this respect; such names as Zeiss, Goerz, Anschütz, Steinheil, Busch, &c., are household words in British optical circles. Some British firms are compelled to employ foreign mathematicians.

No practical text-book of optics exists in English, and the principal technical literature on the subject of optical progress and inventions is in German. The Northampton Institute is the sole place in England where the Gauss system of computing simple lenses and lens systems is properly taught. English optical instrument makers who wish to keep abreast of their science and industry are compelled to learn German and teach themselves.

In spite of these drawbacks, many important recent inventions have been made in England; in fact, as regards the quality, the English optical inventions are probably unrivalled, although in quantity they are less. As British enterprise and manual skill are not inferior to German, it is reasonable to suppose that this country would easily hold its own if the necessary opportunities for full instruction were provided. In former times optical problems were simpler and technical methods less complex. This has entirely changed, and to-day Germany, the country with the best optical literature and instruction, produces most inventions and has the biggest output and export.

In spite of the advances made in optical instruction in Germany, it does not appear that the optical trade is by any means content with what has been done. The instrument-making schools are being improved and expanded, and trade classes for instrument-making at other technical schools are being increased and developed. To give two recent examples—the Göttingen school has just moved into a new building, and the Munich course has been converted into an independent department. Technical optical lectures are increasing at technical and older universities. There is a strong feeling that much more could be done by the State and municipalities for the further advancement of technical optics. This is very significant in view of the fact that the British industry at present is pressing for only a part of the educational facilities already at the disposition of the German industry.

Comparison between the Extent of the British and German Optical Industries.—Germany, the country with the most numerous and best-equipped schools, departments, and courses for teaching instrument making, and with the best technical universities, has captured the largest amount of the world's optical trade. Starting well behind France and England, she has thoroughly beaten both countries in the amount of her production and export. In both countries there is considerable difficulty in obtaining trustworthy figures as to capital and the number of workmen employed. Fairly definite figures, however, can be obtained from the export and import results and the British census of production figures.

The net British exports of scientific instruments, &c., have only increased from 395,009*l*. in 1900 to 509,185*l*. in 1909. But at the same time there has been a heavy import, commencing at 595,305*l*. in 1900 and rising to 666,563*l*. in 1909.

The German export of scientific instruments, &c., was valued at 1,200,000*l*. in 1898, and for 1909 it was valued at 2,276,550*l*. Since 1904 alone it has increased by 776,550*l*. Imports into Germany appear to be very low, whilst in England the imports are so heavy as to be larger than the exports. At the present moment the German export of optical instruments is almost as great as the whole of the British production. Apparently the British trade has no true exports in the sense of excess of exports over imports, and is dependent upon foreign imports for a part of the home consumption. In spite of all these disadvantages, however, the British industry continues to exist and do excellent work. The Germans state that at the Brussels Exhibition, 1910, both the British and French industries were well represented, and they direct special attention to the large English catalogue with its good illustrations.

Germany and France appear to possess almost a monopoly in the production of the special glass required for optical instruments; the French glass is made from German formulæ. Large quantities of raw optical glass and of partially and fully finished glasses and lenses are annually exported to England. If this export were interfered with by any cause, a large section of the British industry might possibly find itself in a very grave position.

It is not technical education alone which has assisted the German industry. There has evidently been a keen demand for the finest instruments of precision made in the country itself on the part of men of science, professors, professional men, the army, the navy, and manufacturers. Great help has also been afforded by the following factors:—

German Association of Instrument Makers.—The association was founded in 1881. It looks after the interest of the trade in every respect with regard to general education, technical training, commercial education, international and other exhibitions, and finally by representations to the Imperial Government. This last point seems of some importance, and some details may therefore be given. It appears that, as far back as 1890, the association was agitating for the proper differentiation, in official documents, between optical and other fine instruments. The difficulties caused by the lack of a suitable scheme of classification have already been mentioned. At the same time the association was making representations against a protective tariff for instruments manufactured in Germany, as their second market lay in foreign countries, and reprisals were feared. Other negotiations have been carried on with the Government with regard to avoiding the duties paid on the re-import of instruments for purposes of repair. This is most significant, as it shows that instruments sold abroad cannot be repaired abroad, but have to be returned to Germany for this purpose. The association deals very fully with all questions regarding the participation of German firms in international exhibitions and with representations concerning the imposition of foreign tariffs on German goods. In one case it approached the Danish Government with reference to obtaining a larger amount of Iceland spar for optical purposes.

Jena and the Optical Industry.—Much of the success of the German industry comes from the town of Jena, where the firm of Zeiss is situated. Three men combined together in order to produce what was required for the optical industry. These were Dr. Schott, a glass manufacturer; Prof. Abbe, an oculist; and Carl Zeiss, a microscope maker. Prof. Abbe's efforts have had great influence upon the German industry. He introduced many improvements, and endeavoured not only to benefit his own firm but the whole industry. Dr. Schott obtained a grant from the Prussian Government for the purpose of investigating the best kinds of glass for optical purposes, especially with regard to the relation between the optical properties of glass and the chemical composition of solid amorphous fluxes. The result is that Schott has almost a world's monopoly for the best kind of special glass for optical purposes. Where one of the very few English glass manu-

facturers will quote at most about twenty-five different meltings, Schott of Jena, and Parra-Mantois of Paris will quote anything between 100 and 150. It may be mentioned that the University of Jena has benefited to the extent of about 100,000*l.* by the success of the firm of Zeiss. At the present time the firm of Zeiss employs about fourteen graduates who are either mathematicians or medical men.

Imperial Physical-Technical Institute.—Very great assistance has been rendered by the Imperial Physical-Technical Institute in Charlottenburg, which, as above mentioned, should not be confused with the Technical University in the same town. It was founded in 1887, and is concerned partly with physical research and partly with the development, standardising, and testing of fine instruments of almost every description. Its relations to the optical industry are numerous and intimate, and the manufacture of optical instruments has benefited accordingly.

The British Optical Society.—Some account may be given of the Optical Society on account of its relations to the optical department at the Northampton Institute and the trade generally.

The society was founded in 1899, and has over 400 members in London and the provinces at the present time. It has kept alive the interest of the different branches of the trade in the technical optics classes at the institute, and has for a series of years contributed about 110*l.* per annum towards the expenditure for the same.

It has also been instrumental in placing the trade in communication with the institute with regard to the details of optical work. In 1901 it appointed an educational committee for the purpose of inquiring into the question of optical education generally. In 1902 Prof. Silvanus Thompson read an important paper on "Technical Optics" before the Society of Arts, in which he strongly urged the establishment of a real optico-technical institute either at the Northampton Institute or elsewhere. The same conclusion was arrived at by the Education Committee of the Optical Society. The committee pointed out that it was only by the provision of such educational facilities that the optical trade of this country could be expected to compete with its foreign rivals, and that the Northampton Institute, with its teaching staff and equipment, would be the suitable place for the new optico-technical institute.

The German industry has received much more benefit from its association than the British industry from the corresponding association in England. Finally, as the German research and standardising institute at Charlottenburg came into existence long before the corresponding English institute, it has consequently been enabled to get into closer and more fruitful touch with the optical industry.

The Optical Convention in 1905.—The convention dealt not only with scientific and trade subjects, but devoted considerable attention to the problem of optical education. On this last point it adopted the following resolution:—

"That the Optical Convention hereby expresses the cordial approval of the project of founding an optical technical institute for the training of opticians in the scientific principles of optics and their technical applications which it regards as a matter of industrial importance to the nation; and in view of the backward state of optical teaching in this country it urges the London County Council to push forward, as a matter of pressing need, the foundation of such an institution on the lines of the scheme which was under the consideration of the late Technical Education Board."

THE PARAMOUNT IMPORTANCE OF THE OPTICAL INDUSTRY FOR INDUSTRIAL, SCIENTIFIC, AND NATIONAL PURPOSES.

It may be urged that the expenditure contemplated (amounting to 35,000*l.*, together with an annual maintenance grant rising eventually to 5000*l.*) is comparatively large in proportion to the extent of the optical industry, its capital, number of employees, and production. But this objection can scarcely be maintained when the problem is studied in all its far-reaching aspects.

In the first place, there are very few industries where the ultimate value of the goods produced represents so much in wages for the skilled designers and workmen and so little in the actual scrap-value of the materials employed. It is difficult to find an exact parallel in other branches of manufacture. For example, the production of valuable chemical products from certain raw materials as the result of intricate investigation and a long series of reactions. Or, perhaps the case of artistic products in which the actual value of the materials is very little compared with the value conferred by the insight of the artist and the cunning of his hand.

The overwhelming importance of the optical industry on the larger scientific and national issues involved was very clearly stated by Mr. Conrad Beck on the occasion of the deputation of the optical industry to the Technical Education Board in 1902. He pointed out that the number of instruments, for the manufacture of which optical knowledge is required, was very great indeed, ranging from ordinary spectacles, opera glasses, field glasses, telescopes, nautical instruments, microscopes, photographic lenses, photographic apparatus, and so forth, to surveying instruments, astronomical instruments, lanterns, range finders, gun sights, lighthouse prisms and reflectors, heliographs, periscopes, and almost every kind of optical instrument.

These instruments are widely used in the prosecution of science, in industrial processes, in the exercise of many important professions, in our shipping trade, the greatest in the world, and in the nation's naval and military lines of defence.

It cannot be too clearly understood that the success of the manufacture of all the instruments mentioned depends upon a thorough knowledge of practical optics on the part of designers and managers, and upon a constant supply of skilled foremen and workmen.

In times of peace the War Office and the Admiralty probably require something like 25,000 field glasses and telescopes per annum, and much larger number in times of war; the numbers sold to private individuals are, of course, much greater. Both the War Office and the Admiralty have been approached with regard to the influence which the proposed optical institute will have upon the production of the finest kinds of optical instruments used in the army and navy.

Spectacles, sooner or later, are worn by large numbers of persons. Field glasses and telescopes alone constitute a large business. All medical, biological, and many other students require microscopes; every ship's officer requires a sextant. Engineers require large numbers of levels and theodolites. The number of photographic lenses sold annually is extremely large. The illustrations of magazines, newspapers, and the majority of books are produced by photographic printing processes, largely depending for success on optical principles.

The advent of long range guns has been responsible for a special section of the optical industry concerned with the manufacture of elaborate optical gun sights and special telescopes of peculiar construction; new methods for range finding by optical instruments are being constantly sought.

In various industries a microscope is becoming each year of greater importance. It is used in the testing of steel and iron and for brewing, butter making, silk and textile manufacture, sugar making, and in numerous other industries. The photographic industry alone, which has assumed such great dimensions during recent years, is entirely dependent upon optical principles. Although large amounts of chemicals are used in photography and various materials for the construction of cameras, all the work employed would be entirely useless without the proper designing of the lenses employed.

Finally—although it cannot be definitely stated in concrete terms—there would appear to be some relation between the general efficiency of a nation and its manufacture of the finest instruments of precision for purposes of observation, research, measurement, and control. The material development of a nation is largely concerned with the utmost utilisation of the natural forces and materials at its disposal, and both pure and applied science are becoming increasingly dependent upon the help afforded by the finest instruments. A nation should have for this purpose an ample supply of the finest instruments. It should manufacture these itself for its own special purposes, and keep itself in a condition to repair and improve existing instruments and invent and construct new ones. It is significant to observe that both England and France have fallen behind Germany in this respect.

Final Remarks and Recommendations.

I have no hesitation in stating that a case has been made out for the establishment of the institute on broad and comprehensive lines, an institute which shall not only serve the needs of London, but also be of use to everyone connected with optical matters in the United Kingdom. The state of the industry, scientific opinion, and the other considerations involved, point to the need of the establishment of an institute without further delay. At the present moment an opportunity is afforded for utilising to the full the experience gained in foreign countries, the optical instruments of which have, to a large extent, supplanted our own. The Optical Institute, if founded, might become, under proper management, the first of its kind in the world. The material for doing this is at hand; it should be remembered that even in its present incomplete condition the optical department of the Northampton Institute has been visited by foreign technical experts, and many of its leading features copied.

The investigation has shown that the widest cooperation may reasonably be expected from eminent men of science, from the leading manufacturers, and from the University of London, other universities, and the Imperial College. The institute is thus assured of the best scientific advice possible and of actual practical help from interested manufacturers, and it will benefit by being linked up with institutions of university rank for the purposes of the finest research directly applicable to practical and industrial purposes.

The principal decision to be arrived at by the subcommittee at the present stage is whether capital expenditure, amounting to 35,000*l*., and an annual maintenance grant rising eventually to 5000*l*., for the benefit of the optical industry is justifiable, bearing in mind the great national and industrial issues involved. Most of the further details must be considered later and must form the subjects of special reports. Such details will include the proportion of instruction to be devoted to optical instruments in particular and to other fine instruments of precision, the final arrangement of the rooms, details of staffing, the nature of the equipment, the prosecution of research in optical instruments and in optical glass, and so forth. A sum of 5000*l*. in respect of the contemplated expenditure has been included in the capital estimates for 1911–12, and I recommend:—

(1) That a grant of 35,000*l*., including 5000*l*. for equipment, be allowed to the governors of the Northampton Polytechnic Institute (*Finsbury, C.*), in respect of an institute for technical optics as set forth in the foregoing report.

(2) That the institute be built upon the site already purchased by the governors of the Northampton Polytechnic Institute.

(3) That the institute be governed by the governing body of the Northampton Polytechnic Institute.

(4) That a consultative committee be formed for advisory purposes, on which the optical trade shall be adequately represented.

(5) That, for research and other purposes, steps be taken to affiliate the institute to the Imperial College of Science and Technology, and to associate it closely with the National Physical Laboratory at Teddington and institutions of university rank.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Announcement of generous bequests to Aberdeen University is made in *The Times*. From this source we learn that the late Miss Anne Hamilton Cruickshank, daughter of the late Prof. John Cruickshank, who held the chair of mathematics in Aberdeen University, has provided by her will for a professorship or lectureship in astronomy, including navigation and meteorology, in the University, and for a science library at Marischal College. Miss Cruickshank bequeaths 10,000*l*., from which the trustees are to apply such amounts as, with the funds already in their hands for the same purpose, will make up a total of 10,000*l*. for the institution and endowment of a lectureship or chair of astronomy, including navigation and meteorology. Any balance of the 10,000*l*., after deduction of the sum required for the institution of a chair of astronomy and the cost of the windows, is to be set aside and applied in such manner as the special trustees may think proper for the library at Marischal College. Miss Cruickshank also leaves 10,000*l*. to the special trustees for the founding and supporting in Marischal College of a science library, to be called the Cruickshank Science Library.

Lady Kelvin has made a gift of 500*l*. to the University of Glasgow for the purpose of founding therein a prize for original research in physics, in memory of the late Chancellor. The prize, which will be accompanied by a gold medal, will be awarded once in three years to a doctor of science who has graduated in the interval, and whose dissertation contains evidence of original experimental work deserving of this special distinction. A similar prize was recently founded by the pupils and friends of Prof. William Jack, to be awarded for the most distinguished mathematical thesis offered for the degree of D.Sc.

At a meeting of members and officials of local education committees, held at Aberystwyth on April 18 in connection with the Conference of the National Union of Teachers, a discussion upon the necessity for further financial aid for education from the central exchequer was opened by a paper read by Mr. G. S. Baxter, secretary of the Sheffield Education Committee. The following facts from Mr. Baxter's paper are of interest. For the year 1904–5, the expenditure of local education authorities on current account for all purposes pertaining to elementary education only was 18¼ millions, towards which Government grants of 9½ millions were received, whilst for the year 1908–9 (the latest available official returns) the expenditure of local authorities had increased to 23 millions and the Government grant to 11½ millions. Therefore, although local charges increased by 4¾ millions in four years, the State contribution only advanced by about 1½ millions. In addition to the added responsibilities in respect of elementary education, the cost of supplying and aiding secondary, technical, and higher education for the year ended March 31, 1909, amounted to 4½ millions, towards which Government grants were received amounting to less than 2 millions. Taking elementary, secondary, technical, and higher education together, therefore, local authorities in England and Wales expended in 1908–9 a total sum of 27½ millions, of which the Government contributed just over 13 millions, or 48 per cent., leaving about 14½ millions, or 52 per cent., of the amount to be provided locally.

At the Aberystwyth Conference of the National Union of Teachers, the following resolution, proposed on behalf of the executive, was adopted:—"This conference is of opinion that (*a*) no exemption (either partial or whole time) from school attendance should be granted until the age of fourteen years is attained; (*b*) all wage-earning child labour out of school hours under the age of fourteen should be forbidden by law; (*c*) a system of compulsory attendance at continuation schools from the age of fourteen to eighteen, accompanied by provisions which should safeguard the young people against undue physical or mental overstrain, should be an integral part of a national system of education; (*d*) it should be the statutory duty of the local education authority of each county and county borough to make suitable provision for such further education; (*e*) it should be the statutory duty of every employer of any young person under eighteen years of age (1) to enable him or her to attend continuation classes for such periods of time and at such hours as may be required by the Act, and (2) to supply the names of all such young persons to the local authority on demand; (*f*) all employers should be forbidden under penalty to employ or continue to employ any young person under eighteen years of age who failed periodically to produce a card attesting his or her attendance and good conduct at continuation classes or other educational institutions in conformity with the Act; (*g*) it shall be the duty of the State to make provision for the maintenance of any young person who may be deprived of the means of living as a result of the operation of any national system of education such as is outlined in the foregoing resolutions."

SOCIETIES AND ACADEMIES.

London.

Royal Meteorological Society, April 19.—Dr. H. N. Dickson, president, in the chair.—W. **Marriott**: Variations in the English climate during the thirty years 1881–1910. The Royal Meteorological Society in 1874 commenced the organisation of a series of "second-order stations" at which observations of pressure, temperature, humidity, rainfall, and wind are made twice a day, viz. at 9 a.m. and 9 p.m. In addition to these, another class of stations, termed "climatological," at which observations are made once a day, viz. at 9 a.m., was organised in 1880. The monthly results from all these stations have been published in the "Meteorological Record." The author has taken the general monthly means of all these results as representing the means for England and Wales, and these general means were exhibited to the meeting in the form of an interesting series of diagrams, in which the variations of the various elements for each month were shown in red when above the average, and in blue when below the average, for the thirty years 1881–1910. The warmest months were August, 1899, July, 1900, and July, 1901, while the coldest months were February, 1895, January, 1881, and December, 1890. During the last fourteen years the temperature in October was above the average, with only one exception, viz. 1905. The years with the highest mean temperature were 1898, 1893, and 1899, and the years with the lowest temperature were 1892, 1888, and 1887. The month with the highest mean pressure was February, 1891, and that with the lowest pressure was March, 1909. On the average, April is the month with the least rainfall, and October the month with the heaviest rainfall, while June has the least number of days of rain. The wettest months during the thirty years were October, 1903, and October, 1891, and the driest months were February, 1891, and April, 1893. The years with the heaviest rainfall were 1903 and 1891, and the years with the least rainfall were 1887 and 1893. The wind diagrams showed that the prevailing winds were from the south-west and west, but that in April, May, and June north-easterly winds were more pronounced than in the other months of the year.—Captain C. H. **Ley**: (1) The value of the two-theodolite method for determining vertical air motion; (2) an automatic valve for pilot balloons.

Manchester.

Literary and Philosophical Society, March 21.—Mr. Francis Jones, president, in the chair.—W. **Thomson**: The influence of atmospheric pressure and humidity on animal metabolism. In a previous paper the author stated he had found that the percentage of carbonic acid gas contained in the exhaled air from the lungs was greater when breathing dry than when breathing damp air, also when breathing in mountainous districts where the atmospheric pressure was low than when breathing in the valley, and, again, was greater when breathing in the valley than when breathing at the bottom of a deep coal-pit, where the pressure is still greater. The experiments recorded in the present paper were made upon the exhaled air from three men and one boy, and upon guinea-pigs and mice, and the results from all show that, as a rule, when the barometer fell the percentage of carbonic acid in the exhaled air rose, and when the barometer rose the percentage of carbonic acid fell. As the air became more moist the percentage of carbonic acid fell, and it rose when the air became drier. There was a lower percentage of carbonic acid in the exhaled air when the weather was warm than when it was cold.—Miss Margaret C. **March**: The ornament of *Trigonia clavellata* and some of its derivatives.

April 4.—Mr. Francis Jones, president, in the chair.—Prof. W. W. Haldane **Gee** and A. **Adamson**: Dioptriemeters. The methods of measuring the focal power of thin lenses directly in *dioptrics* have been investigated. In the case of converging lenses, the method of obtaining this value directly from observations on the optical bench is to determine the reciprocal of the focal length in metres by calculation, by scale or table of reciprocals, or by a graphical construction which will enable the value in dioptrics to be read off from a uniform scale placed at right angles to the line along which the focal length has been measured. In the case of concave lenses (as well as converging lenses) the authors have adopted a method originally suggested by Guilloz, but practically unknown in physical laboratories. They have designed an instrument called a "dioptriemeter," which is of great simplicity and convenience. It consists essentially of a scale of concentric circles 1 mm. apart, which is viewed through a pin-hole at a distance of 200 mm. Midway between the pin-holes and scale is a disc with a circular opening of 10 mm. radius, so that twenty circles are seen. If a concave lens be placed against the disc more circles are seen, the excess above twenty giving the power in dioptries. The circles are so numbered that the value is directly read off. The same method is applied to a convex lens. The instrument is especially useful for investigating the properties of cylindrical lenses and the combinations of lenses. It can further be employed for finding the deviation of light by thin prisms and estimating their power in *prism-dioptries*. The method employed in the instrument has been found to be quite as accurate in principle as the usual optical-bench methods for thin lenses.—Prof. E. **Knecht**: The action of hydrogen peroxide on quinone. It was shown that when hydrogen peroxide is allowed to act on quinone in presence of ammonia, the solution becomes heated, and a brisk evolution of oxygen takes place. On acidulating the solution and extracting with ether, hydroquinone was found to have been formed in considerable amount. Toluquinone behaves in a similar way to ordinary quinone.—Dr. A. N. **Meldrum**: The development of the atomic theory: (vi.) the reception accorded to the theory as advocated by Dalton. At first Dalton's physical atomic theory met with keen opposition, and his chemical theory with neglect. To make the chemical theory known required, in addition to Dalton's own efforts, the zeal of Thomas Thomson and the support of William Hyde Wollaston. For years it came to almost nothing, except in Sweden and Italy. In Sweden, J. J. Berzelius, learning of it in the year 1808 from a memoir by Wollaston, received it with enthusiasm, and set himself, with immense success, to test it on the grand scale. In Italy it was the knowledge of Dalton's theory which stimulated Amadeo Avogadro to enunciate and maintain, exactly a hundred years ago, the hypothesis that equal volumes of different gases contain under the same conditions the same number of molecules. This hypothesis, after the lapse of fifty years, became the fundamental dogma of molecular science.

Paris.

Academy of Sciences, April 10.—M. Armand Gautier in the chair.—M. **Gouy**: Intercathodic action in a uniform magnetic field. It has been shown by experiment that intercathodic action is produced when the negative charges are connected by the lines of magnetic force. It is now shown that this condition may be replaced by another which is equivalent to it, that there is a maximum of electric potential on the path of the electrons.—M. **Salet**: The absorption and diffusion of light by meteorites of the intersideral space. The number of meteorites received by the earth in a year has been estimated at over 10^{11}, and their mass to be of the order of 1 gram. If these meteorites do not form a stream displaced with the sun, the number per unit volume in space is of the order of 10^{-8}. Some consequences of the diffusion of light by these meteorites are developed, and also of the bearing on the calculations of Pearson on the standard deviation.—Ch. **Fabry** and H. **Buisson**: Some applications of the phenomena of interference to the study of nebulæ. The method of applying the Fabry interferometer to a telescope is described: interference rings have been obtained with this apparatus from the nebula in Orion without difficulty.—A. **Buhl**: Development of a method due to M. Darboux on the theory of moments of inertia.—M. **Darboux**: Remarks on the preceding note.—André **Broca**: The measurement of geodesic angles by the method of repetition. Construction of a suitable apparatus and results of the measurements. The maximum error found was 1 in 300,000.—J. **Le Roux**: The fundamental covariants of the second order in the finite deformation of a continuous medium.—L. **Hartmann**: The mechanism of the permanent deformation in metals submitted to extension. A study of the manner in which the layer of oxide formed on tempered steel comes off when the elastic limit is passed.—G. A. **Hemsalech**: The line spectrum of air given

by the electric spark. The existence of a second line spectrum of air has been established, emitted exclusively by the oscillations of the electric spark.—P. **Pascal**: Researches on the magnetic properties of fluorine. A detailed study of the magnetic susceptibility of fluorbenzene and parafluorphenetol.—A. **Tian**: The decomposition of water by ultraviolet light. Under the action of the radiations from a quartz mercury vapour lamp, water is decomposed into hydrogen and hydrogen peroxide, the latter, decomposing in its turn, giving rise to oxygen. After a sufficient lapse of time for the equilibrium to be established, the effect of the ultraviolet light is identical, so far as the gases evolved are concerned, with electrolysis.—E. **Fleurent** and Lucien **Lévi**: The estimation of phosphorus in milk. Remarks on a recent paper of Bordas and Touplain.—H. **Jumelle** and H. **Perrier de la Bathie**: The leafless Asclepiads of the west of Madagascar.—Lucien **Daniel**: Biometrical study of the descent of grafted and non-grafted beans.—J. **Granier** and L. **Boule**: The heterogamic character of the *gemini* in *Impatiens glanduligera*.—M. **Truschel**: Contribution to the study of the sense of direction in the blind. A study of what has been termed the "sixth sense" in the blind leads to the conclusion that this is really of an auditive nature.—Armand **Juillet**: Relations between the air sacs and the bronchia in birds.—Jules **Courmont** and A. **Rochaix**: The antitoxic immunisation by intestinal antityphoid vaccination. Intestinal vaccination produces immunity against typhoid toxins and the serum of the vaccinated subjects is antitoxic.—M. **Schaller**: A new arrangement for photographing lesions of the skin or mucous membranes, giving configuration and the value of the morbid colorations.—M. **Weinberg** and A. **Julien**: An example of an acquired immunity towards a verminous toxin.—P. A. **Dangeard**. The conjugation of the ciliated Infusoria.—Ph. **Négris**. The distinctive characters of the breccia arising from the erosion of transported breccia in the Peloponnesus.—J. **Thoulet**: A bathy-lithologic chart of the gulf between Têt and Gruissan.

CONTENTS.

THURSDAY, MAY 4, 1911.

THE GOLDEN BOUGH.

The Golden Bough: a Study in Magic and Religion. By Prof. J. G. Frazer. Third edition. Part i. (in two vols.), The Magic Art and the Evolution of Kings. Vol i., pp. xxxii+426. Vol ii., pp. xi+417. (London: Macmillan and Co., Ltd., 1911.) Price 20*s.* net, two vols.

THE third edition of Prof. Frazer's book will be in six parts, comprising at least seven volumes. As the subject of "the dying god," to which the last four parts will be devoted, has proved, in the author's words, to be "a fruitful subject," the number of volumes will probably reach a total of nine. The two volumes of the first part, which lie before us, contain more than eight hundred pages of octavo.

In its new form of "a series of separate dissertations loosely linked together by a slender thread of connection" with the original subject (to which the book owes its title), it has been resolved into its elements. But the result is that we have a closer study of each element, while the whole inquiry actually gains in organic unity. Thus in the two volumes of the first part, dealing with "The Magic Art, and the Evolution of Kings," the space devoted to these subjects in the second edition is more than doubled, but we have a fuller analysis of each on one hand, and on the other we gain a clearer notion of the passage from magical control of the forces of nature to the system of Departmental Gods.

This first part presents no striking newness of theory as did the second edition. The author has been credited with a proneness to hypothesis to which actually he is not liable. There are few writers who are more content to be led by the facts. But interesting subjects which before were incidentally treated are now more or less exhaustively studied. Such are "The Sacred Marriage," or "The Marriage of the Gods," "The King's Fire," "The Fire Drill," "Father Jove and Mother Vesta," and "The Origin of Perpetual Fires." The latter group was the subject of one of the author's earliest papers, printed in *The Journal of Philology,* in which, among other results, he exposed the unscientific character of the orthodox German school of mythological inquiry.

Some new terms are introduced. Magic is divided into homœopathic and contagious. The former "commits the mistake of assuming that things which resemble each other are the same"; the latter assumes "that things which have once been in contact with each other are always in contact." The latter, again, generally involves an application of the former. The older term, imitative, obscured the mechanical nature of sympathetic magic, but the above description seems to show that the new terms are far from satisfactory. The former suggests to the ordinary student a theory of medicine, the latter a theory of disease; and thus a wrong impression of the nature and application of magic may be conveyed. There is also a good deal more to be said on the origin and meaning of these primitive forms of the inductive methods, than is given either by the author or by Mr. Hirn, to whom is due the term homœopathic. In fact, there is a fruitful field here awaiting the psychologist. The methods of primitive thought, adequately analysed, would throw light on much that is obscure in the evolution of logic and the elementary processes of mind.

After all the details recounted so minutely and illustrated so clearly by Prof. Frazer, one still does not really understand either the meaning or mental process of the savage principle that "things which have once been in contact with each other are always in contact." No academic principle of association of ideas will help us here, nor even the author's happy comparison with modern physical theory, "the impulse being transmitted from one to the other" (of two things in magical rapport)

"by means of what we may conceive as a kind of invisible ether, not unlike that which is postulated by modern science for a precisely similar purpose, namely, to explain how things can physically affect each other through a space which appears to be empty."

The savage does not so think, and Prof. Frazer does not suggest that he does so think, of the matter of "secret sympathy." Is it not more probable, for example, that a solution of the problem will begin with the obvious fact that in these matters the elemental intelligence simply ignores the categories of space and time?

Under magic is included an interesting suggestion as to the origin of circumcision, originally put forth by the author in *The Independent Review.* The suggestion is that the mutilation was

"originally intended to ensure the re-birth at some future time of the circumcised man by disposing of the severed portion of his body in such a way as to provide him with a stock of energy on which his disembodied spirit could draw when the critical moment of reincarnation came round."

The question raised is applicable generally to the method of "The Golden Bough," and the author's other work in the explanation of origins. The point is not whether barbarous or civilised men can or do continue to practise such operations as painful mutilation because of a superstitious fancy or religious dogma—that is abundantly proved in human history. The point is, Did primitive men, not far removed from *Homo alalus, institute* such mutilations for so slender and so unpractical a reason? Any *a priori* discussion of the point must take into account the fact that such rites are always organised by the old men, and also the possibility that they were instituted at a stage of culture very little less advanced than that in which we see them now.

In an analogous problem, Prof. Frazer observes:—

"While I have shown reason to think that in many communities sacred kings have been developed out of magicians, I am far from supposing that this has been universally true. The causes which have determined the establishment of monarchy have no doubt varied greatly in different countries and at different times."

L

It is difficult to imagine *any* kingship at any period or in any country being originally instituted for any other reason than the practical need of a *leader.* Facts, however, show that other reasons, of superstition, have actually operated.

"Writers," says the author, "on the origin of political institutions . . . have not laid their account sufficiently with the enormous influence which superstition has exerted in shaping the human past."

Of course, the solution of the difficulty is that, when superstition creates a monarchy, it *does create a leader,* whose power is no less real because it is merely magical. Once more, we may note that such questions invite the attention of the psychologist, in this case the student of the mind of society rather than of the individual.

This new edition is, as we have hinted, something more than a mere enlargement. It is a new book, or a series of books; yet it is the same "Golden Bough." The reader will find it full of good things, new and old. He will also realise that "The Golden Bough" is a great book, one of the great books of our time. As such, it has a character and an aim. It is extraordinarily simple, hence its powerful appeal. Every fact is presented, as it might be by a demonstrator, completely, minutely, and luminously; but each fact is a human document. The aim of the book has, perhaps, grown with its growth; the author's words, cited above, may describe it:—To show "the enormous influence which superstition has exerted in shaping the human past." There is, indeed, no better introduction to the social and political history of the world than "The Golden Bough"; it is a book every statesman should be acquainted with, for it enables us to understand something of the workings of the mind of man in the mass, not only when it leads us from early savagery to the great world-religions which still exercise a profound influence on man's fate, but also when it deals with politics. Men in the mass are nothing if not superstitious, whether the superstition be a religious dogma or a political principle. It is not too much to say that this book, now in its majority—the first edition was published in 1890—has already helped the world towards a scientific view of nature and of man, the lack of which has made history a panorama of atrocity and error.

A. E. CRAWLEY.

AN INDIAN FOREST FLORA.

A Forest Flora of Chota Nagpur, including Gangpur and the Santal-Parganahs: a Description of all the Indigenous Trees, Shrubs, and Climbers, the Principal Economic Herbs, and the most commonly cultivated Trees and Shrubs. By H. H. Haines. Pp. vii + 634 + xxxvii. (Calcutta: Superintendent of Government Printing, India, 1910.)

THE author of this work, who has served largely and travelled extensively in the region with which it deals, and has studied its vegetation long and carefully, ought to be well qualified to give a satisfactory account of its flora. That area constitutes the north-eastern portion of the highland region of Central India, which forms part of the province of Bengal. It includes the administrative division of Chota Nagpur with the tributary State of Gangpur in its south-western border, and one other district—the Santal-Parganahs to the north-east—which belongs to the Bhagalpur division. This district, though an outlying one from the point of view of the administrator, is topographically and botanically an integral part of the upland tracts to the west of the Lower and to the south of the Upper Gangetic Plain. Its annexation is therefore fully justified on scientific grounds; and, as the work is prepared primarily with reference to forest requirements, has the practical advantage of enabling the author to deal with all the western forest subdivisions of Bengal.

In his treatment of the task before him the author does not disappoint us. The concise and well-arranged introductory remarks show that he is intimately acquainted with his country, and fully appreciates the factors which have determined the character of its vegetation. One only regrets that departmental exigencies have debarred him from dealing with those elements which fall outside the category of "economic" plants, and from giving us the complete review of the flora which he is so clearly competent to provide.

The technical portion of the work affords constantly recurring evidence of careful and independent study, and demonstrates that it is in no sense a compilation. Where his field observation of critical species has led him to adopt individual views, these are stated with judgment and caution. There are doubtless cases in which those with material from more extended areas before them may not be able to accept the author's conclusions; even so, the close study on which these conclusions have been based will still be fully appreciated. We may doubt, more particularly, whether the author has done well in departing from the sequence of the natural families observed in most standard Indian floras. No serial presentation of natural units can be wholly satisfactory, and the question is not as to whether the sequence adopted by the author be an improvement on the sequence it replaces, but whether the adoption of an improved sequence, in a work of "local" scope, can compensate for the inconvenience which results when that work has to be consulted simultaneously with another treatise of a more "general" nature.

The characters given for the species, if few and briefly stated, are well selected and clearly expressed. The economic notes and the local names, which are added when possible, increase the practical value of the work; this is further enhanced by the addition of an excellent map. This map, prepared by the Forest Survey, and published by the Survey of India, is worthy of these two State departments, but the appearance of the book itself is unattractive and disappointing. In spite of this drawback, however, our author's flora cannot fail to prove a useful companion to those resident in the area with which it deals, who may be interested in its vegetation.

ORDERS OF INFINITY.

Orders of Infinity: the "Infinitärcalcül" of Paul du Bois-Reymond. By G. H. Hardy, F.R.S. Pp. iv+62. (Cambridge: University Press, 1910.) Price 2*s.* 6*d.* net.

THE subject of this tract has been hitherto inaccessible to English readers, and it is not altogether easy to give a brief account of its contents. Perhaps the simplest method is to start from the familiar facts that log x and e^x both tend to infinity with x, but in very different ways, namely, $(\log x)/x^\delta$ tends to zero, however small δ may be, and e^x/x^Δ tends to infinity, however large Δ may be (it is understood that δ, Δ do not vary with x). These results would be expressed in du Bois-Reymond's notation by the symbols

$$\log x \prec x^\delta \text{ and } e^x \succ x^\Delta;$$

in addition to these two symbols, du Bois-Reymond used another to imply that the ratio of two functions f, ϕ lies between finite limits (when x tends to infinity). But later writers have found it convenient to make the notation rather more precise, and to write

$$f \asymp \phi$$

to imply the relation just mentioned, and further to use $f \sim \phi$ to imply that lim $(f/\phi)=1$; there are also other sub-cases for which reference must be made to Mr. Hardy's tract.

The ideas mentioned above lead very naturally to the *logarithmic scale of infinity*, represented by the sequence of functions

$$\ldots, l_3x, l_2x, l_1x, x, e_1x, e_2x, e_3x, \ldots$$

where

$$l_nx = \log(l_{n-1}x),\ l_1x = \log x,$$

and

$$e_nx = \quad (e_{n-1}x),\ e_1x = e^x.$$

This scale has the property that any element tends to infinity more slowly than any positive power δ of the following element, and more rapidly than any positive power Δ of the preceding element; and it is possible to utilise the scale to classify all ordinary functions of analysis. Mr. Hardy has considered (pp. 16–36) the question as to what more or less artificial functions do and do not fall into place in the scale; we must content ourselves with mentioning the comparatively simple function $\Sigma x^\nu/\nu\,!$ obtained by selecting certain terms from the exponential series; this *does* fit into the scale if ν takes the values 1, 4, 9 . . . $(\nu=n^2)$ but does *not* if ν has the values 1, 8, 27, . . . $(\nu=n^3)$, nor if $\nu=1, 2, 4, 8, \ldots (\nu=2^n)$.

In Appendix ii. (pp. 48–57) Mr. Hardy has made a most interesting summary of recent results in analysis, in which du Bois-Reymond's ideas have proved helpful, and readers who are less interested in logic than in results may be advised to turn to this appendix first. Appendix iii. gives a large variety of numerical results to emphasise the amazing rapidity of increase of the logarithmic scale at the upper end, and its corresponding slowness of increase at the lower end.

We may, perhaps, quote the largest number suggested by physical considerations, namely, the number of molecules in the earth, which is found to be of the order

$$1{\cdot}08\times 10^{51} \text{ or } 42\,! \text{ or } e_2(4{\cdot}77).$$

This is considerably larger than the number of sodium wave-lengths which light could traverse in geological time, a number of the order 30! or $e_2(4{\cdot}32)$. Both of these numbers are quite small when expressed in terms of second order exponentials, and are far smaller than 9^{9^9}, the largest number expressible in terms of three digits; this last number contains 369,693,100 digits when written at full length, and (printed with 16 digits to the inch) would cover more than 350 miles.

T. J. I'A. B.

MAYA ASTRONOMY.

The Numeration, Calendar Systems, and Astronomical Knowledge of the Mayas. By C. P. Bowditch. Pp. xviii+346+xix plates. (Cambridge: University Press, 1910. Privately printed.)

THIS volume offers to the reader "a statement of the knowledge which we possess of the numeration, calendar, and astronomical attainments of [a] wonderful people."

The sources of information are primarily the records of the Mayas themselves; secondarily, the writings of Spaniards and others about the Mayas. The first source may be subdivided into:—

(i) The books of Chilan Balam.
(ii) The codices.
(iii) Inscriptions.

The Book of Chilan Balam of Mani (Mani being the name of a village added to the title for the purposes of identification) was composed before 1595. All books of this class were copies of older manuscripts, with occasional addenda of current interest. They were regarded with superstitious veneration by the village to which they belonged.

The codices, of which three are extant, contain accounts of Mayan histories, ceremonies, sacrifices, and calendar.

Bishop Landa, at Mani, in 1562, carried out so far as possible a "general destruction of everything which related to the ancient life of the nation." He was a Franciscan friar, and subsequently became Bishop of Yucatan. He was a sincere friend and protector to the natives; he has preserved the Maya alphabet, and with it the key to the inscriptions, a service which "wipes out over and over again his faults, which were those of the century."

The Mayas used a series of twenty day-names in an invariable order, Kan, Chicchan, &c., the first following the last without a break, just as the days of the week do with us. The period of twenty days is referred to as a month.

In addition to this, a device was used of counting up to thirteen, and then beginning again, so that the complete cycle becomes 260 days; just as we should have a complete cycle of 210 days if every month contained thirty days, and if it were usual to name only the day of the week and the day of the month without naming the month. The series of 260 days is called Tonalamatl.

As an illustration of the ingenuity that has to be applied in deciphering the results, we transcribe here from p. 28 an example in which we have merely changed the notation for the convenience of printing. Thus we use four symbols, p, q, P, Q, where the original uses lines and dotes either black or red. We have replaced red signs by small letters, black signs by capitals, dots by p or P, lines by q or Q. We use brackets to divide one group of symbols from another. Then we have to decipher (p)(PPQQQ)(q)-(PPPPQQQ)(pqq)(PQ)(pppp)(QQ)(p). The following interpretation may be considered correct, because it makes sense (the process may be compared with solving an equation by trial and error):—Let p or P denote unity, q or Q denote five; then the sentence reads: One, add seventeen, leaves remainder five; add, nineteen, leaves remainder eleven; add six, leaves remainder four; add ten, leaves remainder one. By "leaves remainder" we mean on dividing by thirteen. It is, as we might say, Sunday; in ten days it will be Wednesday; in five more, Monday; in twelve more, Saturday; and in eight more, Sunday again.

With this sample of the contents we must leave the book to our readers. Some will, no doubt, be interested in the problems of decipherment, others in the results obtained; perhaps still more will feel that they cannot be interested in everything, and other problems and other people have greater claims upon their attention. The world at large would regret to see any branch of knowledge die out or remain stationary, and will, in consequence, feel grateful to the author for his labours.

A MONOGRAPH OF DENDROBIUM.

Das Pflanzenreich, Regni vegetabilis conspectus. Edited by A. Engler. N. 50, II., B. 21, Orchidaceæ, Monandræ, Dendrobiinæ. Pars i., genera n. 275–277. By Fr. Kränzlin. Pp. 382. (Leipzig: W. Engelmann, 1910.) Price 19.20 marks.

THE present volume is the forty-fifth of a series of monographs, comprising the "Pflanzenreich," and the third which deals with the great family of orchids. Of the three latter, the few diandrous genera formed the subject of the first, the work of the late Prof. Ernest Pfitzer, while the second volume, begun by Pfitzer, and completed by Dr. Kränzlin, dealt with the small group of the Coelogyninæ. The bulky "Heft" by Dr. Kränzlin, which is the subject of this notice, is devoted to the great genus Dendrobium and its immediate allies. It is evident therefore that there is still very much to be done before we have, what has been a desideratum since the time of Lindley, a complete monograph of this large and important natural order.

The plan of arrangement of tribes and genera adopted in the "Pflanzenreich" is that which was elaborated by Pfitzer in his account of the Orchidaceæ in the "Pflanzenfamilien." Dr. Kränzlin, however, takes a somewhat different view of the limitations of genera. He is here treating of that portion of the section Dendrobiinæ which is characterised by the presence in the anthers of four pollinia without appendages, and in Pfitzer's arrangement included three genera, Latourea (a monotypic genus), Dendrobium (with 300 species), and Aporum (with twelve species). Dr. Kränzlin points out that the first of these was founded on a misconception, and must be regarded as a synonym of the larger genus, in which he also includes the small genus Aporum. On the other hand, he finds reason for resuscitating the very doubtful genus Callista of Loureiro, which depends on a fragmentary specimen of Loureiro's in the British Museum herbarium, and the genera Sarcopodium of Lindley and Desmotrichum of Blume. He also raises to generic rank the sections Inobulbon and Diplocaulobium, and maintains the genus Adrorhizon, founded by Sir Joseph Hooker on a single species from Ceylon.

The number of species admitted is more than double the estimate given by Pfitzer in the "Pflanzenfamilien" in 1889. The great genus Dendrobium includes more than 600 species, which are distributed among ten subgenera, and the grand total of species contained in the seven genera recognised is more than 700. This great increase in number of species is an index of the large and widespread interest which has been taken in the family of orchids during the last twenty years, a period which, by a strange coincidence, starts from the date of the abrupt termination of the work of the younger Reichenbach. During the whole of this period Dr. Kränzlin has been working continuously and steadily on the order, and with the completion of his monograph of one of the largest genera, as well as one of great interest, to botanists and horticulturists, he has earned a new debt of gratitude from workers both in the pure and applied aspects of the science. A. B. R.

ANTHROPOLOGY.

History of Anthropology. By Dr. A. C. Haddon, F.R.S., with the help of A. H. Quiggin. Pp. x+158. (London: Watts and Co., 1910.) Price 1s. net.

THIS is a fascinating little volume, and deals in a masterly manner with the history of anthropology in so far as that can be done within the compass of some 150 pages. Anthropology is now so vast a subject that it is necessary for the individual student, if he wishes to become a specialist, to confine his attention to a comparatively small fraction of the whole, and very often the specialist in one department knows little or nothing of what has been done in other departments. To such specialists this short history will be of the greatest value, and the science of anthropology as a whole will benefit by the coordination of results obtained in different departments.

The authors divide their subject into the two main divisions of physical anthropology and cultural anthropology, and these again are divided into chapters with somewhat eclectic titles, dealing with the more important and interesting sections. We have, for example, chapters on the "Pioneers of Physical Anthropology," "Anthropological Controversies," and "The Unfolding of the Antiquity of Man," under the

first division; and chapters on "Ethnology, "The History of Archæological Discovery," "Technology," and "Sociology and Religion," under the second division.

It is, we think, unfortunate that the authors have to a great extent followed the somewhat confused and redundant classification of Dieserud, in the subdivision of their material; it is impossible, for example, to prevent some overlappng in chapters dealing with "The Unfolding of the Antiquity of Man," and "The History of Archæological Discovery." Similar difficulties are met with in connection with other chapters in the book. The question of the classification of the subject-matter of anthropology is confessedly full of difficulties, and the authors no doubt found themselves to a certain extent tied down to the illogical systems at present in use.

The authors confess that their limited space necessitated many omissions, but we were surprised to find no mention of the Gibraltar skull in the chapter on "The Antiquity of Man." The chapter on "Anthropological Controversies" is full of interest, as showing how theology, politics, and economics interfered with the progress of the science.

There have been few, if any, complete histories of anthropology published before the appearance of this work, and the origin of each branch of this subject is so thoroughly explored to its source, that, we are impressed with the fact, that a great deal of original historical research must have been carried out by the authors in the collection of their material.

SOME BOOKS ON CHEMISTRY.

(1) *Inorganic Chemistry for Advanced Students.* By the Right. Hon. Sir H. Roscoe, F.R.S., and Dr. A. Harden, F.R.S. 2nd edition. Pp. viii+476. (London: Macmillan and Co., Ltd., 1910.) Price 4*s.* 6*d.*

(2) *Chemistry for Beginners.* By T. Jenks. Pp. x+309. (New York: F. A. Stokes Co.; London and Edinburgh: W. R. Chambers, Ltd., 1910.) Price 3*s.* 6*d.* (Chambers's Wonder Books.)

(3) *The M.C.C. Periodic Chart of the Elements.* Pp. 45 (introduction) and chart (folded and bound). (London: Metallic Compositions Co., n.d.) Price 8*s.* 6*d.*

(1) THE new edition of Roscoe and Harden's "Inorganic Chemistry for Advanced Students" differs from its predecessor (reviewed in NATURE of December 7th, 1899), mainly in the addition of new lessons or chapters on carbon compounds and on the radio-active elements. It is, however, very gratifying to see the new method of making hydrazine from ammonia incorporated so quickly in a text-book, and to find calcium cyanamide duly described as an inorganic compound amongst the compounds of calcium in a chapter which includes a brief but accurate description of the technical preparation of the metal by electrolysis of the fused chloride. The lesson dealing with crystals and isomorphism remains in some need of revision, as three distinct methods are used to indicate the faces of the crystals in the various diagrams that are reproduced; as the symbols used are not explained the simplest remedy would probably be to omit them altogether from the diagrams. The issue of the new edition has supplied an opportunity for introducing the system of atomic weights in which $O=16$ instead of $H=1$, and these values are now used throughout the book. The larger volume is intended to be used as a sequel to Roscoe and Lunt's "Inorganic Chemistry for Beginners," and an element such as chlorine, which has already been described in the smaller volume, is now referred to only under its metallic derivatives. In this way space has been saved for the introduction of more advanced work than could otherwise have been included within the limits of less than 500 pages.

(2) The "Wonder Book" on chemistry is the third venture which the author has made in seeking to interpret to the non-technical reader some of the more important facts and theories of modern science; the preceding volumes on electricity and photography are dedicated to "Young Readers"; the third volume is for "Beginners." The story is a readable one, and the statements made are usually accurate, at least when dealing with the facts of chemistry; the introduction of theories is responsible for a certain number of errors, as, for instance, where the existence of monatomic molecules is denied (p. 67), or ions are described as "even smaller than atoms" (p. 243); but the author has not hesitated to introduce his youthful readers not only to the atomic and molecular theories, but also to the periodic law and the theory of electrolytic dissociation. A less ambitious programme might have deprived reader and writer alike of the satisfaction of having covered the whole of the subject; but it is precisely because such a sense of perfected knowledge might arise after a perusal of the volume that one would hesitate to commend it to any but the lay reader who intends to remain a layman. As an introduction to the further study of chemistry its value would be very doubtful, since a teacher would probably prefer to deal with a beginner who had not made any attempt to study the subject rather than with one who had imbibed the theories somewhat vaguely outlined by the author. The book is well illustrated, and contains an excellent series of portraits of famous chemists, from Priestley to Mendeléeff.

(3) "The Chart of the Elements," compiled by the Metallic Compositions Company, is intended to summarise in diagrammatic and tabular form the properties of the elements as elucidated by the periodic system. It is intended largely for non-chemical readers who have occasion to make use of metals in various ways, and desire to know something of the properties of related elements which may possibly prove to have valuable technical qualities. An introduction of forty-eight pages is provided, the second part of which, on "The Periodic Law and its relation to Speculative Thought," differs fundamentally from the earlier descriptive and explanatory pages and reveals the author at work on what is evidently a favourite hobby or recreation.

T. M. L.

OUR BOOK SHELF.

Das Radium in der Biologie und Medizin. By E. S. London. Pp. vi+199. (Leipzig: Akademische Verlagsgesellschaft m. b. H., 1911.) Price 6 marks.

In the fourteen years since the discovery of radium a large mass of observations has arisen on the effects of radium rays on the various tissues of the living organism. The present work aims at collecting data from the publications of all countries and systematising the results obtained with normal as well as pathological tissues; and the effects on plants and animals as well as on man. The author expresses his keen desire to arrange his material so as to show some definite general principles resulting from the physiological actions of radium rays. Unfortunately he has had to own himself quite unable to achieve this ambition. He has therefore decided to divide the work into a biological and a medical section, and to divide each of these into an experimental and a clinical side. The work does not pretend to be a text-book; it is offered merely as a complete compilation up to date.

The physiological properties of radium rays are fully described, including the decomposition of lecithin, with the separation from it of cholin, a substance which is capable of producing considerable changes in the organism. The author then passes on to the action of radium rays on bacteria and on the lower fungi. The results here are not very striking. In dealing with the ferments, toxins, and antitoxins of the body, some very interesting facts are brought to light, and it is shown that radium, whether inhaled or injected in the form of solutions of emanation, has the power of increasing the activity of certain of the body's ferments. Other ferments appear actually to be reduced in activity by radium rays. This leads us to the recent use of radium and of radium emanation in the treatment of gout, in which perfectly definite results have already been obtained, although far more observations are required before this treatment can be applied extensively. The action of radium on the skin and on cancerous tissues is also fully described.

The book is a careful and conscientious compilation, and must prove of great value to those engaged in practical work with radio-active substances. A. C. J.

Die Adamellogruppe, ein alpines Zentralmassiv, und seine Bedeutung für die Gebirgsbildung und unsere Kenntnis von dem Mechanismus der Intrusionen. By W. Salomon. II. Teil, Quartär, Intrusivgesteine. Pp. vi+435–603+Taf. ix–xi. (Wien: R. Lechner (W. Müller), 1910.) Price 12 kronen.

The first part of Herr Salomon's great monograph on the Adamello group was noticed in our columns on July 22, 1910. In this second one he describes the diluvium (for he retains this term consecrated by ancient error), such as the different types of moraines, the erratics from the central mass (which have been carried far), and the erosive effects of the ice. In regard to the last, considerations of space forbid us to say more than that he has a firm faith in the excavating powers of glaciers, and regards them as agents of no small importance in the sculpture of the Alps. The remaining and larger portion is devoted to a study of the intrusive rock of the *massif* and its enclosures. The former, as might be expected, exhibits several varieties, which are often closely associated, and indicate a differentiation in the original magma, before it arrived at its present position, with an approach to solidification in the more basic portions. Thus sometimes the latter have been carried away as actual fragments (not very happily named *Lacerationssphäroide*) in the more liquid material, while sometimes a kind of mottling or streaking is produced, as may be seen in the Guernsey diorite. Not seldom also the rock is cut by aplitic and pegmatitic veins, representing the most acid residue, as the fragments do the earliest and most basic segregate. Of these we find some excellent photographs, with others of a more general character.

Every detail is so elaborately worked up that the memoir bids fair to rival the mountain in magnitude, and we cannot but think, since the counterparts of many of the facts occur elsewhere in well-known places, that greater brevity would have been an improvement. These monumental memoirs, thought containing much that is really valuable, sometimes tempt the student to doubt, as in the well-known instance, whether it is worth going through so much to get to so little.

Cassell's Cyclopaedia of Photography. Edited by B. E. Jones. Part i. (London: Cassell and Co., Ltd., 1911.) Price 7*d.* net.

Messrs. Cassell's "Cyclopædia of Photography," of which the first part is before us, is edited by Mr. Bernard E. Jones, who is assisted by about twenty "chief contributors," well known in the photographic world in connection with that particular branch of the subject that each is associated with. The work is to be completed in twelve parts, to be published at fortnightly intervals. The editor aims at including every accepted photographic term, and at paying particular attention to the requirements of both amateurs and professionals. As an indication of the wide range of subjects included, we give the headings that occur on the first page of the first number:—"Abat-jour," "Abaxial," "Abbe Condenser," "Abbe, Ernst," "Aberration," "Abrading Powder." The articles in this number that exceed one page in length, are titled:—"Acetylene Generator," "Albumen Process," "Aphengescope," and "Autochrome Process."

New Ideas on Inorganic Chemistry. By Prof. A. Werner. Translated, with the author's sanction, from the second German edition, by Dr. E. P. Hedley. Pp. xvi+268. (London: Longmans, Green, and Co., 1911.) Price 7*s.* 6*d.* net.

The first German edition of Prof. Werner's treatise was reviewed in these columns on March 8, 1906 (vol. lxxiii., p. 433). As compared with the first, the second German edition was to a great extent rewritten, and in part extended. The chief object of the revision was the harmonising of the sections discussing the problem of valency. New sections on work done between the dates of the two editions were added. But on the whole the book has preserved its original character. An index would add to the usefulness of the work.

The Natural History of Selborne. By Gilbert White. With Notes by Richard Kearton, and 123 illustrations and photographs by Cherry and Richard Kearton. Pp. xvi+294. (London: Cassell and Co., Ltd., 1911.) Price 3*s.* 6*d.*

The first edition of this very attractive production of a widely known classic was reviewed in the issue of Nature for March 5, 1903 (vol. lxvii., p. 419). The fact that the book has been reprinted three times since then shows that the notes and illustrations of Messrs. Kearton have been very successful in extending the knowledge of White's letters on natural history.

How to Build an Aëroplane. By Robert Petit. Translated from the French by T. O'B. Hubbard and J. H. Ledeboer. With 93 illustrations. Second edition. (London: Williams and Norgate, 1911.) Price 2*s.* 6*d.* net.

The present differs in no essential respects from the first edition, reviewed in Nature of August 25 last (vol. lxxxiv., p. 229). The translators have not felt justified in incorporating details of the numerous variations of original types of aëroplanes.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Caliature Wood.

DURING the preparation for the press, in 1895, of the "Diary and Consultation Book of the Agent, Governor and Council of Fort St. George," for 1682–5, Mr. A. T. Pringle, the editor, inquired if I could throw any light on the origin of caliature, a name for redwood (*Pterocarpus santalinus*), frequently referred to as an article of trade in Madras. Presuming the name to be that of a port on the east coast, it has evidently disappeared from nearly all the available gazetteers and modern atlases. Inquiries were made in London, Holland, and Java with no results; but recent researches in the libraries of Calcutta have been more successful, and the following notes on the early trade of the country form an interesting chapter on the history of red-sanders wood.

To Rumphius belongs the credit of giving the origin of the term "caliture." In "Herbarium Amboiense," 1750, vol. ii., 48, he speaks of "Santalum rubrum" being known in his country and in Europe, and as coming from a tree from which "lignum calitour" is derived. The wood is very hard, solid, and dull-red, which he says could be obtained in great abundance from the northern parts of the Coromandel coast. Various kinds of furniture were made of it, as benches and elegantly carved chairs. Only the mature trees afforded good sandalwood, as was shown in letters sent to him in 1689. The wood was also used as a tincture in the arts, and the Armenians in Shiraz and Ispahan added it to distilled spirit of wine to give it a beautiful and intense red colour. The identity of the town by Rumphius I will quote in the original Latin:—"Hisce addo ex iisdem litteris locum Caliatour quondam dictum, hodie in ora Coromandelensi hoc nomine non amplius esse notum, sed tempore mutatum fuisse in *Krusjua-Patanum*, seu *Kisjua-Patan*, ita ut primi nominis memoria inter Europæos tantum conservetur."

The town of Kistnapatam, referred to in this paragraph, is in the Nellore district of the Madras Presidency. It is now a village, situated at 14° 17′ north latitude, 82 miles north of Madras; it has a fine backwater of great depth, and is a shelter for native craft during the monsoon. In an old glossary it is said to be the Greek σωπατρα, and "title otherwise Calitore." In a map accompanying "A True and Exact description of the most celebrated East India Coasts of Malabar and Coromandel" (1672), by (Rev.) Philip Baldæus, Callerture is shown between Armagon and Penne (Penner River). In a map of the "Peninsola deli India" (dated 1683), by Giacomo Cantelli da Vignola, a Portuguese, the town is indicated as "Caletur." It is evident that while the town was known to foreigners as Calitore or Caletur, it was not recognised by that name by the British factors.

The trees yielding red sandal-wood occupy a small area including portions of the Cuddapah, Nellore, and North Arcot districts, chiefly on the Sashachellam, Lankamali, and Veligonda ranges of hills. Mr. Gamble remarks that "in range there is perhaps no important Indian tree of so circumscribed a distribution." We need not suppose that the area under *P. santalinus* has shifted its position during the past two hundred years. A glance at the map of India will show that produce from this area would find outlets on the coast at Caleture, Armagon, and Pulicat, frequented by Dutch ships in the seventeenth century. Turning to the text of Baldæus's description of the Coromandel coast, we do not, however, find reference to the trade in redwood, but on p. 654 he says that between "Penna and Caleture" the best "Essaye Roots" are found, referring to chayroot (*Oldenlandia umbellata*); and he refers to the bark of a tree, of a darker colour, which is probably *Ventilago madraspatana*. Numerous vegetable dyes must have been in use at this time to prepare the large quantities of coloured cotton goods exported from this coast.

The earliest English factory was planted in 1625 at Masulipatam, where trade was carried on with varying fortune for several years. In 1628 the agent, pressed by the Dutch rivalry, migrated southwards to Armegam. In 1639 Armegam in its turn gave way to Fort St. George, Madras, which in 1653 was raised to the rank of an independent presidency. Between this young growing factory and the Court of the Hon. East India Company there was considerable correspondence, and interesting extracts are made in the Diary and Consultation Book of the Agent and Governor. In their despatch dated February 8, 1681, the Court wrote as follows:—"And we do further order that you make the like provision of 300 tons Reddwood for our next yeares shipping. The Dutch call this Reddwood by the name of Calliature wood, and we do p̄ the Nathaniell and Williamson send a pattern therof which came from India. We are informed that it costs about 2½ Pag° p̄ candy, they are usually in pieces of about 3 yards long but you may have it sawed into pieces of about 2 foot more or less as the Comanders shall desire for conveniency, it being to be ground to powder here and used in dying."

Contracts for the supply of the wood were negotiated by the Governor, and the question of advances was settled with the merchants. In September, 1682, the following entry in the Diary occurs:—"The Calliature or Redwood merchants having made a contract with yᵉ Agent, &c., for — candy of red wood, declared that without they might have half the money before hand they could not comply with their contract wᶜʰ upon their promise of giving security was granted them."

Redwood was frequently used as ballast in home-going ships. A specific case is recorded in the Diary for 1682:—"Captain Willshaw of the Resolution complained that he would not be able to ride out yᵉ storm without sufficient Quintelage [ballast] therefor ordered that the warehousekeeper doe lade on board him 100: Tonns saltpetre and what Calliature wood can be got to stiffen his ship and inable him the better to ride out yᵉ storm."

In 1683 the Governor found it necessary to define the terms of freight with Captain Willshaw, a skipper of somewhat independent character. On January 1 the following official letter was sent to him:—"Wee do likewise acquaint you concerning Redwood or Calliature wood that (provided you are fully laden) except you are contented to receive but half freight for it wee shall not lade any upon your ship wee being ordered to send none home upon any other terms than that to which wee desire your answer that accordingly wee may lade or not lade the same upon you." Willshaw replied:—"As to the other particulars of the redwood I shall be willing to take it in for £9 10 p̄ Tunne being the ½ freight of Grosse goods provided that according to contract your worᵖ may have men aboard to saw and split it to which if yoʳ worᵖ and Councell will not condescend I am as ready to deliver both the petre and wood as I was willing to request the Lading it on board for the securitie of his Maᵗⁱᵉˢ subjects and the Companys concern therefore desire to know your Resolution till when none of the Petre or wood shall be stowed away but what is already stowed."

During the years 1683 and 1684 various payments were ordered to be made to the redwood merchants for the Honble. Company's account, and orders were regularly issued to the warehousemen to load the wood on English ships in the harbour. In order to maintain the supply in Madras, "Generalls" or letters were addressed to the northern factories in Vizagapatam and Masulipatam with requisitions for the wood to be sent down in coasting vessels.

In 1685 as much as 1337 pagodas were paid to the local redwood merchants in seven instalments during the year. Calculating the pagoda at 9*s*., this amounts to 605*l*. This, however, indicates only a portion of the trade for the year.

Reference to "The Private Diary of Ananda Ranga Pillai from 1736 to 1761" proves that the trade in red-sanders wood was still brisk. In 1743 the ship *Fleury* sailed for France with 1000 candies (candy = 500 lb.) and the *Phénix* with 2000 candies of redwood. It might be mentioned that the *James and Mary*, that gave its name to the dreaded sandbank in the Hooghly, and was wrecked on September 24, 1694, carried a cargo of redwood taken up at Madras.

In the "Letters received by the East India Company

from its Servant in the East, 1602–1617," there are numerous references to the various kinds of sanders wood, but they are easily distinguished. The red sanders wood always came from the Madras coast, and was sent to Europe for dyeing purposes. The white sandal wood (*Santalum album*) was used as a perfume, for medicinal baths, and for presents. Sappan wood, sapang, patanga, or Brazil wood came from Malaya and Siam from the tree called *Caesalpinia sappan*. It was one of the "vendiblest" commodities in the trade between Siam and Japan in 1615.

There is still a demand for red sanders wood, but the drug is not of so much importance as it was years ago. The reasons are well known—on account of the artificial substitutes now employed for dyeing purposes. Evidence of this is seen in the last issue of a Madras newspaper just to hand. It describes the visit of the Governor of Madras to a large modern cotton mill. One sentence reads:—"His excellency passed on to the reeling room and then to the dye house, where the dyes used are mostly aniline dyes." DAVID HOOPER.

Anguillula glutinis—Paste Eels.

IN Carpenter's work on the microscope, the eighth edition, so ably edited by the late Dr. Dallinger, occurs the following passage (p. 945): "This last [*A. glutinis*] frequently makes its appearance spontaneously in the midst of paste that is turning sour; but the best means of securing a supply for any occasion consists in allowing a portion of any mass of paste in which they may present themselves to dry up and then laying this by so long as it may not be wanted, to introduce it into a mass of fresh paste, which, if kept warm and moist, will be found after a few days to swarm with these curious little creatures."

As he also says that "a writhing mass of any of these species of 'eels,' is one of the most curious spectacles which the microscopist can exhibit to the unscientific observer," very many young microscopists have been led to try to obtain the eels by allowing paste to stand until sour, and also by getting dried paste known at one time to have contained "eels." Unfortunately, in this country at least so far as I know, such attempts have always failed, and I have received many letters asking for the cause of such failure.

Of course, it is generally acknowledged that no animals of the grade of these nematoid worms ever appear *spontaneously;* they were probably present in the water used to dilute the paste, but in paste that has been boiled and diluted with water that has been boiled they never appear, and I have tried hundreds, perhaps thousands, of experiments in this direction. And even when cold water from a pond or brook was used to dilute the paste, I never found them.

In regard to dried paste also, my experience has been different from that of Dr. Carpenter. When paste has been thoroughly dried in the open air in our climate, no eels can be made to appear by transferring some of this paste to fresh material and keeping it warm and moist. Paste may dry up to a stiff mass and the eels still live, but I have never been able to keep paste in a thin layer exposed to the air in our dry climate for one month and then resuscitate the eels. I have tried it over and over again, and the eels always disappeared. By keeping the paste slightly moist, however, the eels (or their progeny) may be kept indefinitely.

The fact that Carpenter could keep them alive after the paste had apparently dried up, may perhaps have been due to the moistness of the English climate in comparison with ours.

Fortunately, the "eels" may be found in most bookbinder's paste tubs, and a sufficient amount for a start may, if properly packed, be sent by mail provided the time of transit is not more than two weeks. JOHN PHIN.

Paterson, N.J., U.S.A.

The Fox and the Fleas.

THE story of the fox and the fleas, published in NATURE of March 23, is not current among Celtic people only. As Bohemia is a country full of fields, pastures, ponds, brooks, and forests, the last often being inhabited by foxes, it is no wonder that my father, who was a close observer of nature, told me the same story nearly fifty years ago. But the Bohemian fox was in one point distinguished from the English fox, for, being unable to find sheep-wool and probably not trusting to hay, and yet wishing to get rid of the fleas, he was obliged to sacrifice his own fur, and so he plucked out as much of his own wool or hair with his teeth as might easily serve to collect the fleas; and the effect was superior, for the fleas could creep into the hair without noticing any change of medium during the water trick.

As regards the question about the origin of the fleas, raised by Prof. Hughes in NATURE of April 13, my experience as an old hunter is that, at least in our comparatively dry climate, the animals living in forests have an ample opportunity of gathering fleas there. If you happen to shoot a squirrel, never put it into your bag or pocket, or else in a few minutes you will be swarming with fleas which are quickly leaving the dead animal.

Once I placed a freshly shot squirrel on a newspaper, and was surprised to find what an enormous quantity of little fleas of a peculiar kind (all these different kinds of fleas were studied by Baron Rothschild) were leaving the dead animal; and yet the squirrel lives more in the trees than on the ground, and hardly approaches stables or inhabited buildings; how much more easily can a fox collect his parasites on the ground of the forest!

Some readers of NATURE may ask what means the crayfish on the immersed tail of the left-hand side fox in the interesting figure on p. 211. To this I found an answer in the invaluable book on "Animal Intelligence" by Romanes, p. 432, according to which "Olaus witnessed the fact of a fox dropping his tail among the rocks on the *sea* shore to catch the *crabs* below, and hauling up and devouring such as laid hold of it." On the contrary, it is not clear what is the matter with the tail of the right-hand fox in the figure.

I may add that while ski-ing in deep winter in the Bohemian Forest I often watched the footsteps of different wild game in the snow, and once I found a trace of a fox without being able to tell which way he was going. After having followed it for about half a mile to the summit of a mountain, I found that the fox made a turn there and walked a long way back exactly in his own footsteps. Did he intend to conceal in which direction he was going? That the fox has sometimes this intention is shown by the fact that in the proximity of inhabited places the footsteps of the fox in the snow suddenly disappear, the fox having effaced them by his tail.

Belladonna Plaister for Bee-Stings.

SOME years ago it occurred to me to try the experiment of treating bee-stings with belladonna plaister; and, as this remedy is remarkably efficacious, and as I have met no one who was aware of the cure, I have intended for a long time to ask you to put the fact on record in your columns. If the sting is but slight, there are no unpleasant effects at all when belladonna is at once applied, and the plaister may be removed after a comparatively short time; if the sting is severe—*i.e.*, as I suppose, if it has entered a vein—it may be necessary to retain the plaister for several days; and in such case, although there will be swelling and some irritation, both these unpleasant effects will be very notably less than in cases where no belladonna has been used. Of course, as some people are extremely susceptible to bee-poison, it is quite possible that they may not find a belladonna-treated sting so small a matter as I find it; but I presume that they will find at least a proportionate alleviation. In the summer-time my children run about the garden bare-footed, and not unfrequently they step upon a bee and get stung. At once there is a shout for "belladonna"; it is put on; and we never hear another word about the sting. I have also found belladonna give great relief from a wasp-sting. I should be very glad to hear the result if anyone living in a "mosquito"-ridden part of the country would try the experiment of applying belladonna to mosquito-bites. It might well be quite useless; but, on the other hand, it might serve.

April 25, 1911.

THE TOTAL SOLAR ECLIPSE, APRIL 28, 1911.

NEWS of the results of this eclipse arrived in England from Vavau on Saturday afternoon, April 29, in the form of a cable through Reuter's Agency from Mr. P. Baracchi, Government astronomer at Melbourne, Australia. He reported that the observations of the eclipse were considerably interfered with by passing clouds, and that the results were only partially successful.

No news regarding the experience of the English parties observing at Vavau was available until Sunday morning, April 30, when Sir Norman Lockyer received a cable from Dr. Lockyer, sent by wireless from H.M.S. *Encounter*, at Vavau, to H.M.S. *Pegasus*, at Auckland, thence by cable, stating that the expedition from the Solar Physics Observatory had not been successful, in consequence of bad weather. With regard to the two most important spectroscopic instruments—a 6-inch prismatic camera with four large objective prisms of 45° angle, and a concave grating spectrograph of 10 feet radius of curvature—poor results have been secured by the first; photographs of the corona, with the two large coronagraphs of 16 feet and 8 feet focal length, were obtained, but of inferior quality.

A general description is given of the visual observations made of the form of the corona, from which we learn that it was of the typical minimum type, with long equatorial extensions. The general description of the eclipse is that it was not a dark one, and in consequence comparatively few stars were observed during totality.

The second English party under Father Cortie has been also unfortunate, but as yet no news is to hand regarding the experience of the German and American astronomers who proposed to occupy one or more of the islands to the north-east of Vavau.

In an interesting letter received from Dr. Lockyer he emphasises the generous and enthusiastic help afforded to the expedition by the Australian authorities. Mr. H. A. Hunt, the Commonwealth Meteorologist, at the request of the Government, invited Dr. Lockyer to inspect the site of the new Solar Physics Observatory, which is to be established near the new capital; this is a little more than twelve hours' railway journey from Sydney. It will be the only southern observatory having solar observations as its prime duty, and it fills a longitude gap between India and the United States. It is therefore anticipated that the results from such a locality will be of the greatest importance.

Towards the end of March the heavy equipment taken out from England was safely stored on board H.M.S. *Encounter*, of the Australian squadron, and the official party, in company with that of Father Cortie and Mr. Baracchi, sailed from Sydney on March 25, reaching Vavau on April 2. On the way arrangements would have been made for the organisation of the various parties, taking charge of each section of observation. Captain Colomb, R.N., assisted the expedition in every way, and from a telegram received last week we learned that on the call for volunteers more than 100 of the ship's company signified their willingness to take part in the observations. Parties would be formed for sketching the corona, observations of shadow bands, landscape colours, aids for the working of each of the large instruments, timekeepers, &c. By means of pictures of rmer eclipses which have been successfully observed and general descriptions by the astronomers in charge, all the members of these different sections would soon be rendered conversant with their individual duties. On landing steps would first be taken to select the most suitable site; then the ground would be roughly surveyed, and the positions selected for the pillars of the large instruments. This done, more accurate observations of the meridian line would be made, so that each instrument could be adjusted exactly in the proper orientation. When the instruments were satisfactorily installed and protected, periodical drills would be instituted, when all the operations, down to the smallest detail, would be practised, exactly as if the eclipse were really taking place. After two or three of these drills everyone becomes very proficient in their duty, and it is only such unavoidable misfortune as has attended the present occasion which can prevent good observations from being secured.

The latest information is that a second message has been received from Mr. Baracchi stating that some of the results of the Australian party are better than was at first anticipated. Thirty pictures of the corona have been obtained. CHARLES P. BUTLER.

STANDARD BREAD.

ALMOST every people boasting the rudiments of agriculture makes use of cereals as part of its food. The cereals comprise all grains or corn-bearing plants, and are grasses which by long cultivation and selection have developed a maximum of food material with a minimum of husk. Wheat, barley, oats, rye, maize, millet, and rice are the principal cereals, and the first four have an extraordinarily wide geographical distribution. The following is the average composition of cereals:—

	Per cent.
Proteins	10–12
Carbohydrates...	65–75
Fat	0·5–8
Mineral salts	2
Water	10–12

Maize and oats are the richest in fat, wheat and rye contain respectively 1·7 and 2·3 per cent. of fat, while rice contains the maximum of carbohydrate and the minimum of protein and fat. Regarded as a diet the cereals contain a large excess of carbohydrate and a deficiency of protein and fat. Wheat and rye are alone suitable for bread-making; this is due to the fact that they contain a peculiar protein "glutin," which becomes viscid when mixed with water, and determines the binding properties of the dough. Glutin does not exist as such in the grain or flour, but is developed by the interaction in the presence of water of two proteins, gliadin and glutinin.

For the preparation of flour the grain is ground or milled, and in the process, which by means of

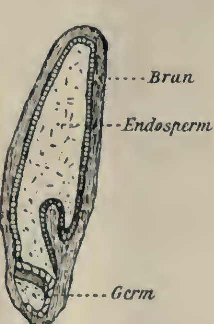

FIG. 1.—Diagram of structure of wheat grain.

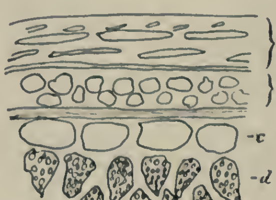

FIG. 2.—Diagram of layers of wheat grain.

modern machinery in the iron roller mills has been brought to an extraordinary degree of perfection, various constituents of the grain are

separated. A grain of wheat consists of (1) an outer envelope or husk, which constitutes the bran, (2) the kernel or endosperm, and (3) the germ (see Fig. 1). The husk has an outer cuticle from which delicate hairs spring (Fig. 3), under which are three other layers, the two outer consisting of elongated cells (Fig. 2, *a*), the third of well-defined rounded cells (Fig. 2, *b*). Then comes the envelope of the seed proper, the "testa" or "episperm," under which is a layer of large quadrilateral "cerealin" cells (Fig. 2, *c*), which encloses the endosperm; the latter consists of numbers of large cells with delicate walls filled with starch granules (Fig. 2, *d*). The husk, constituting the bran, consists mainly of cellulose with pigment and

Fig. 3.—Outer cuticle with hairs of grain.

Fig. 4.—Inner skin or epicarp of grain.

mineral salts, the endosperm consists largely of starch, and the germ, relatively a small portion of the whole, is rich in protein and fat. In the process of milling the grain is broken up and various "mill products" are obtained. The outer coats yield bran, fine pollards, sharps, and middlings, the germ is removed as offal, while ordinary flour is derived almost solely from the endosperm. The flour itself is divided into a larger portion, "bakers" or "households," and a smaller, very white and poor in protein, known as "patents," from which genuine Vienna bread and the best class of fancy breads and pastries are made. The semolina, derived from the central part of hard wheat, and rich in glutin, is also lacking in white flour.

It will thus be seen that ordinary white flour and white bread made therefrom contain little or none of the bran, germ, and semolina, and valuable food con-

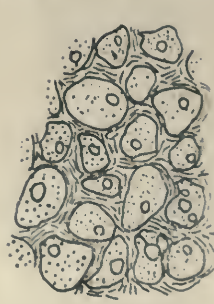

Fig. 5.—Large-celled endocarp layer of grain.

stituents—mineral matter and protein of the bran and semolina, and fat and protein of the germ—are lost. Wholemeal bread is therefore richer in the nutritive constituents and has more flavour, but is darker in colour than white bread, owing partly to the inclusion of the bran and partly to an interaction by which dextrin and sugar are formed which undergo darkening in the oven. Wholemeal bread is, however, apt to be irritating on account of the cellulose and silica of the outer coat, but by removal of the outer layers of the husk the irritant material may be excluded, and the valuable mineral, protein, and fatty constituents of the inner branny coat, semolina, and germ, are retained. Such a flour constitutes the "80 per cent. flour" employed in making the so-called "standard" bread. The term "80 per cent. flour" means that a wheat a bushel of which weighs 64 lb. yields 80 per cent. flour. In the old method of milling the wheat is ground between stones, the flour being separated by sifting, and in this way some of the "offal" is retained; hence the term "stone-ground."

"Standard" bread is distinctly cream-coloured, and contains pale brown particles derived from the branny coats of the grain. It has more flavour and is moister than ordinary white bread, and contains more phosphates and other mineral salts. Microscopically various branny constituents can be recognised, *e.g.* cuticle with hairs (Fig. 3), inner skin or epicarp (Fig. 4), and large-celled endocarp layer (Fig. 5), and these figures are reproduced from actual drawings of a sample of "Standard" bread examined. There is doubtless some difference of opinion as to the relative values of ordinary and "Standard" flour, and the bread made therefrom. The roller mills cleanse the wheat in a very efficient manner. Chemical analysis, except as regards salts, shows little difference between the two; "standard" bread may even be slightly poorer than ordinary bread in protein, owing to the greater percentage of moisture. On the whole, however, we think there can be little doubt that "Standard" flour and bread are to be preferred. Their use will also tend to revive wheat growing and the small miller in England.

THE HOME LIFE OF THE SHANS.[1]

THE Shan States under the control of the Government of Burma form two groups, the northern and the southern, separated for some distance by the Nam Tu or Myitnge River in the eastern portion of the province. Ethnologically, the Shans are a branch of the great Tai people, "the free," who at present exercise sovereignty only in Siam. The affinities of the branches of this people are obscured by the bewildering variety of names which disguises their identity, while the dialects are mutually incomprehensible, and, as if this were not enough, are recorded in at least six forms of written character. Even the origin of the name Shan is a puzzle, the only reasonable explanation being that of Sir J. G. Scott, who points out that they were known to the Burmese as Tarok or Taret, and possibly gained their present title from their Chinese designation, Han Jen. Our knowledge of them is derived from the accounts of earlier travellers like Dr. Richardson, Captain Macleod, and Sir H. Yule; from the translation of tribal chronicles by Mr. Ney Elias and Sir J. G. Scott, and of Chinese authorities by Mr. G. H. Parker; and, in particular, from the monograph on their history and ethnography written for the Census Report of Burma, 1892, by Dr. J. N. Cushing. In the present book the information thus collected has been carefully summarised in two chapters on tribal history and literature by Mr. W. W. Cochrane.

Mrs. Leslie Milne spent about twenty months in a Shan village with the object of studying the language of the Palaung or Palê, a neighbouring hill tribe who

[1] "Shans at Home." By Mrs. L. Milne. With Two Chapters on Shan History and Literature by the Rev. W. W. Cochrane. Pp. xxiv+289. (London: J. Murray, 1910.) Price 15s. net.

trade with the Shans, but are allied to them neither by race nor language. She is a careful and sympathetic observer, and has profited by information received from the officials of the American Mission. At the same time, she has not avoided that almost idyllic conception of their character and beliefs which is prominent in the accounts of Burman life and psychology by enthusiasts like Sir J. G. Scott and Mr. Hall Fielding. The truth is that their views are largely based upon the obvious contrast between the races of Burma and those of the Indian plains. While the latter, mainly owing to the bondage of the caste system, are reticent, suspicious, and unwilling to associate with the foreigner, the former are cheerful, kindly, and beset by none of those taboos of food and personal pollution which in India proper form an effective barrier between the people and their rulers.

FIG. 1.—Circles of sand made by Shans in shallow parts of muddy streams, in order to act as water filters. From "Shans at Home."

Such views naturally lead to exaggeration. In the case of religious beliefs, for instance, Mrs. Milne has failed to grasp the fact that their beliefs are almost purely animistic, and that Buddhism is only a thin veneer concealing the predominant workship of Nats or spirits. It is true, as she observes, that among them "there is no great fear of death; they all feel that they have all lived and died so often that death and its mystery is not talked of in a whisper, but is a favourite topic of discussion in Shan houses." "They place," she goes on to say, "religion and the study of their scriptures, and a temperate life on a higher level than money or the comforts and luxuries that money brings. Their lives are very happy. Any man may marry the girl he loves if he can persuade her that she loves him better than any other man. There is always money enough, and food for the children that come to gladden their homes. Starving people do not exist, and there are few unemployed, because any man or woman may easily earn a livelihood by asking for jungle land, by clearing and cultivating, and by selling the produce that is grown upon it." When British rule was introduced

FIG. 2.—Market Day. From "Shans at Home."

we found them harassed by raids of the neighbouring Kachins and torn by internecine war. Now they are clamouring for roads which will enable them to bring their produce to the railway. It will be interesting to watch how long this almost idyllic social state remains unaffected by the pressure of commercialism.

Mrs. Milne's account of their home life and industries is clear and comprehensive; and the value of her book is increased by an excellent collection of photographs. It is certain to survive as the standard account of a most interesting people recorded at a time when they were little affected by external influences.

BELGIUM'S CONTRIBUTION TO THE PLAICE PROBLEM.[1]

THE plaice problem still occupies a prominent position in the foreground of the international investigations. The reason is not that the plaice is the sea-fish which contributes most wealth to the countries concerned. In respect of total value landed the fish is surpassed in England by the haddock, the herring, and the cod, while in Belgium the total value of soles annually landed is more than twice that of plaice, which stands fourth in the list, after haddock and herring.

The reasons why the plaice is of such importance that it has been made the principal object of investigation on the parts of England, Germany, Denmark, Holland, and Belgium are as follows:—

(1) This fish constitutes a proportionately large as well as much appreciated element in the ordinary dietary of the poorer classes in the five countries named.

(2) The livelihood of large numbers of fishermen in these countries depend on their ability to maintain an adequate supply of this fish in the markets.

(3) It is especially in regard to the plaice that the cry of "depletion" of the fishing grounds, and of the undue destruction of undersized and immature fish, has been, and is still being, raised.

(4) The plaice lends itself perhaps more readily than any other fish to protective legislation, on account of its comparatively restricted range, its regular distribution from the coast seawards according to size, and its slow rate of growth.

In view then of the urgent need which was expressed in discussions on the plaice at Royal Commissions and fishery conferences of a satisfactory knowledge of the natural history of the fish on one hand, and for trustworthy statistics showing the actual condition of the fishery in time and space on the other, it is not surprising that the International Council took the matter in hand at the outset of its career and arranged for a thorough investigation of the plaice fisheries both from the biological and from the economic point of view, an investigation in which each of the five countries most interested was appointed a share. The result of the large amount of research which has been expended on the plaice during the past few years is that we now possess a considerable amount of information respecting the movements of the fish at all stages of its career, the age of the fishes, and their growth-rate in different parts of the sea, their age and size at maturity, and so forth, while the sea fishery statistics of the various countries bordering on the North Sea have been so completely reorganised that they now show us, for a quinquennial period at least, something like the actual yield of different fishing grounds from year to year and from month to month.

Although we have no continuous or sufficiently exact statistics of the plaice fishery extending into last century, there can be no reasonable doubt that the condition of the fishery and the composition of the plaice population on the fishing grounds are very different to-day from what they have been in the memory of the older fishermen, and fragmentary statistics of the number of baskets formerly taken are not altogether wanting to show this. If the destruction of an "accumulated stock" of old fishes (such as is to be found in the Barents Sea at the present day, and not so many years ago at Iceland) was inevitable, and quite rational and economic, the same can scarcely be said if the supply of fish at the present day is being maintained at the sacrifice of an increasing proportion of the smaller and much less valuable sizes. If this actually is the trend of the fishery at the present day, then, apart from the possibility of an ultimate shortage of supply which is at any rate threatened, it is obvious that the fishery is not being exploited in a rational way. As Prof. Gilson, in his important memoir, says:—"On sait qu'il faut considérer la capture en grande masse de jeunes plies, inaptes à la reproduction pour la plupart et *capable de gagner en une année le double et même le triple de leur valeur*, comme une opération antiéconomique appelant une reforme."

It is greatly to the credit of Prof. Gustav Gilson, of Louvain, the Belgian delegate to the International Council, that he has been able to carry out a plan of researches in accordance with the international programme, in spite of the great disadvantages attending the lack of a special research steamer able to work on the fishing grounds at all seasons, and of a coastal laboratory where material could be examined fresh and continuously.

The institution in Belgium which has assumed the task of participating in the international investigations is the Royal Museum of Natural History, which maintains a station for sea fishery research at Ostend. Solely with the aid of the resources of this institution and entirely outside the official machinery, Prof. Gilson has reorganised the sea-fishery statistics at Ostend. Previous to 1904 these gave only the total quantities and value of fish landed at the port without distinction of species, size, number of baskets or fishes, place of capture, &c. From 1904 onwards, thanks to Prof. Gilson's efforts, all these and other essential particulars are given in the statistical returns, so that now the Belgian statistics are equally precise and detailed as those of other countries bordering the North Sea.

In the memoir under review the data collected with regard to the plaice landed at Ostend are analysed and coordinated from two points of views:—(1) So as to show the principal features in the evolution of the Belgian plaice fishery during the quinquennial period (1904–8), and (2) to furnish indications of the influence which a raising of the minimal size legally established (18 centimetres) would probably exercise on one hand on the reserves of plaice in the sea, and, on the other, on the product of the fishing industry in weight and value.

It is impossible to indicate all the features in the evolution of the Belgian plaice fishery during the period 1904 to 1908 which are revealed by Prof. Gilson's analysis of the Ostend statistics. It will suffice to point out the most important feature from the point of view of the present discussion. This is to be found in the progressive increase from year to year of the proportion of small fish in the catches of the *sailing* trawlers, which boats are re-

[1] Contribution à l'Etude biologique et économique de la Plie. Par G. Gilson. Délégué de la Belgique au Conseil international pour l'exploration de la mer. Travaux de la Station de Recherches relatives à la Pêche maritime. Ostende. Fascicule IV. (Bruxelles: Imprimerie Polleunis et Ceuterick, 1910.)

sponsible for the great bulk of the plaice landed at Ostend at the present day. Now it is clearly shown that this increase in the proportion of small fish is not due to a change in the field of action of the boats concerned, for the displacement which has actually occurred has been of such a nature that it ought to have produced a *contrary* effect. It is in consequence of a modification of the composition of the reserves of plaice inhabiting the Southern Bight of the North Sea. The curves for the various divisions of the Southern North Sea show this very clearly. The proportion of small fish in the annual catches in *each* of these divisions shows a gradual rise from 1904 to 1908. That the change in the composition of the plaice population on these fishing grounds consists in a diminution in the number of large individuals and *not* in an increase in the number of small is also fairly clear.

This is the important point: the supply of plaice in the Belgian market is apparently being maintained at the sacrifice of an increasing proportion of the smaller and much less valuable sizes. Researches on similar lines which have been made by the other four nations most interested have apparently much the same tale to tell; but, as these have not been co-ordinated and compared, it would be premature to make any general statement about the condition of the plaice fishery in the North Sea as a whole.

As a remedy for the state of things revealed in the Belgian statistics, Prof. Gilson suggests the *tentative* imposition of a minimum size of 23 centimetres, below which it should be illegal on the part of the sailing trawlers to land or sell fish, and a similar standard of 25 centimetres for steam trawlers. The reasons for the selection of these particular size limits and for a distinction between the two classes of vessels in this respect are fully discussed in the report and hardly need be recapitulated. Very similar size limits for plaice have been suggested by certain of Prof. Gilson's colleagues on the International Council, who will probably be found unanimous in agreeing with him that all such measures designed for the protection of undersized plaice should be of an experimental and elastic nature. In view of the still very incomplete state of our knowledge of the plaice problem, which is far more complex than was at first supposed, certainly no State would be justified in making such legislation final or irrevocable. It would be impossible to predict the effect of the imposition of a given size limit, or the amount of inconvenience attending its enforcement. It is inevitably a case of "try and see." Moreover, a size limit is not the *only* possible means of bettering the plaice fishery. Transplantation to the Dogger Bank, and other grounds richer in food, has been tried on an experimental scale with striking results, in view of which it is worth considering as a possible commercial enterprise.

Finally, one cannot but agree with Prof. Gilson that if we are ever to have experimental legislation for plaice, then it is clear that the scientific control of its effects is indispensable. In other words, there ought to be a permanent International Commission to continue researches on points not yet elucidated, to study the statistics from year to year, and to carry out biological investigations designed to show the changes in the composition of the plaice population on the fishing grounds and in the rate of growth of the fishes which might be expected to result from the legislation. As Prof. Gilson truly says:—"C'est à ce prix seulement que l'on peut espérer de réparer le mal accompli et de porter remède à la rupture encore récente de l'équilibre qui s'était établi, au cours des siècles, entre la puissance alimentaire des mers, le pouvoir reproducteur des espèces et les causes de destruction aux quelles celles-ci étaient soumises avant l'intervention de l'homme."

WILLIAM WALLACE.

NOTES.

MR. A. E. SHIPLEY, F.R.S., has been elected a foreign corresponding member of the Helminthological Society of Washington.

WE regret to announce the death, on April 15, at seventy-nine years of age, of Prof. J. Bosscha, correspondant of the physics section of the Paris Academy of Sciences, and formerly permanent secretary of the Dutch Society of Sciences at Haarlem.

THE National Geographical Society of America is sending out in the summer an expedition for the further study of the glaciers of Alaska. It will be led by Prof. Ralph S. Tarr, of Cornell University, and Prof. Martin, of the University of Wisconsin.

AN expedition, under the charge of Prof. Homer R. Dill, taxidermist of the University of Iowa, has left San Francisco for Layson Island. This island, which is situated in the Pacific about midway between California and Japan, is only about three and a half square miles in area, but is estimated to support a bird population of about eight millions.

THE tenth International Congress of Geography will be held at Rome on October 15 and the six following days. Excursions in northern and central Italy, as well as southern Italy and Sicily, will be arranged, of which the details will be published later. The subscription for membership of the congress is *1l.*, and all persons desirous of joining are requested to remit this sum at an early date to the treasurer of the committee, 102 Via del Plebescito, Rome.

THE Victoria League has in operation a scheme for sending newspapers and magazines, when done with, to addresses in distant parts of the Empire. Although more than 81,000 newspapers and magazines are being sent away annually there are still many applicants unprovided for, and in South Africa and Victoria, Australia, particularly, we are informed copies of NATURE would be gratefully received. Any reader willing to help the movement should apply to the hon. sec. of the Newspaper Scheme, 2 Millbank House, Wood Street, Westminster, S.W.

PROF. HANS MEYER will undertake in May his fourth journey in East Africa. Starting from Bukoba, on the west shore of Lake Victoria, he proposes to march to Lake Kiva and the Kirunga group of volcanoes, in order to study the relations of the volcanic phenomena to the tectonic structure of the western rift system at this point. From Kiva the expedition will travel by Lake Tanganyika and, if time permits, also to Lake Nyassa. Besides geological studies, the botany, zoology, and ethnology of the region traversed will also be investigated.

DR. PÖCK, in the April number of *Petermann's Mitteilungen*, discusses the distribution of plague during recent years, and illustrates it by two maps. The first shows the location of areas where it is endemic, and also those over which it has recently spread, as well as the places where isolated cases have occurred in different years. The second map shows the probable area of origin of the recent outbreak in Manchuria, and the region which was affected.

The influence of modern facilities of communication on the spread of the disease is insisted upon as constituting a factor acting against and sometimes having greater effect than the resources of modern sanitary science in some regions.

At a meeting of the Research Department of the Royal Geographical Society on April 27, Mr. A. R. Hinks discussed recent progress in geodesy. Invar tapes and wires have revolutionised base measurement; gravity surveys have been carried out over large areas, while abnormalities of gravity in more restricted regions have been determined with remarkable accuracy by the torsion balance; arcs of meridian have recently been measured in Spitsbergen, Africa, and Peru. In view of so much activity in geodetic work, it is to be regretted that so little has been done of late years in the United Kingdom. The measurement of an arc of meridian and a detailed gravity survey were instanced as pieces of work which should be carried out in these islands, and discussion on these matters was invited.

A Reuter message from Sydney states that the schooner *Kainan Maru*, the ship of the Japanese Antarctic Expedition, arrived there on April 30, the object of the expedition having been abandoned. The vessel, which left New Zealand in February for the Antarctic continent, was obliged to turn back on account of the ice packs and icebergs which she encountered, and reached Coulman Island, off the coast of Victoria Land. The decision of the explorers to abandon the attempt to reach the Pole was also influenced by the fact that ten of the twelve Eskimo dogs which were to have been used to pull the sledges succumbed to the cold. After cruising in the vicinity of Coulman Island for four days, the *Kainan Maru* set out for Sydney. A Reuter message from Hamburg reports that preparations are complete for the departure of the German Antarctic Expedition on May 3 on board the 598-ton barque *Deutschland*. The vessel will go first to Bremerhaven, whence she will start for Buenos Aires on May 7.

We regret to announce the death, on April 28, in his fifty-third year, of Dr. J. Tatham Thompson, the well-known ophthalmic surgeon of Cardiff. He had suffered for many months from a painful and incurable illness. Dr. Thompson was born at York, educated at Bootham School in that city, and received his medical training at the University of Edinburgh, where he had a distinguished career and graduated M.B., C.M., in the year 1885. For some time he acted as assistant to the late Dr. Argyll Robertson, of the Edinburgh Royal Infirmary, and afterwards he obtained the appointment of ophthalmic surgeon to the Edinburgh Western Dispensary. During his stay in Edinburgh, he was distinguished by his artistic abilities, and many of the drawings in Berry's "Diseases of the Eye" were from his clever pencil. Dr. Thompson, however, soon went to South Wales, where he obtained the appointment of ophthalmic surgeon to the Cardiff Infirmary, which he held for many years. During this time his pen was seldom idle. He found time to write upon many ophthalmic subjects, including the influence of school life upon eyesight, nystagmus among Welsh miners, and the removal of foreign bodies from the interior of the eye by the aid of the magnet. At the time of his death Dr. Thompson was one of the vice-presidents of the Ophthalmological Society of the United Kingdom.

The death is announced of Dr. F. J. C. Terby, who worked long and assiduously to promote astronomical science. In a private observatory, which he constructed at Louvain, he mounted a Grubb equatorial of 8 inches aperture, and employed it mainly and usefully in the study of the surface markings of the planets. Mars particularly interested him, and he made a careful discussion of the physical features of this planet, recorded from the time of Fontana. This is a very valuable contribution to observational history. It puts into the hands of astronomers an accurate and ready summary of a great amount of detailed information, acquired by industry and sifted with intelligence. His observations of Venus appear to have been accurate and systematic, supporting Schiaparelli's view of the coincidence of the period of rotation with that of revolution. As an amateur astronomer, comets naturally attracted his attention, and the record of his observations of the physical features of many will be found in the pages of the Memoirs of the Royal Academy of Belgium and in the Bulletins. Of late years his observations appear to have been less frequent, probably on account of ill-health, but for many years he worked zealously, and his memory should be treasured as of one who laboured to inspire others with enthusiasm, and to make the science of astronomy respected.

The Times records the death of Mr. Henry Scherren, at his residence in Cavendish Road, Harringay, on April 25. Mr. Scherren had been a Carthusian monk, but abandoned his orders in the year 1878, and subsequently resided in London, where he devoted himself to journalism, more especially in regard to its natural history side. One of his favourite subjects was the zoological gardens of Europe, on which he wrote many articles, the last appearing in *The Field* of April 29, after his death. He also wrote an interesting history of the Zoological Society of London, of which he was elected a fellow in 1889. Among his contributions to zoology may be mentioned an account of the early history of Grèvy's zebra, and another of the giraffe presented to King George IV. Mr. Scherren was born at Weymouth in 1842, and educated at the Romanist College at Mill Hill. For a period of twenty years he was in the employ of Messrs. Cassell, during which he acted as sub-editor of their "Encyclopædic Dictionary." He also wrote for *The Leisure Hour* and other journals.

Three letters have recently appeared in *The Times* (April 24, 25, 27) relating to a mysterious heraldic animal known as the "jall" or "eall," of which the effigy has been recognised in St. George's Chapel, Westminster, on a stall-plate supporting the arms of John Duke of Somerset, 1440. Later, the jall appeared among the Sovereign's cognizances. Although described as having horns, tusks, and a short fluffy tail, the jall has been identified with the goat, but the Rev. H. F. Westlake, custodian of Westminster Abbey, adopts the view that it was "the" antelope. In an old document quoted by Mr. G. C. Druce, the eall is stated to be as large as a horse, with a tail like that of an elephant, goat-like jaws, and horns capable of movement, its colour being black. Other accounts state, however, that it has jaws like a wild boar and cloven hoofs. It may be suggested, if the beast ever had corporeal existence, that the African wart-hog may have formed the original type, that animal having a black hide, cloven hoofs, an elephant-like tail, large tusks, and big face-warts which might perhaps be regarded as elastic horns.

Much interest attaches to the description, by Mr. O. Thomas at the meeting of the Zoological Society on April 25, of a new form of takin from the Tsin-lin range of southern Shen-si, Central China. The typical Mishmi

takin (*Budorcas taxicolor*) is a dark-coloured animal with a large tawny area—traversed by a black spinal stripe—on the back. In the Sze-chuen takin (*B. tibetanus*) nearly the whole of the upper parts, exclusive of the face and ears, which are black, have become either golden-yellow or whitish-grey, and this tendency to the development of yellow culminates in the new Tsin-lin takin, in which all the black has disappeared, so that the whole fur, which is very long, is a beautiful golden-yellow. Mr. Thomas has named this takin *Budorcas bedfordi,* in honour of the Duke of Bedford, who is defraying the cost of the expedition which resulted in its acquisition. Whether the three forms are regarded as distinct species or as colour phases of one species, they are of great interest as showing the evolution of a golden from a black and chocolate type of colouring. What renders this the more remarkable is the fact that a similar development occurs in the case of the snub-nosed monkeys (Rhinopithecus), in which the comparatively low Mekon species is slate-coloured, while the elevated Sze-chuen form is bright golden-yellow.

THE second Irish Road Congress, held in Dublin on April 19, 20, and 21, attracted a large attendance of members, most of whom were men actually engaged in the construction and maintenance of Irish roads. The work of the congress was divided into three sections, dealing respectively with the laws and procedure relating to road construction, statistics, &c.; road construction and maintenance; and modes of locomotion. Twenty-five papers were submitted, mainly of a practical nature; but the chief subject dealt with in the discussions was the treatment of Ireland by the newly constituted Road Board, the general opinion of the members finding expression in a unanimous resolution to the effect that, in allocating the funds at its disposal, the Board had not carried out the avowed intentions of the sponsors of the Development and Road Improvement Act in Parliament, viz. that the proceeds of the special taxes raised with this object would be distributed without reference to the sources from which the money was drawn. The address of the president, Mr. P. J. O'Neill, J.P., chairman, General Council of County Councils, was almost entirely confined to this aspect of the road question, and gave the key-note to the proceedings; but the discussions, in which Sir George Gibb, president of the Road Board, and Colonel Crompton, consulting engineer to that body, took part, also included subjects of practical importance, such as the testing of materials, direct labour as opposed to the contract system, and the effect of motor traffic on the roads.

AT a meeting of the Royal Dublin Society held on April 25, the Boyle medal of the society was presented to Prof. John Joly, F.R.S. A report upon his work was read by Dr. J. M. Purser, and some of the subjects mentioned in it are here summarised. Prof. Joly's researches deal with physics, geology, mineralogy, botany, and biological theory. In 1886 Joly published the method of condensation in calorimetry, and investigated the specific heats of minerals. He also determined the specific heats of gases at constant volume. By the meldometer he determined the fusion points of minerals, and showed the use of the instrument in carrying out reactions of pyrochemistry. He determined the volume change of rocks and minerals on fusion. He also invented the incandescent electric furnace. Joly advanced a physical theory on the origin of the canals of Mars, accounting for the linear markings on the planet. In 1896, he invented a method of colour-photography to reproduce with accuracy the colours of nature on a transparent plate. In 1898 he showed how the sodium content of the ocean could be used as a measure of geological time. The theory of sedimentation has also been advanced by his researches on electrolytic precipitation. By many researches he has laid the sciences of petrology and mineralogy under obligations to him. We would specially notice his invention of a polariser whereby the value of birefringence as a means of identification is increased, and his application of the microscope to the determination of the quality of paving-sets and road-metal. In connection with radioactivity, he has advanced our knowledge of the properties of radio-active substances. His explanation of Pleochroic Haloes in rocks as due to radioactivity leads to conclusions as to the non-existence of alpha-radiation from common elements. By the determination of the thorium content of rocks, he has established a mean value for its distribution in the surface-materials of the earth.

THE council of the Institution of Civil Engineers has made the following awards for papers read and discussed during the session 1910–11:—Telford gold medals to Mr. W. J. Wilgus (New York) and Mr. J. Walker Smith (Edinburgh); a George Stephenson gold medal to Mr. Philip Dawson (London); Telford premiums to Messrs. G. W. Humphreys (London), H. K. G. Bamber (Greenhithe), A. E. Carey (London), William Dawson (Crewe), and C. S. R. Palmer (London); and the Trevithick premium to Mr. A. T. Blackall (Reading).

AT the annual general meeting of the Institution of Civil Engineers, held on April 25, the result of the ballot for the election of officers was declared as follows:—*President,* Dr. W. C. Unwin (London); *vice-presidents,* Mr. R. Elliott-Cooper (London), Mr. A. G. Lyster (Liverpool), Mr. B. Hall-Blyth (Edinburgh), and Mr. J. Strain (Glasgow); *other members of council,* Mr. J. A. F. Aspinall (Liverpool), Mr. J. A. Brodie (Liverpool), Mr. W. B. Bryan (London), Colonel R. E. B. Crompton, C.B. (London), Mr. W. Davidson (Australasia), Mr. J. M. Dobson (London), Mr. H. F. Donaldson, C.B. (London), Mr. E. B. Ellington (London), Mr. Maurice Fitzmaurice, C.M.G. (London), Mr. J. P. Griffith (Ireland), Dr. C. A. Harrison (Newcastle-on-Tyne), Mr. W. Hunter (London), Mr. G. R. Jebb (Birmingham), Mr. H. E. Jones (London), Mr. E. H. Keating (Canada), Sir Wm. Thos. Lewis, Bart., K.C.V.O. (Aberdare), Sir Thomas Matthews (London), Mr. W. Henry Maw (London), Hon. C. A. Parsons, C.B. (Wylam-on-Tyne), Mr. F. E. Robertson, C.I.E. (London), Mr. Alexander Ross (London), Mr. J. W. Shores, C.M.G. (South Africa), Hon. F. J. E. Spring, C.I.E. (India), Sir Philip Watts, K.C.B. (London), Mr. W. B. Worthington (Derby), and Mr. A. F. Yarrow (Glasgow). This council will take office on the first Tuesday in November.

AMERICAN scholars are at present busily engaged in exploring the materials for the study of the history of their continent which are stored in the record-rooms of Europe. A useful contribution to this inquiry is the catalogue of the Italian documents, which has been prepared by Prof. C. R. Fish, and recently published by the Carnegie Institution of Washington. Students of the history of countries other than America will be interested in the descriptions of the manuscript collections at the Vatican, the Propaganda Fide, and other repositories at Rome, Naples, Venice, Turin, and Florence, with the conditions under which they are available for examination.

IN one of those comprehensive discussions of special anthropological problems, of which the French reviews hold an almost complete monopoly, M. B. P. Van der Voo in the April issue of *La Revue des Idées* examines the origin in the belief in metempsychosis. Finding its origin to lie in the same group of conceptions which include the

passage of the soul into animals and plants, he discusses in order the Indian evidence, the conception of the moon as the abode of spirits and the deity of life, its influence on the rain, and that of the rain on human life. He next deals with the various forms of reincarnation—in the Carnivora, snakes, birds, and, finally, in human beings. This essay, with its abundant references to the literature of the subject, must be of the greatest value to students.

The Ethnographic Survey of India, with a view to the preparation of revised editions of the accounts of the tribes and castes of Bengal, the United Provinces, and other parts of the Empire where the information has been tabulated, publishes occasional monographs on special subjects of interest. The most recent of these is an account of the marriage rites of the Prabhus of western India, who, like many castes engaged in literary pursuits, now claim to be of Kshatriya or warrior origin. The monograph, as Mr. Annandale remarks in his prefatory note, would be improved by compression; but it supplies abundant evidence of the predominating belief in the efficacy of magic to counteract the power of malignant spirits and the evil eye, which is the chief basis of the domestic rites of the Hindus. Its value for European readers would be much enhanced by a few photographs illustrating the arrangement of the marriage booth, the sacred fire, and the other appliances of the rites, which would assist students of the ceremony who have not enjoyed the chance of witnessing a high-caste marriage.

We have received a copy of the second report of the Jerusalem Society for the Prevention of Cruelty to Animals. In view of the ill-treatment to which domesticated animals are subjected in many parts of the East, the movement is well worthy of sympathy and support.

The second number of the Journal of the East Africa and Uganda Natural History Society contains a large amount of interesting matter relating to the fauna of our East African possessions, Mr. F. J. Jackson contributing a synopsis of the game-birds of the district, while Mr. C. W. Hobley discusses spitting cobras. For a long time naturalists were very shy in accepting the assertions of settlers that an African snake possesses the power of ejecting their venom to considerable distances. The statement has, however, of late years been verified by indisputable evidence, and Mr. Hobley has now been able to identify the species as the black-necked cobra (*Naia nigricollis*). Additional testimony as to the spitting power of these serpents is given by the author himself, who on one occasion in the Athi saw a dog put up a cobra from a bush. "It swayed its head slightly and gradually drew it back, and I expected any second to see it strike the dog, but, instead of that, a stream of colourless liquid shot out of its mouth into the dog's face, and the snake dropped and wriggled into the bush." The flashlight photograph by Mr. Cherry Kearton of a lion going to drink is unsurpassed.

Part v. of the Ceylon Marine Biological Reports is devoted to an account of the scientific work on the local pearl-banks during 1910, and in one section of the report Mr. T. Southwell discusses the present condition and future prospects of the banks. As these cover an area of more than 700 square miles, it will be obvious that the task of ascertaining their general condition—let alone any attempt at controlling the natural factors—is of stupendous difficulty. Furthermore, the Ceylon pearl-oyster has the sexes separate, instead of being, like the continental species, hermaphrodite, while it thrives best in the open sea at a depth of about 6 fathoms in place of in intertidal waters, consequently the system of culture which has been found to succeed in the case of the mainland species proved practically useless when applied to the Ceylon banks. At the present time these banks are almost unproductive; and it seems that there are periodical spells of barrenness, when not a single adult oyster is to be found over the whole area. During such a period the banks may, however, become suddenly replenished and covered in countless numbers with spat over several square miles, and the problem now awaiting solution is the origin of this presumably foreign spat. The second problem is connected with the disappearance of the oysters, both old and young. Although it has been proved that predaceous fish and boring molluscs have a share in the destruction, there still remains a considerable percentage of oysters which die for some reason at present unknown, although disease may be the cause. When these problems are solved, and measures taken to counteract the evil, hopes are entertained for the future of the beds.

In our issue of January 19, 1911, we gave a full account of the paper read by Dr. Johan Hjort before the Royal Geographical Society, describing the oceanographical expedition of the s.s. *Michael Sars* in the North Atlantic. The April number of *The Geographical Journal* contains the first instalment of the complete paper, which is illustrated by three excellent plates showing some of the deep-sea fishes which were captured by the expedition, as well as by a considerable number of text figures. The vertical distribution of the two fishes, *Cyclothone microdon* and *Cyclothone signata*, is clearly shown by a series of diagrams representing the numbers of fishes of different sizes captured at various depths down to 1500 meters. These results prove the value of the methods adopted by the expedition of making simultaneous hauls, lasting for a considerable time, at many different depths.

Dr. Johan Gehrke (Publ. de Circonstance, No. 52, Internat. Comm. Marine Invest.) gives an account of the hydrography of the Baltic, with details of the salinity, temperature, and oxygen content of the waters of different regions of that sea. Dr. Arwidsson (No. 54) records detailed observations on the mass, colour, reproductive organs, scales, and food of 148 examples of salmon (*Salmo salar*) from the river Laga, in south-west Sweden, and concludes that, in all probability, the fish go down this river to the sea for the first time in the spring following the completion of their second year.

Prof. Ermanno Giglio-Tos, formerly of the Royal University of Cagliari, has succeeded the late Prof. Giglioli in the chair of zoology, anatomy, and physiology of vertebrates in the Reale Istituto di Studi Superiori of Florence. His introductory address dealt with the subjects of organic evolution, natural selection, and the origin of species. He distinguishes somatic variations of two kinds:—(1) somatogenous, produced by the environment, and not giving rise to modifications in the germ, and therefore of no importance in regard to the origin of species (*e.g.* in Artemia); (2) blastogenous, which do produce germinal modification, and are therefore of great importance. Prof. Giglio-Tos believes that cytological investigations of the gametes may reveal variations of their structure, for instance, alteration of the number of chromosomes, sufficient to be the cause of somatic changes leading to the formation of new species.

The April number of the *Quarterly Journal of Microscopical Science* (vol. lvi., part iii.) is an unusually attractive one. This is, in part, owing to the beauty of the lithographic plates, nearly all of which, we notice, have been

executed in Germany. Mr. C. Clifford Dobell contributes a long memoir on the much-discussed question of the presence of a nucleus in bacteria. He concludes that "all bacteria which have been adequately investigated are—like all other protista—nucleate cells," but a good deal seems to depend, in making this generalisation, upon how one chooses to define the term nucleus. If, for example, we are prepared to admit that "a discrete system of granules (chromidia)" may legitimately be called a nucleus, well and good, but probably many biologists will hesitate before accepting this view. Mr. Dobell also contributes a memoir on those remarkable unicellular organisms, the spirochæts, with special reference to *Cristispira veneris*, a form occurring in the crystalline style of a lamellibranchiate mollusc (*Venus casta*). Mr. Cresswell Shearer's paper on the trochophore larva of Eupomatus will be welcomed by embryologists as a valuable contribution to our knowledge of Annelid development. The illustrations accompanying this paper are particularly worthy of admiration.

A SEQUEL to the information regarding precipitation and absorption of iron, submitted by Prof. H. Molisch in his book on iron bacteria, is furnished by a note in the *Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften*, Vienna (October, 1910), in which he states that various aquatic plants induce precipitation of iron from iron salts, and that Elodea readily absorbs and accumulates oxide of iron in its leaves, in the outer walls of the epidermal cells.

THE elementary species obtained by Prof. de Vries as a break from *Œnothera Lamarckiana*, and designated by him as *Œnothera nanella*, forms the subject of a communication by Mr. H. H. Zeijlstra in the *Biologisches Centralblatt* (March 1). It is indicated that the type of the original diagnosis is an abnormal plant deformed by the internal growth of bacterium colonies, presumably a species of Micrococcus, and that similar characters and form are transmitted to the descendants of abnormal plants. In addition to this, the common form, there is said to be an uncommon but normal form of the species, distinguished from the abnormal chiefly by certain stem and leaf characters, and resembling *Œ. Lamarckiana* except for its dwarf habit; up to the present, seeds of the normal form have not been obtained.

IT is apparent from the experiments on transpiration and sap flow, recorded by Mr. J. B. Overton in *The Botanical Gazette* (January and February), that the umbrella plant, *Cyperus alternifolius*, is a convenient plant for ordinary transpiration experiments. It was particularly suitable for the requirements of the author, whose chief object was to study the effects of killing portions of the stem by immersion in steam or poisonous solutions, as the apical tuft of leaves can be readily slipped through a glass cylinder, which is then fixed at the desired position on the stem. So long as the portion of the stem killed is short, the plant withers less rapidly than a cut piece, but immersion in steam proved to be an unsatisfactory method for killing, as the contents of the cells are disorganised. It was also found that the application of certain poisonous solutions, particularly of corrosive sublimate, causes increased transpiration.

AN extensive and important investigation into the nature of crown-gall of plants has been published by the United States Department of Agriculture as Bulletin No. 213 of the Bureau of Plant Industry, in which is provided a detailed account of experiments extending over six years. A bacterial origin was suspected by Dr. E. F. Smith, one of the authors of the bulletin, in 1904, but definite proof was not obtained until two years later, when a bacterium was isolated, and infection resulting in gall-production was transmitted from pure cultures; to this organism, a short, rod-like form, was given the name *Bacterium tumefaciens*. The inquiry started with galls upon hot-house plants of *Chrysanthemum frutescens*, but subsequently similar malformations were examined on apple, peach, grape, sugar-beet, and other plants; there are probably different physiological races of the bacterium, but cross-inoculation was generally possible. Dr. Smith suggests that the manner of growth resembles certain malignant animal tumours.

Two short papers on seismograms of the great Turkestan earthquake of January 4 are contained in the Journal of the Meteorological Society of Japan for last February. Prof. Omori estimates that the epicentre was situated at about 5230 km. in the direction of N. 65° W. from Tokio, or in the Kashgar province of Turkestan, and that the earthquake occurred at 11h. 16m. 42s. p.m. on January 3 (Greenwich mean time). Two maxima of the principal portion of the movement were recorded, the second 2h. 8m. 27s. after the first, and due to surface-waves travelling over the longer portion of the great circle through Tokio and the epicentre giving the usual mean velocity of 3·1 km. per second for the surface-waves. The total duration of the disturbance was more than four hours at Tokio and 2h. 20m. at Osaka.

IN a recent number of the valuable publication *Aus dem Archiv der Deutschen Seewarte* (No. 4, 1910), Dr. O. Steffens gives an account of new meteorological apparatus constructed or improved by himself. It includes an arrangement, beautifully illustrated, for exhibiting the indications of the aneroid-barometer, thermometer, and hygrometer, either separately or on one cylinder, with rectilinear instead of the more usual curved ordinates. Various anemometers registering direction and velocity separately or on the same cylinder, with damping arrangements for eliminating the small oscillations of the wind-vane, are also described and clearly illustrated.

SOME of the results of the international balloon ascents specially arranged for the week July 27 to August 1, 1908, are summarised by Mr. W. H. Dines in *Symons's Meteorological Magazine* for April. He states that the figures show several points of interest, and would repay a careful analysis; we can only quote here a few facts relating to the particular ascent for each day in which the greatest height of trustworthy record in miles was attained, with the temperature (F.) at the greatest height, the height in miles of the commencement of the isothermal column, the temperature at the bottom of the column, and direction of falling point of the balloon.

No large changes of pressure occurred during the week. On July 27 it was high over the Azores and Lapland; by July 29 it had disappeared over Lapland, but increased over the Azores and moved to the south of Ireland. On July 30 and 31 it had again decreased, but still lay over England, with low pressure on July 31 in the Gulf of Bothnia. On August 1 there was little change.

THE April number of the Journal of the Franklin Institute contains a well-illustrated article on the properties of the new metallic filaments used in incandescent lamps, by

Mr. G. S. Merrill, of the National Electric Lamp Association, Cleveland, Ohio. The properties dealt with are the resistance, melting point, emissivity, and mechanical strength, and the tungsten filament receives most attention. The strength is determined by loading a short length of filament placed on two knife edges half a centimetre apart, at a point half-way between the supports, and measuring the depression under increasing load till the filament breaks. The change in the structure of the filament from a mixture of finely-divided tungsten and binding material, to pure crystalline tungsten as the temperature is raised during manufacture, is well shown by a series of micro-photographs. The effect of use in increasing the size of the crystals and in roughening the surface of the filament is shown in the same way. These changes are accompanied by a decrease in strength of the filament, which occurs mainly in the first 100 hours of use. The conclusion drawn from the observations is that a compact fine-grained structure is most desirable in lamp filaments.

An extension for a further term of seven years of the major part of Sir Oliver Lodge's patent No. 11,575 of 1897 for "Improvements in Syntonised Telegraphy without Line Wires" has recently been granted as a result of a case argued before Mr. Justice Parker, the extension being allowed mainly on the grounds that the patentee had not been adequately remunerated for his invention. The patent covers the radiating and receiving apparatus of a complete system of wireless telegraphy and the methods of tuning the sending and receiving circuits to the same frequency, and describes how messages may be sent to each of a number of suitably tuned receiving stations by change of the frequency of the oscillations that are generated. The aërials described are of different forms, but all consist of a pair of "capacity areas" connected by inductances the magnitudes of which control the period of oscillation. The eleven claims of the specification are concerned with the insertion of these inductances into the radiating and receiving circuits; with the adaptation of a single aërial for sending and receiving the insertion in turn of inductances of various magnitudes in order to attain the selectivity already referred to; with the details of a coherer consisting of a fine metal point resting on a flat metallic spring; and, lastly, with methods of setting up the oscillations by discharges into the oscillator across air-gaps and receiving through an oscillation transformer, in order to separate both the oscillator and the resonator from metallic connection with other circuits, thus enabling them to vibrate in their own free periods so as to get precise tuning. The whole specification has been extended for the further term except the portions covering the use of the same circuits for sending and receiving, the use of various frequencies to select various receiving stations, and the use of the particular form of coherer. It thus appears that the patentee holds a master-patent covering the tuning of electrical circuits by means of inductances, and as the use of such tuned circuits is common to methods of signalling used by wireless telegraph companies operating in England, the situation will probably give rise to interesting developments.

The report of the council of the Hampstead Scientific Society for the year 1910 shows that the object for which the society was founded in 1899, namely, the encouragement of a popular interest in science, has been pursued diligently and successfully. During the year eighty new members were elected, the membership rising to 334, the largest in the history of the society. Twenty-nine meetings, general and sectional, were held in 1910, in addition to five vacation meetings, a summer excursion organised by the photographic section, and four Christmas lectures to juveniles. The feature of the society's work for the year was the development of the astronomical section since the establishment of the observatory near the Whitestone Pond. The meteorological station at the same place has been efficiently conducted. An observer attended at 9 a.m. and 9 p.m. every day during the year, without intermission, and the results, after reduction, have been published monthly by the Meteorological Office.

The Carnegie Institution of Washington has issued a list of the various works which it has published, together with those it has in the press. Copies of each publication, except the Index Medicus, are sent gratuitously to a limited number of the great libraries of the world, and the remainder of the edition is on sale at cost price. As the catalogue shows, this arrangement enables workers in science to obtain accounts of many important researches at a minimum cost. Descriptive lists of the books available will be sent to any interested person on application to the Carnegie Institution of Washington, Washington, D.C.

A supplement—covering works added to the library during the years 1908–9—to the Catalogue of Lewis's Medical and Scientific Circulating Library has been issued from the library at 136 Gower Street, London. The catalogue, the price of which is sixpence, contains a classified index of subjects with the names of the authors who have treated upon them, in addition to the ordinary alphabetical list of titles.

OUR ASTRONOMICAL COLUMN.

New Minor Planets.—A Central News telegram of Tuesday states that the Transvaal Observatory reports the discovery of two minor planets. The discovery was made during an attempt to photograph the eighth satellite of Jupiter. The following are the positions of the new planetoids:—No. 1, R.A. 14h. 41m., Dec. 12° 34′ S.; No. 2, R.A. 14h. 48m., Dec. 15° 18′ S. It is stated that these are the first minor planets found by an observatory south of the equator.

Nova Lacertæ.—Photometric measures of Nova Lacertæ, made between January 4 and March 15 by Mr. H. Shapley at the Laws Observatory, are recorded in No. 4493 of the *Astronomische Nachrichten*. During that period there was a general decline of brightness from mag. 7·67 to mag. 9·23. Four neighbouring B.D. stars were used for comparison, and it is suggested that one of them, B.D. + 51° 3420 (mag. 8·7), is a variable with a range of at least 0·4 magnitude; if this is so, several anomalies in the photometric results may be explained.

In the same journal Dr. Slocum records observations of two coloured B.D. stars near the nova, to which M. Luizet previously directed attention and suggested that B.D. + 51° 3414 diminished in brightness by 1·5 magnitudes between January 2 and February 21. The photographic observations at Yerkes, with coloured screens, indicate that both stars are abnormally coloured, B.D. + 51° 3416 showing a greater preponderance of red rays and B.D. + 51° 3414 a greater preponderance of rays of shorter wave-length than a normal star of the A type.

Halley's and Faye's Comets.—An observation by Prof. Barnard, using the 40-inch refractor, showed that on March 19 Halley's comet was of magnitude 13·5, and very easy to observe. It was round, and the middle showed a slight brightening, with possibly a faint, but uncertain, nucleus; its measured diameter, probably too large, was 45″ (*Astronomische Nachrichten*, No. 4492).

Dr. Ebell continues his ephemeris, giving places and magnitudes for Faye's comet (1910*e*) up to May 14. At present the comet is about 20 m. and slightly north of

ξ Geminorum, and its calculated magnitude is 15·0. The observation by Dr. Wolf on March 19 showed the actual brightness to be about one magnitude fainter than the ephemeris value (*Astronomische Nachrichten*, No. 4485).

PROPER MOTIONS IN SUN-SPOT GROUPS.—Dr. W. Brunner, Zurich, has an important and interesting paper in No. 3, vol. xl., of the *Memorie di Astrofisica ed Astronomia*, in which he discusses the relations existing between the proper motions observed in spot-groups and the solar activity producing the groups. The discussion is based on the examination of Wolfer's Zurich drawings for the period 1887–1905, and the spots born on the visible hemisphere are considered separately from those which, having first broken out on the invisible hemisphere, are first seen at the eastern limb; only the proper motions in longitude are discussed, and, in general, these are in the sense which makes the various members of the group diverge *inter se*.

The general conclusions, in brief, are that this divergence is not accidental, but is connected with the phase of development of the group. In the early stages of development the diverging tendency is strongly marked, but it rapidly wanes until it disappears seven or eight days after the first outbreak, unless a recrudescence of activity takes place, when the same phenomena reappear. Taking as positive the proper motion, which is in the direction of the diurnal motion, it is found that the groups in which negative motion is dominant are more numerous at the epochs of maxima in the undecennial period. But it is found that the magnitude of the proper motion is independent of the phase of the solar activity and also of the heliographic latitude. As naturally follows from the first conclusion, those spots born on the invisible hemisphere, being several days old when first seen, exhibit the proper motions in a less marked degree than those of which the primary phases of development are observed.

THE RATIO BETWEEN THE DIAMETER OF A PHOTOGRAPHIC IMAGE AND EXPOSURE.—In the measurement of photographic magnitudes by measuring the diameter of the star images it is assumed, in the formula usually employed, that the diameter is proportional to the square of the intensity of the light. Not agreeing with the principle of this assumption, Dr. Kenneth Mees recently made some experiments, under laboratory conditions, in which he produced easily measurable images with greatly differing exposures. He finds that the diameter of the small image of a fine slit or point is proportional to the logarithm of the exposure given, and assuming that increase of exposure is effectively equivalent to increase of intensity, this would mean that the diameter of a star image should be proportional to the logarithm of the intensity of the light-source rather than to its square. Dr. Mees suggests that the astronomical equation is based upon a modification of the true law dependent on the conditions of the formation of images in telescopes (*Astrophysical Journal*, vol. xxxiii., No. 1).

PHOTOGRAPHIC MEASURES OF STELLAR TEMPERATURES AND DIAMETERS.—In No. 4483 of the *Astronomische Nachrichten* Herr Adolph Hnatek publishes an interesting paper on a photospectroscopic method of determining the effective temperatures and relative diameters of stars. The photographic intensities of various parts of the spectrum are compared, and from the resulting data a temperature scale is formed. This ranges from 4000° for η Pegasi to 11600 for Algol, eight stars being considered, and agrees fairly well with the Potsdam values where comparable. It also places the eight stars in the progressive order shown by the Kensington temperature curve. The comparison of diameters shows that α Lyræ is 6·1 greater than the sun, whilst α Aquilæ is but 1·9 times greater.

CANADIAN OBSERVER'S HANDBOOK FOR 1911.—An excellent handbook for amateur and other astronomers is issued by the Royal Astronomical Society of Canada, and edited by Mr. C. A. Chant. The first two numbers were published in 1907 and 1908, and then the experiment of publishing the information in instalments in the society's Journal was tried. This proved unsatisfactory, and the former custom of having a separate volume has been reverted to. The book should prove of invaluable assistance to the rapidly growing body of amateur astronomers in the Dominion, and it is hoped to publish the volume for 1912 before the beginning of the new year.

THE IMPERIAL EDUCATION CONFERENCE.

THE public sessions of the first conference of delegates summoned by the British Government to represent the Overseas Dominions were held in London on four afternoons, April 25–28. The President of the Board of Education welcomed the representatives, and presided at each meeting. Administrative problems were, it is believed, discussed at the morning sessions, to which only the official delegates were invited. The proceedings at these morning meetings were private, the conference agreeing at its first meeting that, in order not to hamper discussion, no report should be made until the close of the conference, when an official summary will be issued. At the time of writing, all that can be said with certainty is that the private sessions are being prolonged into the week following the public meetings. Admission to the afternoon discussions was by tickets issued to representative administrators and teachers. The attendance of the overseas delegates in the afternoons was not large. The programme drawn up by the Board of Education included papers on the teaching of geography, history and arithmetic, manual work, the organisation of secondary education in Scotland, engineering, and vocational education. All the papers were by well-known British workers in the educational field.

Chairman's Prologue.

Mr. Runciman said that the conference originated from requests made in 1907 to the Imperial Government to summon an Imperial Conference to deal purely with educational affairs. ("The Federal Conference on Education," held in 1907, was initiated by the League of the Empire, and was unofficial and highly successful.) Since 1907 the Department of Special Inquiries and Reports had been in direct communication with the Dominions, India, and the Colonies, there had been improved circulation of reports, and memoranda had been compiled during the four years which would be issued shortly. Assistance was being given every day in the week in the selection of teachers, *e.g.* for Alberta, Australia, and South Africa. They had also arranged through the Department that the privileges now given to the teachers in the United Kingdom in French and German schools should be extended to teachers throughout the Empire. Assistance was continually being given to visiting officials. A library of considerable dimensions had grown up containing carefully selected and organised contributions from all over the world. The problems to be faced here and overseas were very similar. There were the difficulties of the supply and training of teachers, the problem of giving freedom of organisation while retaining control of finance. All the subjects of pedagogy were of universal interest. They had to deal with the puzzle of the classification of schools, with rural, urban, and technical problems. The United Kingdom might learn from Canada, Canada from Australia, Australia from South Africa, and so forth. They wished to bring to the common stock the intellectual forces of the whole Empire, and feed the very root of Imperial strength. The Empire was a practical working concern, not merely a sentimental vision, and they were met to discuss practical questions.

Imperial History and Geography.

Mr. H. J. Mackinder, M.P., read a paper on the teaching of geography from an imperial point of view, and the use which could and should be made of visual instruction. He asked for attention to a mode of teaching which might have peculiar value in the consolidation of the Empire, a work in which the part of the teacher must be as great as that of the statesman. The Empire existed by the free consent of the peoples, and this consent must be based on a reasonable agreement in regard to aims and sympathy in regard to difficulties. It was the part of the teacher to exorcise the devils of ignorance and local prejudice. Geography should be taught as a special mode of thought—a special form of visualisation which he would not describe otherwise than as "thinking geographically." He went on to describe the work of the Visual Instruction Committee, and concluded by urging that geography should be the chief outlook subject in our school curriculum, and should be taught by methods which demand visualisation. We should aim at educating the citizens of the many parts of the British Empire to

sympathise with one another and to understand Imperial problems by teaching geography visually, not only from the point of view of the Homeland, but also of the Empire. Among many other excellent aids to such teaching, there was now becoming available an apparatus of illustrated lectures prepared under the authority of the Visual Instruction Committee of the Colonial Office. Prof. H. E. Egerton, Beit professor of colonial history (Oxford), followed with a paper on some aspects of the teaching of imperial history. He dealt mainly with three subjects:—(1) the mercantile system; (2) the evolution of Colonial self-government; (3) the development of the Federal principle. The mercantile system assumed colonies to be plantations, *colonies d'exploitation*; what was to happen when they proved *colonies de peuplement*, settlements of men? The idea of a self-sufficing Empire postulated a general controlling Parliament; what was to happen when this Parliament represented the selfish interests of one particular portion of the Empire? Round the single principle of the mercantile system they had all the causes which led to the development and dissolution of the first English colonial empire. They would all admit that the evolution of Colonial self-government was a subject which, on a smaller scale and with simpler material, would bring out the underlying principles of the British Constitution. Referring to the Federal principle, Prof. Egerton declared that a more systematic organism must be found for the disjointed portions of the British Empire. For such an undertaking there could be no better preparation than the study of what has been done by our kinsfolk in the past.

The discussion was well maintained by well-known English teachers, but unfortunately no Colonial delegate spoke.

Arithmetic in Elementary Schools.

At the second public session Mr. Marshall Jackman read a paper on experimental work in connection with the teaching of arithmetic in elementary schools. The word "experimental" was justified by the fact that the methods employed were a departure from the Code at the time, ten years ago, when Mr. Jackman adopted the principles on which he has successfully worked ever since. These principles may be inferred from the facts that (1) the concentric method is adopted; (2) no set method of solving a problem is insisted upon; (3) the terms used in the problems are familiar to the children and the problems dealt with transactions within their grasp; (4) no problem is set which cannot be solved mentally. He claimed that, in addition to securing the teaching of arithmetic on more rational lines, the methods pursued set free more than eighty minutes a week in the three lower classes of the school; this time was devoted to reading with most beneficial results. Mr. J. V. Thompson (Fiji) said he had attempted to teach arithmetic to young Fijian chiefs in a language not their own. The Fijians delighted in exercise books, and the native master liked to set his class an enormous division sum, knowing that he would then have a most restful half-hour. He would take Mr. Jackman's scheme with him and use it.

Practical Education in Elementary Schools.

Mr. J. G. Legge, Liverpool Director of Education, read a paper on the above subject, and directed attention to the influence of the changed social conditions brought about by the industrial revolution. Of old, education was as much the work of the home as of the school. But the home side had been fading away, and despairing—perhaps too soon—of ever recovering it, we were rushing in where angels might hesitate with proposals for feeding and clothing, medically treating, and apprenticing. After the child is officially taught, officially fed, officially clothed, and officially placed in employment, there but remains the prime condition, to which eugenics is already pointing the finger, that he shall be officially begotten. As a result of a study of educational history, we discovered that manipulative exercises were not mere counter-irritants to book-work, but the right method of applying the universally accepted principles of Pestalozzi. Recently, experimental psychology has taught us that hand training *must* precede trade training if dexterity is to mature in perfection. Henceforward we may base our claim that manipulative exercises shall find a place in our elementary-school curricula, for six reasons, viz.:—(1) to develop centres in the brain; (2) to develop manual dexterity at the age when it must be developed if it is to reach the pitch it should in maturer years; (3) to afford scope for self-expression; (4) to make school subjects more real to the child and to bring in the third dimension; (5) to keep the child in touch with its environment; (6) to give the child something to do which it recognises as definitely useful, and thereby to implant the germ of the idea of usefulness, the fruit of which is social service. Variety of schemes will be necessary; but in any case the limit of the manual side is the point at which it ceases to develop the all-round, intellectual as well as physical, development of the child. By manual work a boy is taught to think clearly towards an end believed by him to be useful. The child should make something for its own use or the use of its home. In a slum school a boy should learn to mend his own breeches, socks, or boots—for educational reasons.

Secondary Schools in Scotland.

Mr. J. Strong described the development of the organisation of secondary education since the passing of the Act of 1872. By control of the leaving certificate examination and virtual control of grants, the Scotch Education Department had a great hold on the secondary school. Curricula, buildings, and the qualifications of teachers were subject to the approval of the Department. A virtual register of teachers had been made, and a high standard fixed for training. To the Department was entrusted the administration of the teachers' superannuation scheme of the 1908 Act, which applies to secondary as well as elementary teachers. Mr. Strong explained the classification of schools and the system of certificates and transition to higher schools, university, or vocations in a lucid manner. Mr. Board (New South Wales) said that in New South Wales they had followed very closely on the lines of Scotland, with the important exception that they had no local control. Centralisation had some disadvantages, but on the whole the gain was greater than the loss. They would hesitate before dividing into such small areas as in Scotland.

Engineering and Technical Education.

Dr. J. A. Ewing, Director of Naval Education, said that the ideal training for the engineer was one which comprised, in addition to means of getting experience, a properly organised course of study in the relevant sciences taught with reference to their practical application. Science helped to determine everything the engineer did. After explaining some features in the organisation of leading engineering schools, he said the engineering professor ought to encourage his better senior students to undertake research, which was vital to the progress of engineering science, and was one of the duties of the college. Experience had proved that the use of tools could be so taught in a college workshop as to have solid professional value. He did not suggest that such an element in the training of engineers could entirely take the place of practical work done on a larger scale under commercial conditions, but much of what apprenticeship was designed to teach could be taught more effectively that way and in less time.

Mr. J. H. Reynolds (Manchester) read a paper on higher technical instruction. In his opinion, no reform in England was more urgent than that secondary schools should receive State recognition, be relieved from external examinations, and have their leaving certificates accepted by higher institutions as giving complete and satisfactory evidence of fitness to enter upon a further stage of advanced study. In 1869 this country was a generation behind Germany, and it was hardly less so to-day. In the United Kingdom the enrolments of students in higher institutions possibly reached 40,000; but in the German Empire the total enrolments were nearly 74,000, whilst the age of entrance and the state of preparation required was admittedly much beyond that prevailing in this country. The doom of the nation was surely set unless they rose up and provided for the people the means of the highest education, alike in their best interests as human beings and as needful for the maintenance and development of her trade and industry.

The discussion was maintained by several men of

eminence in English engineering education, but no Colonial representative took part.

Trade Schools and Continuation Schools.

Mr. R. Blair (London Education Officer) read a paper on the recent development of day schools for boys or girls following immediately on the close of the elementary-school career, the schools being so closely associated with the industry for which they are preparing their students that the preparation is a substitute for the earlier years of apprenticeship. He directed attention to the extent and peculiarities of London's needs, and his valuable remarks were supported by a large amount of useful statistics appended to his paper. He selected for detailed description the work of the Brixton School of Building. The paper is one to be read in full and kept for reference; we must content ourselves with noting that Mr. Blair attributes the success of the schools to the thoroughness of the investigation made into the conditions of a trade before establishing a school or class, and to the appointment of a consultative committee of experts. The striking success of the girls' schools was due to the high standard of devotion and enthusiasm of the staff.

Mr. Graham Balfour (Staffordshire) showed how complicated and varied were the difficulties in organising continuation schools, and the need for resourcefulness and judgment in dealing with each individual locality.

Mr. C. E. Bevan Brown (Christchurch, N.Z.) said that recently an Act had been passed in New Zealand allowing local authorities to make continuation classes compulsory.

A Criticism and a Hope.

Had the papers and discussions been the British part of proceedings to which the Overseas Dominions had contributed a similar share, we should feel that these conferences had made a good beginning. It is to be hoped that when the report of the private sessions appears it will reveal the fact of a useful interchange of experience and ideas between the delegates of the various parts of the Empire. So far as the public sessions are concerned, it cannot be said that a programme consisting solely of contributions from the United Kingdom fulfils even approximately the aspirations with which we regard an Imperial Education Conference. It has been stated in the daily Press that the Colonial Governments were not invited to make suggestions for the business of the conference. In face of the fact that the Board of Education had four years for preparation, this statement appears to us incredible, or, if credible, then discreditable. We hope that one result of the private sessions will be to evolve a method by which the various parts of the Empire can act in concert, so as to carry out in future those aims of the conference which were stated with clear insight by the President of the Board in his opening address.

G. F. D.

BIRD NOTES.

To the April issue of *British Birds*, Messrs. Witherby and Alexander contribute an account of the visitation of crossbills to the British Isles in 1909. The birds made their appearance on Fair Isle on June 23, and before the end of that month were seen in the Shetlands, Orkneys, Outer Hebrides, Merionethshire, and Durham; while in July they were observed all over England except the extreme south-west, as well as in a number of places in Wales, and a few scattered localities in Ireland. The latest record of their being seen at sea was in the Shetlands early in August. The first nest recorded was taken on January 12, 1910, near Thetford, while the latest nests were seen respectively in Sussex and Kent on May 25, the height of the breeding season being in March and April. Nests were recorded from thirteen English counties. The dates of departure of the birds varied locally; in some districts all had gone by the end of 1909, in others there was little or no diminution in the numbers till well on in the following year, but, as a whole, the records indicate that the main departure took place either in February or in April and May. From a second paper in the same issue, it appears, however, that a few crossbills remained to breed in certain localities in the spring of the present year. A note is added in the latter paper on the thin-beaked Scots crossbill (*Loxia curvirostra scotica*), which breeds regularly over a considerable area in Scotland.

The Irish Times of March 31, as quoted in *The Field* of April 8, reports an enormous influx of migratory birds into Ireland, especially the south-eastern districts, during the last week of March. In New Ross on the night of March 29 the town was practically invaded by a vast swarm of starlings, while in Kilkenny on the same day the streets were strewn with the dead bodies of various species, including curlew, while much the same thing happened in Carlow on March 30. There can be little doubt that the influx and subsequent destruction were in some way connected with the abnormally cold weather prevalent at the time.

In *The Emu* for January, Mr. A. J. Cambell describes, under the name of *Erythrotriorchis rufotibia*, a new species of so-called Australasian goshawk, characterised by the rich rufous or chestnut brown of the shank of the leg. This bird inhabits north-western Australia; the other members of the genus are *E. radiatus* of eastern, northern, and central Australia, and *E. doriae* of south-eastern Papua.

To *The Selborne Magazine* for April, Mr. A. H. Macpherson contributes notes on London birds in 1910, in which reference is made to the visit of a great crested grebe to the Serpentine on January 29. To illustrate the article on account of this casual visit with a figure of a nesting grebe, is, perhaps, a little misleading.

Mr. V. Franz gives, in *Himmel und Erde* for March, an illustrated account of the bird-observing station at Rossitten, with figures of the modes of ringing birds' feet, and notes on some of the results which have been obtained by the system of bird-marking.

From a paper by Mr. Grinnell issued in vol. vii., No. 4, of the Zoological Publications of the University of California, it appears that the Californian linnet (*Carpodacus frontalis*) was introduced into the Hawaiian Islands about forty years ago, and that the males of the race now established there differ from the normal form of their continental brethren by the replacement of the crimson head and breast colouring by yellow or orange. This pale colouring of the cock Hawaiian linnet is paralleled sporadically by the linnet of the mainland in a wild state, and constantly in birds kept in confinement. As the change in the Hawaiian bird does not appear to be due to differences in temperature or humidity, change of food, or a diminution in the number of foes, it appears to be connected with deep-seated factors, one of which may be insularity of habitat. "A deficiency in capacity, of the germ, for the formation of the appropriate enzyme may have been intensified through close breeding until the condition was reached where the amount of enzyme produced in the feather anlage is insufficient to carry on oxidation of tyrosin beyond the yellow, or, at farthest, the orange stage.

R. L.

OPTICALLY ACTIVE ALCOHOLS.

The January issue of the Chemical Society's Journal contains an important paper by Dr. R. H. Pickard and Mr. J. Kenyon on the "Dependence of Rotatory Power on Chemical Constitution." Hitherto much of the work that has been done in order to find out the influence on optical rotatory power of temperature, solvent, concentration, and chemical constitution has been based upon the observations of complex compounds, such as nicotine and derivatives of various complex acids and bases. These substances have the advantage that they can be purchased as natural products in optically active forms, but the complexity of their structure has rendered it almost impossible to draw any general conclusions from the vast array of facts that have now been accumulated. In the research now described the authors have endeavoured to reduce the problem to its simplest possible form by studying the properties of the series of secondary alcohols, $R_1.HOH.R_2$, of which the simplest member is secondary butyl alcohol, $CH_3.CHOH.CH_2.CH_3$.

Up to the present no fewer than fourteen of these alcohols have been prepared, and separated into their

optically active constituents by fractional crystallisation of the alkyl strychnine phthalates, $R.O.CO.C_6H_4.CO.O.X$, or similar salts, in which R is the alcohol radical and X is a suitable alkaloid; of these fourteen alcohols, only one had previously been obtained in an optically active form.

The labour involved in resolving so long a series of compounds can scarcely be appreciated except by those who have taken part in similar investigations, but in the present case the effort has been well rewarded by the production of material of unrivalled value for elucidating all the various problems involved in the study of optical rotatory power. The complete series of alcohols from $CH_3.CHOH.C_2H_5$ to $CH_3.CHOH.C_{11}H_{23}$ shows a perfectly regular gradation of properties, except in the case of the initial member, which shows an exceptionally large decrease of rotatory power with rise of temperature.

As illustrating the extreme sensitiveness of rotatory power to small changes of conditions, it may be noticed that ethylhexylcarbinol, $C_2H_5.CHOH.C_6H_{13}$, in complete contrast to methylhexylcarbinol, $CH_3.CHOH.C_6H_{13}$, or the methylheptylcarbinol, $CH_3.CHOH.C_7H_{15}$, with which it is isomeric, has a positive instead of a negative temperature coefficient, the rotatory powers of the isomeric alcohols being equal at 70°, but diverging when the temperature is raised or lowered. An even more drastic change of properties is observed on passing from phenylethylcarbinol, $C_6H_5.CHOH.C_2H_5$, to phenylmethylcarbinol, $C_6H_5.CHOH.CH_3$, or from methylbutylcarbinol,

$$CH_3.CHOH.C_4H_9,$$

to the isomeric methyl*iso*butylcarbinol,

$$CH_3.CHOH.CH_2.CH(CH_3)_2,$$

whereby the rotatory power is almost doubled in each case.

THE TEACHING OF SCIENCE IN SECONDARY SCHOOLS.[1]

THE following notes on the subject of science teaching in grant-earning secondary schools in England are based on the reports and observations of certain of the Board's inspectors, who were instructed to pay special attention to this matter during the past year. While an attempt will be made to note the principal changes that have occurred in recent years, to point out certain directions in which improvements have taken place, and to direct attention to some existing defects, the time has not yet come when a detailed and systematic survey of the state of scientific instruction in English secondary schools could profitably be undertaken. Since 1902, when the schools of science or "organised science schools" of the Science and Art Directory became the Division A Schools of the Regulations of that year, the number of secondary schools recognised for grant has risen from 348 to its present figure, 841. The earlier portion of this period was one which saw a gradual transformation from curricula which were predominantly scientific and mathematical to curricula in which a more even balance of studies was secured; and the whole period of growth and transition has been characterised (quite apart from the effect of alterations in the Board's Regulations) by notable changes in the methods, and to some extent also in the aims, of science teaching.

Changes in the Board's Regulations.

A comparison of the Regulations which in 1902 applied to the 221 schools in Division A (consisting in about equal proportions of municipal schools and higher grade board schools on one hand and schools of the endowed-school type on the other) with the Regulations now in force will show the magnitude of the change which has been brought about in the conditions under which the teaching of science in this section of the grant-earning schools is carried on. Thus in 1902 not fewer than thirteen hours a week were assigned to the obligatory subjects—mathematics, physics, chemistry, drawing, and practical geometry—of which not more than five hours might be assigned to mathematics. Even in the 127 schools belonging to the "Division B" of the Regulations of 1902, nine hours a week, or alternately a third of the total number of hours of instruction, were assigned to mathematics and science, of which four hours, or alternatively half the required minimum for both subjects, were allotted to science. Moreover, the Board not only determined the time which was to be allotted to science in each year of the "course," but indicated the syllabus to be followed in the various subjects of the "advanced courses" taken by the "Division A" schools. At the present time the Board's Regulations impose no conditions as to the syllabus of work to be followed and make no specific requirements as to the time to be assigned to the different subjects of the curriculum. Side by side with the increased freedom which has been given to the schools there has, as a fact, been a considerable reduction in the amount of time allotted to science in schools of the "Division A" type and to some degree also in schools of the "Division B" type. In schools of the former class the time given has commonly been reduced from some seven or eight hours a week to four or five in the upper forms, while in the lower forms the proportionate reduction has been greater. This has entailed considerable modification in the syllabus of work and, in general, a lowering of the possible standard of attainment.

Subjects Studied.

In practically all boys' schools the subjects taken are chemistry and physics, while in the majority of girls' schools botany is the main science subject, a minority taking either physics or more often chemistry. It is usual both in boys' and in girls' schools to find the study of one or other of these subjects preceded by a course of "experimental science" in which the formal separation into chemistry and physics is deliberately avoided. A considerable number of girls' schools, however, still exist in which botany is the only subject taken, or in which the attempt is made to teach botany concurrently with "experimental science"—a plan which, owing to the limited amount of time available, is rarely found to work well.

Hygiene, taught as a science subject, finds a place in the courses of a relatively small number of girls' schools and of a certain number of mixed schools, the subject being taken by the girls only. The inclusion of hygiene in the course is, as a rule, justified primarily on ethical grounds, *i.e.* with a view to the inculcation of hygienic habits. It is perhaps scarcely necessary to observe that there are wide differences of opinion as to the extent to which it is necessary or practicable to give this ethical teaching a formal scientific basis. The number of schools in which other science subjects, *e.g.* geology, astronomy, and zoology, are taught is exceedingly small, though there is some incidental teaching of the two former subjects in connection with the work in geography, while zoology very occasionally appears, and then for examination purposes, in the courses taken in the upper forms. Nature-study, a conveniently elastic term which covers work of the most various kinds, is ordinarily included among the subjects taught in the junior departments of both boys' and girls' schools. The subject is best taught when it is in the hands of a teacher (not necessarily the teacher of science) who is an enthusiast on natural history. In too many girls' schools in which botany is the main science subject the mistake is made of limiting the work to a preliminary study of plant life supplemented, it may be, by the making of weather records. In a few schools the plan of closely associating the early work in geography with nature-study has been tried with encouraging results.

Courses of Work.

(*a*) The differences which exist, and still more perhaps the differences which ought to exist, between the curricula of different grant-earning secondary schools make it practically impossible to comment in general terms on the character of the science work attempted and the standard reached in the several subjects taken. The probable after-careers of the pupils, the facilities for teaching individual subjects offered by the school and its environment, and the time which it is found possible to devote to science teaching are determining factors on which the choice of sub-

[1] From the Report of the Board of Education for the year 1909–10 London: Wyman and Sons, Ltd.). Cd. 5616. Price 8*d*.

jects, the range of the work, and the possible standard of attainment will necessarily depend. A course which is suitable in one school may be quite unsuitable in another. In those schools from which a certain number of the pupils pass on to university work in science, and in which a fair proportion remain until seventeen and over, or in which the course is definitely specialised (*e.g.* schools with a "rural bias"), the problem of the science syllabus tends indeed to solve itself; but in the large number of schools in which school life ends not later than sixteen, this is not so. If in these schools the best possible use is to be made of the time available, it is plainly desirable that the syllabus should represent something more than the initial stages of a study which the pupils will never continue—that it should have, in fact, a purpose and completeness of its own. Again, on the general principle that the curriculum of a school should be narrowed at the top, it should follow that in a certain proportion of schools the allowance of time would be such as to enable boys of sixteen or seventeen to attain a standard in more than one science subject over and above the limited standard required for "school leaving" or "matriculation" examinations. In schools of this type it may well be the function of the science teachers to save the curriculum from the dangers of an all-round mediocrity. This will apply more particularly to urban schools from which a considerable number of pupils pass on to scientific or quasi-scientific occupations.

(*b*) But whatever the circumstances of the school, no treatment of the science work can ever be satisfactory which leaves wholly out of consideration the relations of science to other subjects in the curriculum. Mathematics is an obvious case in point. The adoption of the same reclassification of the pupils for both mathematics and science is a plan for which there is very much to be said; but in the smaller schools there are practical difficulties in the way, which account for the fact that this expedient is rarely adopted. On the other hand, it is much to be wished that a certain proportion of teachers should be encouraged to qualify themselves to take both these subjects, and, questions of organisation apart, that teachers of physics and mathematics should always work in close touch with one another. In this connection a special point (which has received frequent notice in inspection reports for several years past) may be mentioned. It is very desirable that mensuration, which in a considerable number of schools is still included in the science course, should be transferred to its proper place in connection with the teaching of arithmetic to boys and girls in the junior departments. If this were done it would be possible, and often advantageous, to amplify the course in practical physics by the introduction, at some stage in the course, of experimental work in elementary mechanics, a subject which at the present time is too often neglected in schools. In addition to mathematics, geography, advanced manual instruction, and domestic economy may all contribute elements of value to the teaching of science, and be in turn assisted by it. It is necessary, however, to add the warning that the teacher who endeavours to teach two subjects in one may succeed admirably in teaching neither.

(*c*) The detailed syllabuses in particular subjects show in many cases curious, if not inexplicable, limitations. There is, for example, a tendency to refrain from all mention of scientific matters of common interest, because they do not admit in school work of complete and exhaustive treatment. Electricity and magnetism (including magnetic measurements) form part of the work in many boys' schools, but the motor and the dynamo are not even mentioned, because time does not permit of the study of electromagnetism. Every child is interested in soap bubbles, but the majority of boys and girls are not introduced to the simplest consideration of the phenomena connected with surface tension. There is no subject more generally studied than heat, but if a boy leaves school with any knowledge of how a locomotive works it will usually be the result of his own unaided researches. It is certainly unfortunate that pupils who learn science should be sent out into the world wholly ignorant of matters in which they are naturally disposed to be interested. Syllabuses of work, admirable for the purpose of instilling scientific method, may and sometimes do err in the direction of being inhuman.

(*d*) In the same way, it is important that in the actual teaching every opportunity should be taken of illustrating facts and principles learnt in the laboratory by frequent reference to everyday phenomena. This is a matter which requires the most careful attention in boys' schools no less than in girls' schools, in physics no less than in chemistry. Appropriate illustrations give a reality to the work which it sometimes lacks. They should, of course, be introduced as *illustrations*, that is to say, when, and only when, they may happen to be wanted to give point to the teaching. They are useful just in so far as they serve this purpose, and just in so far as it is remembered that the teaching is concerned with science and scientific method, and only in a secondary sense with its application to industry and the arts.

(*e*) Again, it is probably neither possible nor desirable to add to the number of science subjects which the pupils will systematically study in the laboratory and the class-room. There is the more reason why they should be encouraged to interest themselves in some aspects of nature other than those to which attention is given in school hours. For this the "school scientific society" may offer the needed opportunity by providing for the older pupils the occasion of taking up subjects for themselves and sharing their interests with their fellows.

Equipment.

In the matter of laboratory accommodation and equipment it is satisfactory to note that local authorities and governing bodies of endowed schools have commonly shown a generous appreciation of the requirements of science teaching. It is comparatively rare to find, except perhaps in connection with the teaching of botany, that the work is seriously handicapped by deficiencies in equipment, and the occasional suggestions of inspectors under this heading are directed, as a rule, to securing a suitable adaptation of the arrangements of the older laboratories to modern requirements. These will naturally vary in different schools with the character and extent of the course of work attempted, and it is for this reason desirable that the authorities concerned in the planning of new or the alteration of existing laboratories should take every opportunity of effectively consulting the responsible teachers. It is sometimes forgotten that space is more valuable than elaborate fittings, and that suitable provision for upkeep and apparatus is essential to the proper conduct of a laboratory. Economy and efficiency alike demand that a laboratory should not be regarded as something ready-made which can be ordered once for all from a manufacturer. On the contrary, when the essentials have been provided, a laboratory, like a library, should be allowed to grow.

Influence of Examinations.

Any consideration of the present state of science teaching would be obviously incomplete if it avoided all reference to the effects of examinations. In this connection, then, it is satisfactory to observe that the work of the schools, at any rate in the lower and middle forms, is far less determined by examination requirements than was the case even a few years ago, and that there is an increasing tendency among teachers to be guided in their teaching by strictly educational aims. At the same time there has been a marked improvement in the character of the syllabuses of certain examinations commonly taken, and a consequent improvement in the character of the work attempted in many of the schools. Notwithstanding this, it has to be recognised that a detailed syllabus put forward by an examining body, however unexceptional the syllabus may be, has its inevitable disadvantages; for it is only too likely that when a teacher has such a syllabus before him, his teaching will follow a predetermined line, whereas in connection with the teaching of science it is especially desirable, not only that the teacher should, within limits, make his own syllabus, but that he should feel free at any moment to depart from it. An examina-

tion may be unsuitable in a particular school either because the syllabus is so restricted that the last year's work tends to be a mere repetition (sometimes with a minimum of practical work) of what has gone before, or because the syllabus in a particular subject—chemistry, for example—covers so wide a field that the teachers in the limited time available practically confine themselves to this subject alone, and in dealing with it are forced back on mere bookwork and informational teaching.

Relation of Theoretical to Practical Teaching.

Attention has been frequently directed in the reports of inspectors to the necessity of establishing a right relation between the theoretical and practical teaching of science. By this is meant, not only that the two modes of treatment should be closely associated with one another, but that they should be placed in their right order. In this important matter there has been a notable improvement in the methods of teaching followed in the schools, and criticism in this region is likely in the future to be more concerned with details than with matters of principle. Though opinions differ as to the precise methods by which the desired results are to be secured, it is now very widely recognised that the teaching of a class should, so far as possible, be based on the practical work done by the members of the class. As a fact, lectures have largely given place in elementary teaching to class discussions on the practical work assisted by occasional demonstrations, and the change has been beneficial to the work of the lower and middle forms. In some cases, however (as will be pointed out later on), the practical work has not been supplemented by any adequate discussion of its results. In other cases, the reaction against formal lectures has gone so far as to lead teachers to rely exclusively on the experiments carried out by the class. There is reason to think that when this is done the teaching loses in effectiveness.

Practical work in the lower and middle forms ordinarily follows on a brief discussion of the matter to be investigated, and a written account of the experiment to be carried out is regularly required. Such written accounts should, of course, be the outcome of the pupil's own efforts, and not be, to all intents and purposes, dictated by the teacher or copied from a book. So far as these records are concerned, there has been of late considerable improvement. The mechanical entering up of results in spaces set apart for the purpose, or the filling up of columns under the headings "experiment," "observation," "inference," has nearly disappeared; but more remains to be done in regard both to the form and substance of the record. The idea that there are two standards of composition, one which is appropriate for the English lesson, and another which is good enough for the science laboratory, has not yet been eradicated. But, apart from this, the notebooks often include accounts which are satisfactory in so far as they are purely descriptive, but which fail to show how the "conclusion" follows from the observations recorded or to state what assumptions have been made in the argument. It is not, indeed, uncommon to find conclusions recorded which the pupil's own work quite fails to justify. The "doing" is, in fact, unaccompanied by any honest thinking about what has been done. There is, of course, nothing in this to cause surprise. To expect exactness of thought and accuracy of expression from younger pupils is to expect the ripe fruits of scientific education from those who have but lately begun to enjoy its benefits. If these logical errors never occurred, there would be no need to spend time over teaching "scientific method." It is precisely by seizing the opportunities which such mistakes and omissions afford that the teacher can convey to the pupil valuable lessons in the logic of science.

So far as the actual experimental work is concerned, its value depends in different schools on the extent to which the pupil is encouraged to use his own eyes, to apply his powers of reasoning to the problem under consideration, and to criticise his own procedure. The work should, in fact, serve not only to develop the powers of observation and reasoning, but to inculcate "an increasing respect for precision of statement and for that form of veracity which consists in the acknowledgment of difficulties." It is quite possible for pupils to work through a set of disconnected experiments and to get little out of it beyond a certain facility in easy manipulation. Work of this kind may be as mechanical and as far removed from being really practical as anything that is done in a classroom. The necessities of the school time-table often lead to the work being broken up into the performance of a series of isolated experiments, one for each lesson period. There is, therefore, the more reason why teachers should be on their guard against the serious danger of making the single experiment the unit of teaching. The exclusion of experiments which are trivial, or of which the results are self-evident, and the occasional adoption of the plan of allowing different groups in a class to work at different though allied experiments, the results obtained by each group being available for the whole class and used in the subsequent discussion, would do much to widen the pupils' experience and give the work a seriousness and importance which it sometimes lacks.

The remarks in the two preceding paragraphs are intended to apply more particularly to the treatment of the practical work in all science subjects in the lower and middle forms. The methods appropriate to the teaching of the higher forms are, in general, much better understood, and need not now be dealt with. But the teaching of botany requires special notice, especially in view of the important position it occupies in the science work of girls' schools.

Teaching of Botany.

Considerable changes have been effected in recent years in the method and scope of botanical teaching. The time given to the purely descriptive work connected with the classification of plants in their natural orders has been greatly curtailed, and it is now common to find included in the course an experimental treatment of plant physiology and some consideration of the question of habitat. There is, too, an increasing tendency to recognise that no adequate study of botany is possible without some knowledge of the elementary facts and principles of chemistry and physics. The broader treatment which the subject now receives, and the substitution of a partially experimental for a purely descriptive method, have led to a healthier development of science teaching in many girls' schools. But the new methods have brought with them their own special difficulties, which, in most cases, still await solution. It is rare, for example, to find the experimental work on plant physiology really well done, and the possibilities of the school garden as an adjunct to the laboratory are insufficiently realised by teachers of botany.

Though in connection with this subject it is possible to record a general tendency in the right direction, and in a fair number of instances a real advance, it is still the case that in too many schools botany is regarded somewhat in the light of an accomplishment, making no very serious demands on the pupils' intelligence and requiring little more by way of equipment than a classroom and a bunch of flowers.

In conclusion, it may be stated that if attention has been deliberately directed in some of the foregoing paragraphs to certain existing defects in the teaching of science, this is due to no failure to recognise the excellence of the work which in many secondary schools is being done under the guidance of skilled and experienced teachers.

THE SCIENCE MUSEUM AND THE GEOLOGICAL MUSEUM.[1]

THE report of the Departmental Committee on the Science Museum and the Geological Museum was published a few days ago. The committee was appointed in March, 1910, and its terms of reference were:—"To consider and report upon various questions in regard to the present condition and the future development of the valuable collections comprised in the Board's Science

[1] Report of the Departmental Committee on the Science Museum and the Geological Museum. Cd. 552. (London: Wyman & Sons, Ltd. Price 3*d*.

Museum at South Kensington and Geological Museum in Jermyn Street. In particular the committee are asked to advise (*a*) as to the precise educational and other purposes which the collections can best serve in the national interests; (*b*) as to the lines on which the collections should be arranged and developed, and possibly modified, so as more effectively to fulfil these purposes; and (*c*) as to the special characteristics which should be possessed by the new buildings which it is hoped will shortly be erected on the South Kensington site to house these collections, so as to enable the latter to be classified and exhibited in the manner most fitted to accomplish the purposes they are intended to fulfil."

The members of the committee were:—Sir Hugh Bell, Bart., chairman; Dr. J. J. Dobbie, F.R.S.; Sir Archibald Geikie, K.C.B., F.R.S.; Dr. R. T. Glazebrook, C.B., F.R.S.; Mr. Andrew Laing; the Hon. Sir Schomberg McDonnell, K.C.B., C.V.O.; Sir William Ramsay, K.C.B., F.R.S.; Prof. W. Ripper; Sir W. H. White, K.C.B., F.R.S.; Mr. F. G. Ogilvie, C.B., secretary.

The completion of the report is deferred, as the committee is unable to deal in detail with that part of the terms of reference which concerns the adaptation of the general plan of the new buildings to the requirements of classification and exhibition of the collections, until the boundaries of the site are determined. The committee therefore reserves for later consideration and report, when definite information on this point is available, those characteristics of the buildings that will be governed in large measure by special features of the particular site. In the present report the committee sets out the nature, aims, and uses of the collections upon which it proposes to base later recommendations as to the new buildings.

We print below parts of the concluding sections of the report of particular interest.

The Geological Survey Offices and the Museum of Practical Geology.

The Geological Survey Offices and Library and the Museum of Practical Geology are now cramped by the limitations of the building in Jermyn Street. These institutions, which form parts of a connected whole, and must be kept together, should be grouped, as at present, in a single building. We are convinced that if the necessary space can be allotted at South Kensington, it would be of great advantage to have that building erected as part of the general scheme there. The collections in the Science Museum represent the general principles of geology and geography by examples selected from all regions of the world—the stratigraphical collections in the Jermyn Street Museum deal specially with the geology of the British Isles (see Appendix iv., p. 30). If these two were brought together they would provide the basis of a collection that would be complete as regards stratigraphical and economic geology. Such a collection in the new buildings, with the systematic collection of minerals and the palæontological collections arranged according to their natural affinities in the British Museum (Natural History), would represent at a single centre the whole field of geological science.

In the event of the removal of the Museum of Practical Geology from its present site, more extended accommodation must be provided for the exhibited specimens. As matters stand now—to refer to one only of the activities of the Geological Survey—the economic collections, which are arranged with special reference to the requirements of the practical man and of the technological student, cannot be properly developed unless more ample galleries are available for them.

Accommodation Required for the Two Museums.

In dealing with the question of the accommodation that would be required in the new buildings, we must consider both the immediate requirements and the provision to be made for probable future expansion of the collections.

So far as the more immediate needs are concerned, we have prepared an estimate of the minimum floor space which, in our judgment, is necessary for exhibition galleries, offices, workshops, store-rooms, and demonstration rooms, or other meeting rooms, all properly lit. In this estimate we have assumed that there would be further store accommodation suitable for safe-keeping of objects, although not for their examination. The figures, which are given in Appendix vi. (see p. 32), bring out the following totals:—

Science Museum: Total floor space required in the immediate future, *exclusive* of entrance halls, staircases, lavatories, cloakrooms, and reserve stores, and *in addition to* 16,500 square feet already provided in permanent buildings, 300,000 square feet.

Museum of Practical Geology and offices of the Geological Survey: Total floor space required in the immediate future, *exclusive* of entrance hall, staircases, lavatories, and cloakrooms, and reserve stores, 60,000 square feet.

Buildings on this scale would provide for such developments as we can now foresee; we think it likely that they would be well utilised within the next ten years, or even in the course of a shorter period, if active steps were taken to make good the deficiencies of the existing collections. At the same time, the buildings could be designed so as to facilitate arrangements for meeting the possible requirements of a more distant future, and whatever space may be set free from time to time by revision of the collections, the building scheme adopted now should provide for ultimate extension of the floor space beyond the area we have stated. With this matter we shall deal further in a later report when we can discuss it with full knowledge of the site available.

General Statement.

In most of the departments of science and its applications, the museums on which we have been asked to report contain much that is of great historical interest and value. They are rich in specimens, instruments, machines, and models, selected and exhibited in such a manner as to repay systematic examination by the student. They have shown what skilful museum exposition can do to promote an intelligent appreciation of the leading facts and principles of science and of the ways in which invention has applied these to the furtherance of the industrial welfare of the world. In many sections, however, the collections are now far below the standard which it is clear they ought to reach in these matters, and their proper organisation is impossible in the existing accommodation. When suitable buildings are provided on the scale we have indicated, there will be full opportunity and encouragement for working up all the departments, and more frequent gifts and loans will doubtless quickly fill many of the gaps that are now obvious. Some gaps, indeed, would be filled at once by objects which the governors of the Imperial College of Science and Technology are prepared to present to the museum.

In other departments of knowledge, the British Museum and the Victoria and Albert Museum have set a high standard for the national provision of museum facilities. In the domain of science, the requirements of most of the branches of natural history are already admirably provided for at South Kensington in the Natural History Museum. In no way overlapping or duplicating the functions of these great institutions, but representing aspects of human activity which lie outside their scope, not less ample provision is necessary for those departments of knowledge, invention, and discovery the needs of which have been brought so vividly before us in our inquiry, and we are of opinion that no scheme for a national science museum can be regarded as satisfactory unless it provides the buildings necessary for affording to science and the industries all the assistance a museum can give. A science museum in which all branches of physical science, pure and applied, and the scientific and economic work of the Geological Survey, shall be adequately illustrated in close proximity to the other great museums at South Kensington will, we believe, be of incalculable benefit alike to intellectual progress and to industrial development, and will be recognised as an institution of which the country may well be proud.

TRAVELLING AT HIGH SPEEDS ON THE SURFACE OF THE EARTH AND ABOVE IT.[1]

"The Spirit of the time shall teach me Speed."—*King John.*

THERE are few things so important to man from a material point of view as the power of locomotion; seeing, therefore, that in this respect he is far less well endowed by nature than many, if not most, living creatures, it is no wonder that he has striven from the earliest times to overcome his inferiority by means of mechanical devices. The marvellous results of these unceasing attempts which to-day we enjoy, or, as some people would prefer to say, "take advantage of," are accepted by most of us as a mere matter of course, and we are further apt to assume that the progress which has been so marked during the last century, and particularly in recent years, will continue indefinitely. Now, quite apart from mere locomotion, the question of speed is one of great scientific interest, and, more than this, it is the real test of the power of locomotion. This is not a mere accident, but has its root in something far deeper. The desire for speed is a quality inherent in man, and is doubtless a primordial instinct, the reason for which we see in all other animals, being derived from prehistoric ages, when speed was a necessity of life to enable the weak to escape from the strong and to enable the strong to prey upon the weak, and man depended, just as the animals in prehistoric times, for his life on his fleetness and speed of motion.

From what few and somewhat uncertain records we have of the achievements of man in running in the ancient sports, it does not seem there is very much difference between his powers then and in modern times. As to modern times, we find that for the short distance of 100 yards, and for the longer distance of a mile, the records of twenty-five years ago still stand, notwithstanding the strenuous efforts made to improve upon them on many scores of occasions each subsequent year. Thus we have for the former the record of E. Donnovan in 1886, 21·3 miles an hour, and in the same year the record of W. G. George for the mile, 14·2 miles an hour, which have never been beaten; while for one distance, that of 200 yards, the record of Sewards in 1847, or sixty-four years ago, still stands. In fact, a study of all the records of twenty-five distances shows that several of them remain unbroken after comparatively long periods, viz. from a quarter to half a century.

Thus, so far as his own unaided powers of locomotion are concerned, man may be considered, for all practical purposes, to have reached long ago the limit of speed possibility. From earliest times, however, he has brought the muscular effort of other animals into his service, and has devoted his intellect towards improving their speed for his own uses. You will see graphically recorded in Fig. 1 the speeds of all the Derby winners from the year 1856, *i.e.* for more than half a century. The average speed, which may be taken as somewhere above 30 miles an hour, has doubtless slightly increased, but it will be seen from the dotted line which has been drawn at the top of the maximum speeds what comparatively little increase has been obtained for an expenditure of the many millions represented directly and indirectly in the training and breeding of these horses, and it may be reasonably assumed that here again the limit has been reached for the fleetest animal, by the aid of which man can increase his speed of locomotion by using muscular power other than his own.

What, then, are the physical reasons for this limitation? It is not due to the chief cause, which we shall see later puts a practical limit to very high speeds in mechanical locomotion, namely, the resistance of the atmosphere. Neither is it due to the effective work done in movement, since with a body moving along a level plain, *i.e.* at a constant distance from the earth's centre, this effective work is nil. To understand the matter we must study the nature of animal locomotion. The surface of the earth is rough, sliding along it being obviously out of the question; nature has made provision for animal movement as follows:—one part of the body first rests on the ground, another part supported by this is advanced, being raised clear of the ground, to rest in turn upon the ground and serve in turn as a support, so that the part behind may be raised and advanced to a fresh position. In man and other animals the feet form the points of support for this process; but the same method of locomotion is employed by creatures without feet, which have to crawl or glide, such as snakes or worms.

This process, whether with animals or reptiles, as you will see, involves in the raising of the body an expenditure of work which is not recovered, and further an expenditure of work in stopping and starting some portion of the body in its movements. My assistant now walks in front of the blackboard holding a piece of chalk level with his head, and you will see the rising and falling motion. I have prepared a wooden model to represent the action of his legs, and you will see that these legs, being equal to his in length, produce almost exactly the same curve underneath, so that you have a complete explanation of this movement, viz. the rotation of the hip about the ankle as a pivot. There is a third case of loss, namely,

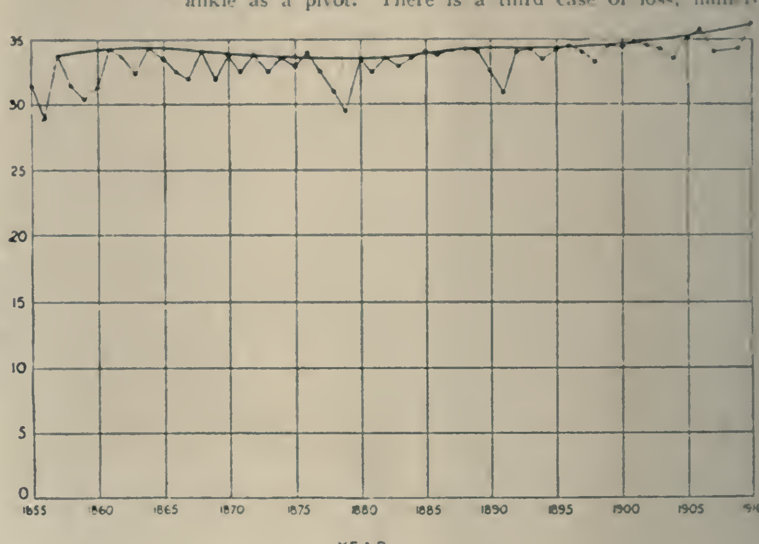

FIG. 1.—Derby Winners for 55 years.

the energy involved in swinging the legs. About thirty years ago the distinguished French professor, Marey, actually investigated the loss involved from each of these three causes, and I have on the wall a diagram in which you will see all three given graphically. The number of steps per minute, you will notice, increases until a pace is reached when it becomes painful to walk faster, and you will also notice from the diagram that at about ninety steps per minute the gait changes to a run, that is to say, a springing action takes place, the hind foot leaving the ground before the front is put down upon it.

I have another diagram showing how the length of stride at first increases with the pace, and afterwards begins to fall off before the walking breaks into a run. The reason why a man or an animal changes his pace at this point is obvious, and it is because a faster speed is possible with a less effort. As the speed of running is increased the total effort becomes greater, but the three elements shown on the diagram are differently divided; the rise and fall element is less, but the work done in swinging the legs is more, while the chief element, in the muscular effort expended, is the loss of energy involved in stopping and starting as each spring reaches a maximum. Time does not permit me to pursue this interesting subject further except to point out that exactly

[1] Discourse delivered at the Royal Institution on Friday, March 31, by Prof. H. S. Hele-Shaw, F.R.S.

similar causes operate in the natural locomotion of other animals which move on legs.

We therefore now know that the limit of speed is controlled by two factors:—

(1) Physical endurance, owing to the expenditure of work occurring at an increasing rate as the speed is increased.

(2) The physical impossibility of giving a reciprocating movement to the legs quicker than a certain limited period of time.

I have prepared a chart, Fig. 2, which shows the maximum recorded velocities of man's progression in walking and running. The speeds are set up as vertical ordinates, and the abscissæ represent the distances over which the respective speeds were maintained. It will be seen that the maximum speed of walking is about 9 miles an hour for a short distance, but when the long distance of 100 miles is covered, the quickest rate recorded falls to $5\frac{1}{2}$ miles an hour. For running, the quickest speed which I have mentioned, viz. $21\frac{1}{2}$ miles an hour for 100 yards, falls to $7\frac{1}{2}$ miles an hour as the average speed for a distance of 100 miles.

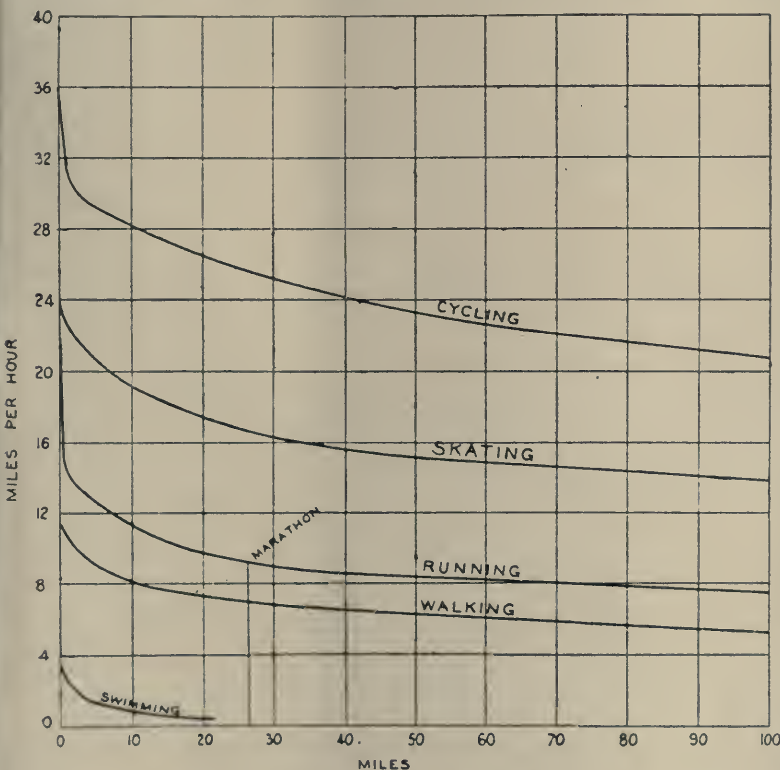

FIG. 2.—Speed Records for Human Muscular Effort.

We do not know the speed of the original historical run from Marathon to Athens, but we do know that Dorando ran the modern Marathon from Windsor Castle to the Stadium at Shepherd's Bush, a distance of 26 miles 385 yards in (to be exact) 2h. 55m. 18 2-5s., or at the rate of 9 miles per hour, which, you see, fits very well on our curve.

We may notice in passing that in walking fast and starting to run the arms swing in time with the opposite leg, as in the modern picture on the diagram exhibited. In the picture, however, copied on the same diagram from an ancient Greek vase, although the attitude of the legs is the same, it might appear at first sight as if the arms were swinging in the contrary way. As a matter of fact, a closer examination shows that in all the figures on the vase the arms are in the same position, although the legs are in different phases. This seems to indicate that the arms of a Greek runner were held in a fixed position as shown, and, from the position of the hands, with the evident intention of cutting the wind. If this is true, it indicates that even then it was clearly recognised that if there was any effect of the wind it was just as important behind as in front, a matter I shall have to allude to hereafter.

What man can do by his muscular effort in the water is shown by the small curve in the corner. The greatest distance shown (Fig. 2) is about 21 miles by Captain Webb at about 1 mile per hour, although for a short distance it will be seen that a man can swim at about 4 miles per hour. I do not put in flying, because man has not yet flown by his own muscular effort, and flying men to-day are using engines of from 20 horse-power to 100 horse-power, *i.e.* from 200 to 1000 *man-power*. Gliding *per se* is no more than falling through the air (more or less) gradually, as in a parachute.

Before proceeding to see what man has done to increase his powers of purely muscular locomotion by means of mechanical devices, we will study the details of locomotion in the other animals. We are able to do this by the method of Mr. Muybridge, since developed in the invention of the kinematograph, and which was explained by Mr. Muybridge for the first time in this country about thirty years ago in a lecture in this hall.

Take, first, the galloping horse. The lantern diagram shows clearly the various phases in the action of a horse, and shows how the animal is not only able to attain its high speed by its length of stride, but by doing what man cannot do to the same extent—drawing up its body and in springing forward, using alternately its fore and hind feet, so as to get a stride which no two-footed creature could attain on the level ground. I may point out that the kangaroo, though using only two legs, makes effective use of its tail in the spring. The horse springs clear of the ground off its forefeet, only you will notice that it uses both its fore and hind legs as the spokes of a wheel on which it rolls when walking (exactly as man does), though it rolls and springs alternately in galloping. The same kind of diagram could be constructed for the effort exerted at different speeds by the horse, as has been produced by Marey for the man, only the distribution of energy would probably be very different.

Turning next to other animals, it is interesting to observe that a greyhound gets its high speed in proportion to its size owing to the great flexibility of its long body, which enables it to draw its hind legs forward each time for the next bound, and also bound forward both from its fore and hind legs. The other animals in galloping have each the same general kind of movement, although the deer, curiously enough, only bounds from its hind legs, and differs in this respect from the horse; and also it will be noticed the want of flexibility in the body of an animal may be one of the causes of its relatively slow speed. But whether it be man, horse, dog, or any other animal, the same characteristic is found, namely, that locomotion, apart from the bounding action, takes place by a sort of rolling action on the ground. The idea which had persisted since the delineation of horses in Assyrian and Egyptian pictures, that both the fore or both the hind legs are put on the ground simultaneously, is thus exploded. As Mr. Muybridge truly said: "When during a gallop, the fore and hind legs are severally and consecutively thrust forwards and backwards to their fullest extent, their comparative inaction may create in the mind of the careless observer an impression of indistinct outlines; these successive appearances were probably combined by the earliest sculptors and painters, and with grotesque exaggeration adopted as the solitary position to illustrate great speed." As a matter of fact, each leg in turn, as it rests on the

ground, stops for a moment just as much as in the forward position above mentioned, and if you watch a dog galloping you can see quite clearly the rolling stroke action I have mentioned.

With the above facts in mind, we can understand exactly the limitations to animal locomotion. In the words of Mr. Muybridge:—"When the body of an animal is being carried forward with uniform motion, the limbs in their relation to it have alternately a progressive and a retrogressive action, their various portions accelerating in comparative speed and repose as they extend downwards to the feet, which are subjected to successive changes from a condition of absolute rest, to a varying increased velocity in comparison with that of the body." Hence all animal locomotion absolutely lacks that continuity of movement, the production of which we shall see is the distinguishing feature and the direct cause of the high speeds attained in mechanical locomotion.

The exchange of the intermittent movement of nature for one having the desired continuity of movement has been effected by means of what is possibly the greatest and yet the simplest of all human inventions, namely, the wheel. The wheel was made and used probably thousands of years before man learnt to replace muscular effort by that of steam and the other forces of nature, the origin of the wheel being absolutely lost in antiquity.

From the models which I now show will be noticed the way in which the wheel acts and how it overcomes the defect of animal locomotion, giving a rotary and continuous movement instead of a reciprocating and variable one. At one and the same time the wheel, therefore, does away with the three causes of loss shown in the diagram as occurring with animal locomotion. The mere use of the wheel has enabled man himself, by his own muscular effort, enormously to increase his individual power of locomotion. The top curve on Fig. 2 shows, in comparison with the other curves of walking and running, his unpaced records on a bicycle, in using which it will be realised that all three causes of loss which occur in running and walking are obviated. You will notice a similar difference in speed as the distance varies to that which is made evident in the curves for walking and running. For the distance of 100 miles the average speed is thus only 21 miles an hour, while that for $\frac{1}{4}$ mile is more than 35 miles an hour. In view of the results shown by the curve, it is not surprising that the bicycle has entered largely into the conditions of modern life. I am not able to give you any exact figures of the quantity of bicycles turned out each year in this country, but I can tell you that in the Post Office alone there are now 12,000 bicycles employed, and their number is always on the increase; the distance covered on them by men and boys in the year is more than 120,000,000 miles

I have not dealt with *paced* bicycle records, as such are not the result of muscular effort, but of being pushed along by the current of wind which follows up the pacing machine such as occurs when a man on a "push" bicycle is paced by a motor vehicle. In a record first set up in America for 60 miles an hour on a bicycle, a man was paced by a locomotive engine, running at 60 miles an hour along a special track; the rider was nearly killed when he tried to drop behind, owing to the whirlwind which was being dragged along by the engine; ultimately his life was saved by his being lifted bodily off his bicycle on to the locomotive. There is no record as to what became of the bicycle.

Curiously enough, records for ice skating and roller skating are almost the same, and far below that on the bicycle, which I think proves distinctly that the reciprocating movement of the limbs limits man's powers, whether he is sliding on the ice or using wheels as with roller skates. This is so, notwithstanding that he carries along with him when on a bicycle the extra weight of the bicycle, but the reciprocating movement of his legs is so slow, owing to the gearing up of the driving wheel, as to give him the material advantage shown by the respective curves. Further, in skating, there is no doubt that the movement of his limbs entails a certain amount of rising and falling, as well as reciprocating motion and consequent loss which occurs in running.

Now, in theory, the wheel is perfect, and in the case of a perfectly hard, circular wheel, rolling on a perfectly hard track, there should be no resistance. This you can well

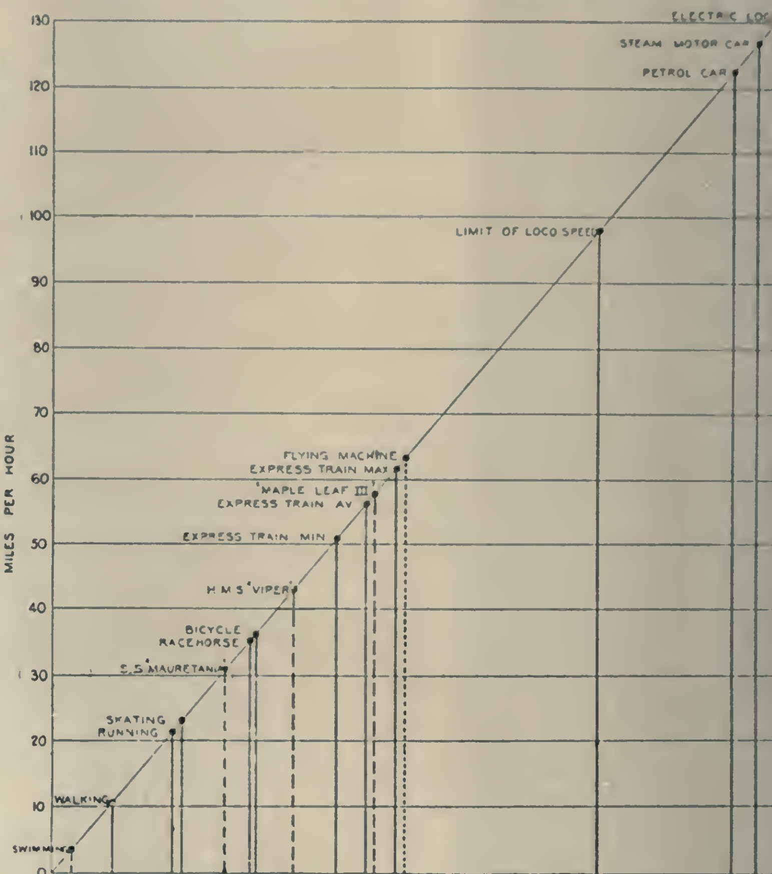

FIG. 3.—Graphical Table of Maximum Speeds.

imagine from the lantern model which I now show in operation. In this there is no appreciable resistance, but it is just in this direction that the wheel has defects unknown to nature's methods, since men and animals move upon the ankle joint in a quite superior way to the rolling of an ordinary wheel. In passing I may remark that the more man improves the roads, and the higher his standard of locomotion becomes, the more will he feel the need of a mechanical walking machine (it will be a *walking* machine, though possibly moving at 20 miles per hour) to progress over parts of the earth where roads do not exist, or are still in an evil condition. The better his mechanical appliances for producing such a walking machine, the sooner will this come about, as this is really a vital factor in the solution of the problem. No wheel, however, is quite hard and round, and no road is quite hard and smooth, and there is always an arc of contact, more or less appreciable, which causes a loss, since rubbing

takes place instead of true rolling, as shown in the next lantern slide. The next lantern working model I show illustrates the other effect, in which the wheel meets obstacles and is deflected by them from its course, giving exactly the same kind of loss which I showed you takes place with a man in walking, and which is made apparent by making the car write its own record on a piece of smoked glass, exactly as my assistant wrote his record of rise and fall on the blackboard.

Thus there are two ways in which the wheel can be improved :—

(1) Is by perfecting the wheel and hardening the track—and that is the secret of the development of the railway system.

(2) The other is by causing the obstacle to be absorbed in the tyre of the wheel—that is the real secret of the success of the pneumatic tyre.

The working model now on the screen illustrates the latter point, and shows at once how the three causes of resistance to animal locomotion are overcome.

To-day we can replace the muscular energy of man by almost unlimited mechanical power, and Fig. 3 is a comparative speed chart which I have prepared and which indicates the enormous advance in the speed record which has been made over the best unaided muscular efforts of any animal. It is curious to see that the highest speed ever attained on a railway is closely approached by that obtained with motor vehicles. The records for the latter are as follows :—

A Darracq car of 200 horse-power has done 122½ miles an hour for 2 miles. A Fiat car, driven by Nazarro at Brooklands, 126 miles an hour. A Stanley steam car, 127 miles an hour, and a Benz car has done 127½ miles an hour.

The maximum recorded speeds of a railway were on the experimental line of Messrs. Siemens, on the Berlin-Zossen High Speed Railway, where a speed of rather more than 130 miles an hour was attained. The electric current employed was 10,000 volts, 400 horse-power motors being used. On the Marienfel-Zossen experimental line, the speed attained with 250 horse-power was apparently rather less, though in that locomotive four motors were employed, the current being, as in the other case, 10,000 volts. The lantern diagrams are a picture of the vehicles actually employed, and of the track on which the experiments were made. As a set-off against the sober engineering pictures, I show a picture taken from an American motor journal, illustrating a motor vehicle and locomotive at top speed, the former passing on a level crossing in front of the latter.

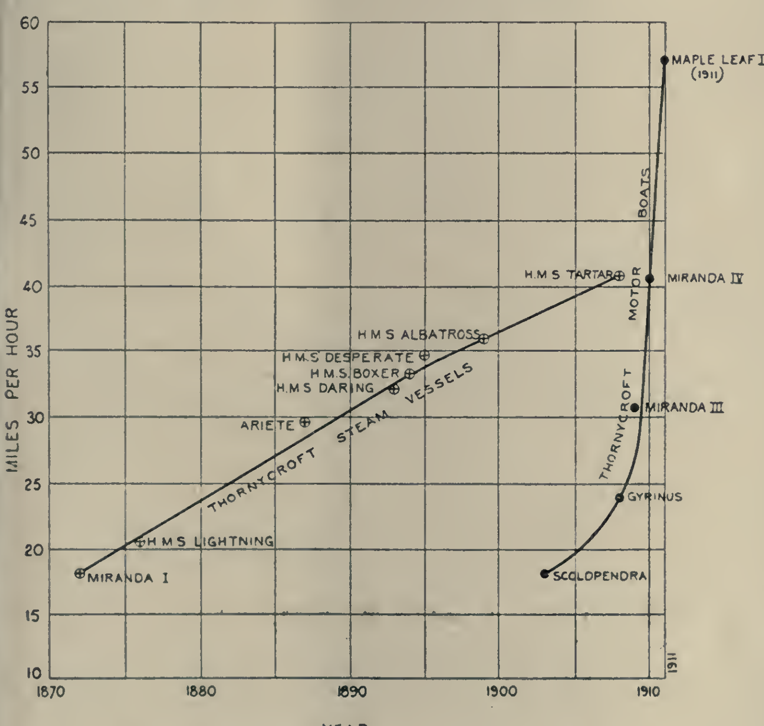

Fig. 4.—Speed Records for Thornycroft Warships and Motor Boats.

The foregoing are the record speeds so far obtained of mechanical locomotion, and it will be interesting to see what are the record speeds attained in the other elements. Until the other day, as Mr. Parsons told us in his lecture, the speed on water which has never been exceeded was that of the ill-fated turbine boats, *Viper* and *Cobra*, of about 43 miles an hour. The ship which at present holds the record for speed is the torpedo destroyer *Tartar*, built by Messrs. John Thornycroft, this, under Admiralty tests, giving a speed of 41 miles an hour.

The diagram, Fig. 4, shows in an interesting manner what the progress in speed has been for this class of boats during the last few years, and may be taken as typical, and about which curves Sir John Thornycroft writes as follows :—

"I do not think the curve would be materially altered if vessels of other builders were brought in, although there would naturally be more points on it."

I am able, however, to give you the results to-night of something which has altogether put in the shade even the speeds of the two first-mentioned boats. This has been attained by a boat which, though corresponding in some respects with previous hydroplane boats, has been designed by Sir John Thornycroft to possess a certain amount of seaworthiness. The rate of progress in the increasing speeds in this class of boat is shown on a separate curve, Fig. 4, from which you will see that the celebrated *Miranda* held as a hydroplane the record with the *Tartar* for speed, the *Ursula* also holding the record of about the same speed as a motor-boat. Only a few days ago, however, the new boat *Maple Leaf III.* has attained the extraordinary speed of nearly 50 knots, that is to say, a speed approaching 60 miles an hour, using 600 horse-power to effect this speed. To use a vulgar expression, this certainly smashes all previous records for speed. I do not pretend to give exact figures in this case, because such have not been officially taken, but the statement is probably on the low side as the boat has not been yet properly tuned up. You will see one remarkable thing from the curve, namely, that the rate of progress has been so rapid in this class of boat, and the curve rises so steeply, that in about three months' time there is due from Sir John Thornycroft a boat which will travel at about 100 miles an hour. I am afraid, however, it would not be fair to press this graphical argument quite so far.

Through the kindness of Sir John Thornycroft, and Mr. Edgar, the owner of the *Maple Leaf*, I am able to show both the *Miranda* and the *Maple Leaf III.* The latter, you will see, is travelling at such an extraordinary rate that the water which is lifted up does not fall to the surface again until the boat itself has travelled several lengths away. You may be interested to see a model of this last boat, which has been kindly prepared for me to show to-night, as well as the *Tartar* and *Miranda*. You will notice the form of the *Maple Leaf III.* is that of a steeped hydroplane, which in a modified form was first suggested by Mr. Ramus many years ago; it is the secret of placing the weight, and also the development of light engines giving large horse-power, which has enabled the dream of Mr. Ramus to be fulfilled.

Turning to the last of the three elements, namely, air, it was my intention to have dealt with it at greater length than I now find it is possible to do, but, thanks to the

daily Press and illustrated journals, this subject is as fresh in the minds of everybody as it is familiar. It is not necessary in this room to remark that the wild talk of almost incredible speeds has very little foundation. Bodies move quickly enough in the air, and very often far too quickly, but what is generally overlooked is that the difficulty of the problem lies in the matter of supporting the body in the air rather than moving through it, a problem which is very much simpler for land and water. The human body itself, while of about equal specific gravity with water, is about 800 times as heavy as air, and probably, taken in conjunction with the motor and aeroplane, the weight which has to be supported is several thousand times as heavy relatively to the air which it displaces. Inasmuch as the support of the air necessitates the use of an inclined plane and a corresponding expenditure of energy, the speeds made horizontally and independently of the wind have, at the present time, barely exceeded half the record speeds made on wheel vehicles. As a matter of fact, only the other day the record for passenger flight was broken by M. Nieuport at Mourmelon, when he flew with two passengers for 1h. 4m. 58 1-5s., and covered 68·35 miles at an average speed of 63 miles per hour. It is difficult to say exactly what the true record speed at present is round a course, but we may safely take it as probably under 70 miles an hour, the record being, so far as I have been able to ascertain, by M. Nieuport on March 9 this year at Chalons—68 miles 168 yards in the hour.

We now see the relative position of the record speeds in the three elements on our speed chart, Fig. 3, and it is obvious that while on land the speed has been far exceeded of the fastest animal, on water it has probably only recently surpassed that speed, while in the air, in all probability, it is still considerably below it. We must not, however, from this argue that flying speeds will for safe flying machines rise so far beyond that of birds as land locomotion has risen above the speed of animals, for it looks as if the speed records on land would be at least equal for some time, if not greater, than that possible with safety in the air. At the same time, there is no doubt that speed is the one great factor of safety in flying, and aërial speed records are sure to go on rising year by year, but time does not permit me to pursue this subject further to-night.

Instead of vague surmises as to what may be done in the future, let us spend a few minutes looking into the question of these limits.

The two chief things on which the limit of speed in locomotion will depend are:—

(1) The motive power available.

(2) The resistance, and the manner in which those resistances operate.

But inasmuch as we are not merely considering the human body as a projectile, we do not take into account such speeds as have been attained by man in such ways as, for instance, in a high dive, say, of nearly 100 miles an hour, or even the thrilling descents such as are made in a bobsleigh. We must really consider speeds which can be made with safety; and there are two further questions which arise:—

(1) Knowledge as to possible obstacles, coupled with a power of safely stopping within the distance to which our knowledge extends, *i.e.* signalling and brakes.

(2) Vibration.

These two latter really limit conditions of high speed for practical travelling.

In daily life, the limiting conditions of speed in travelling depend largely on the distance in which we can safely come to rest. As the population increases and there is less room for everybody, the question of brake-power becomes more and more important, and with it, of course, the power of starting from rest quickly, or, to put it in scientific words, the power of rapidly effecting both positive and negative acceleration. We are very differently constructed from the particles of air in which we live, and do not yet travel as fast, but fortunately, as yet, we are not quite so crowded, since, according to Lord Kelvin, they move about amongst each other at the ordinary atmospheric temperature and pressure at an average speed of 1800 miles an hour, and they cannot avoid fewer than five thousand million collisions in every second. As you see in the streets, and as I shall show you with regard to suburban traffic, high speed is becoming more and more a question of starting and stopping rapidly. I remember in the early days of cycle racing, in order to lighten the machine, the racing men had no brake, until they found what is now well recognised—that the speed at which you can travel depends upon the safe distance in which you can stop. I can illustrate this by dropping an egg from the dome of this building, which I can do without causing it any injury, even when it is travelling at 30 miles an hour, if I have proper means for bringing it to rest. I also drop a wineglass from the same height, and bring it to rest quite safely.

Owing largely to the perfection of the continuous brake, the speed records obtained on several railways are from 96 to 98 miles an hour, which I have put down on the diagram, and it is possible that 100 miles an hour has been reached, and even exceeded; but this is a very different matter from the highest express running which is found really practicable. You will see on the speed chart, Fig. 3, a line indicating the average railway speeds of the fastest running (without stopping) for the fifteen

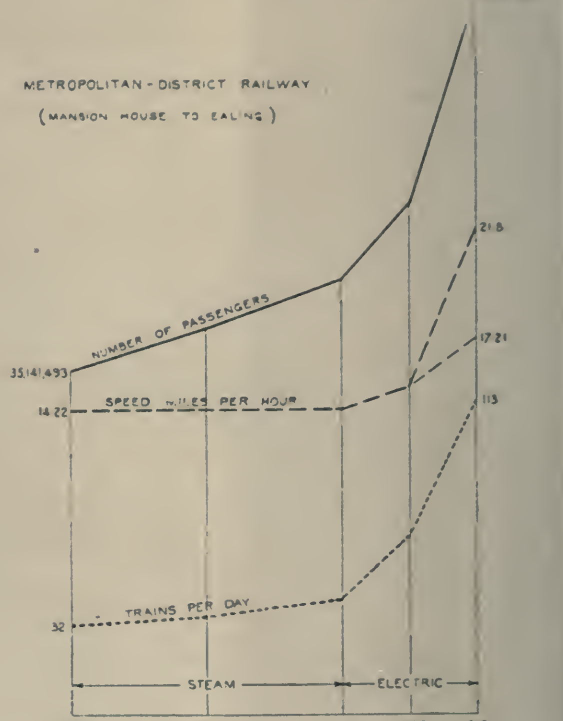

FIG. 5.

principal railways of the country. The average distance of the quick runs is 51·7 miles, and the average fastest running is 56·2 miles per hour. On either side of this line are the two fastest speeds, namely, 61½ miles per hour for 44¼ miles on the North-Eastern Railway from Darlington to York, and the lowest of these is 51 miles an hour, over the 51 miles from Victoria to Brighton on the London, Brighton and South Coast Railway. This shows how little the high speeds of all the railways of this country differ from one another, and indicates, at any rate for the present conditions, the highest speeds of travelling found suitable to our wants.

I will take as another illustration of actual travelling the case of suburban traffic; and we have only time for one example, namely, the traffic from the Mansion House to Ealing on the Metropolitan and District Railway, the details of which have been kindly provided by Mr. Blake, the superintendent of the line. Fig. 5 shows in graphical form the quickening in speed from the opening of the line in 1880 to the present time. You will notice that this increase of speed has been followed by remarkable results; the first immediate result is the possibility of a greater

number of trains, and the curve of the rise in the number of trains is shown on the diagram; but the really significant feature is the rise in the number of passengers carried, 35,000,000—72,000,000, which is the direct result of the increased facility in travelling. Now it is in such a case that the importance of the signalling and braking come to be almost pre-eminent, quite apart from the mere mechanical problem.

I may point out that the District Railway, in common with most other electric railways of this country, has what is known as a "track system of signalling," which, apart from the fact that the driver holds what is known as "the dead man's handle," which upon being released causes the train to stop, the train independently stops itself upon coming to a portion of the line not cleared by the previous train.

I have given you some examples that this country is not so far behind as we are so often told; and we have another in the fact that the District Railway has created a most beautiful system, by which the signalman is now absolutely independent of fog or darkness; he can see every train, or rather its picture, as it moves along the track in an illuminated diagram in front of him. No one could watch, as I have had the privilege of doing, the operation of this system in a signal-box without feeling certain that it must become universal in a very short time. You may like to see an actual panel from a signal-box and a view of what the interior is like with the signalman operating, instead of cumbrous levers, only a few small handles.

With regard to the question of vibration and oscillation, these are gradually being diminished as machinery is perfected, and you will see from the model illustration that

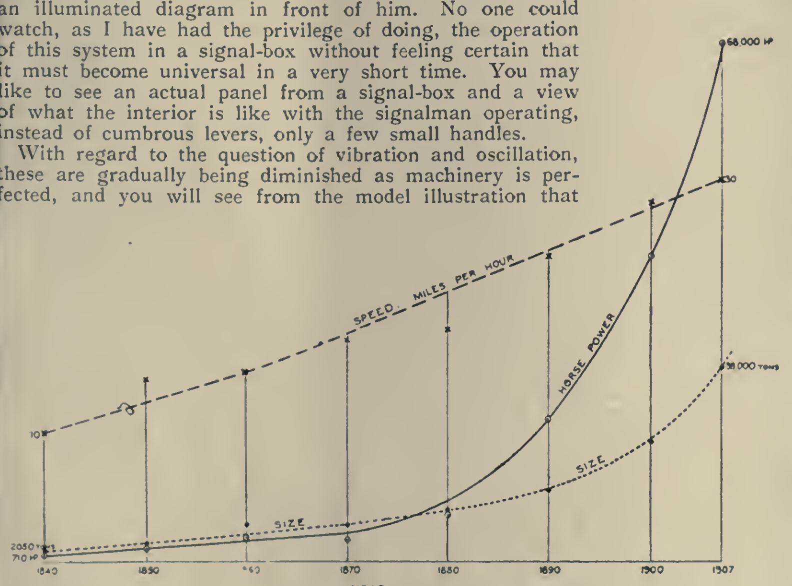

FIG. 6.—Progress in Atlantic Steamers (Cunard).

they are important, and may become very serious. They have, for instance, given Mr. Brennan much trouble in perfecting his wonderful mono-rail, with which we shall yet perhaps see every record broken; and you will remember Mr. Parsons' statement in this hall a week or two ago that an ounce out of balance on the Laval turbine represents an actual pull at the axle of no less than a ton.

There are many other features which I have not time to enter into. There is one, however, which I will briefly touch upon, as it is the secret of our safe railway travelling. I will illustrate the matter by an experiment in which a pair of wheels connected by an axle keyed firmly to both are made to run along a pair of rails. You will notice that the wheels are "coned" instead of having cylindrical rims, and it is easy to see that any movement sideways is at once corrected automatically, and within certain limits no rim at all is required for the flanges in order to keep the wheels upon the rails. The same model illustrates the important property of "super-elevation" applied to the outer rail of a curve. You will see, with proper super-elevation, the wheels run safely round this sharp curve even at a high speed. Time does not permit me to enter at any length on the question of development of power or the nature of resistance to motion. I will content myself with saying that, with regard to the former, we have already seen that the power of flight has been made possible by the invention of the small high-power internal-combustion engine, and it is to the same invention that the marvellous speeds obtained with small boats is due. We can scarcely realise what will be the result when the internal-combustion engine has been developed further for the purpose of locomotion. Our prospects of a further great advance in speed record-breaking appears to lie in this direction, and we already hear of a new car of 250 horse-power with which a speed of 140 miles per hour is confidently expected.

On water, as on land, our actual speed of travelling falls far below maximum speed records, and we do not commercially travel at much more than half the possible speed, as you see from Fig. 3, where the speed of the *Mauretania* is shown graphically. Fig. 6 is a chart of the progress of Atlantic shipping, taking the Cunard line as an example, and these curves indicate that the rate of increase of horse-power and tonnage is rising far faster than the rate of speed, and indicates how relatively highly the rate of power has increased for the gain of speed.

We have now passed briefly in review the nature of the problems which confront us in our continuous efforts to increase the safe and practical speeds of mechanical locomotion. We see that at the root of it all lies the question of artificial power and the harnessing in compact and convenient form the stored-up sources of energy in nature in order to overcome the opposing resistance, and we can realise that, although we have obviously reached the limits of animal locomotion, we are far from having reached any limitation in regard to the speed of self-propelled machines. We see that in all three forms of locomotion, earth, air, and water, the advance has been far more rapid during the last few years than ever before, and we can realise that there is yet a considerable margin by which speed of travelling could be increased as the demand for it is made; and nothing is more certain than that the demand will be made.

I began my lecture by pointing out why speed was instinctively taken as a test and a measure of locomotion from the earliest times. Shakespeare makes one of his characters say, "The spirit of the time shall teach me speed," but he might have said this of any period equally with that of King John, though never more so than of to-day, for the changes in the requirements of civilisation have only altered in detail, and speed is of as much importance as ever in the struggle of life. The probably unconscious recognition of this fact has always led question of speed to be raised as prime factors in proposals for new modes of locomotion, and it is interesting to look back only a comparatively few years to see, in raising these views, this was always the case, but how little any ideas of future possibilities were realised. When George Stevenson, backed up by a few courageous and enterprising men, was fighting the battle of the railway, and in particular trying to secure the passing of the Bill for improved communication between Liverpool and Manchester, the question of speed was the most important one raised; the opposing counsel, Mr. Harrison, spoke as follows:—"When we set out with the original prospectus, we were to gallop, I know not at what rate; I believe it was at the rate of 12 miles an hour. My learned friend, Mr. Adam, contemplated—possibly alluding to Ireland—that some of the Irish members would arrive in the waggons to a division. My learned friend says that they would go at the rate of 12 miles an hour (with the aid of the devil in the form of a locomotive, sitting as postilion on the fore horse, and an honourable member sitting behind him to stir up the fire, and keep it at full speed. But the speed at which these locomotive engines are to

go has slackened: Mr. Adam does not go faster now than 5 miles an hour. The learned serjeant (Spankie) says he should like to have 7, but he would be content to go 6. I will show he cannot go 6; and probably, for any practical purposes, I may be able to show that I can keep up with him *by the canal*. . . . Locomotive engines are liable to be operated upon by the weather. The wind will affect them; and any gale of wind which would affect the traffic on the Mersey would render it *impossible* to set off a locomotive engine either by poking the fire or keeping up the pressure of steam till the boiler was ready to burst." The committee, after hearing the arguments of Mr. Harrison, threw out the Bill for the Liverpool and Manchester Railway by a majority of 19 to 13. In order to realise that the above ideas were general, the following may be quoted from the great journal of the day, *The Quarterly*:—"What can be more palpably absurd and ridiculous than the prospect held out of locomotives travelling *twice as fast as stage coaches?* . . . . We trust that Parliament will, in all railways it may sanction, limit the speed to *eight or nine miles an hour*, which we entirely agree with Mr. Sylvester is as great as can be ventured on with safety."

Even in more recent times we see the struggle for the road locomotion question turned on one of speed, and the supporters of the new departure were unable to make any headway for many years, partly because the speed limit was put at between 3 and 4 miles an hour, that is, the limit of a walking man. A few years ago the speed of 12 miles an hour which, after a great struggle, was obtained, gave place to 20 miles an hour. You can see from the diagrams which Mr. Legros gave in a recent paper before the Institution of Mechanical Engineers, and which have been brought up to date, how the speedier self-propelled vehicle is leading to the disappearance of the horse, at any rate in London, and the difficulty which most people seem to feel is not how to get above the speed limit, but how to keep within it, and the papers show, by a daily crop of sad examples, how only too painfully easy it is not to do so.

Nothing points more clearly to what I have indicated as the basis of our instinctive desire for speed, as the fact that our measure of speed is entirely relative. Thus 60 miles an hour would be a slow speed for a motor-car on a racing track, as seen by the speeds of the motor races at Brooklands last Saturday (April 25th), but this speed, which would be even quite good along the open road to Brighton, would be considered decidedly on the high side for motoring along the Strand. Our ideas of what is slow and what is fast are largely derived from habit, and particularly from surrounding conditions and from our mode of estimation. For instance, we have been carried in this hall during the last hour with the surface of the earth round its axis a distance of about 600 miles. This speed would require a line on our speed chart about as high as the dome of the hall to represent it graphically. But if we judge the speed from observing the apparent rate of motion of the moon and stars overhead, we could never realise this. Far less could we realise by the change in the seasons the speed at which we are travelling with the earth round the sun, accomplishing a distance, as we do, of 540 million miles in 365 days, which represents, roughly, a distance of 60,000 miles per hour. We have thus travelled together, since we came into this hall, a speed of 60,000 miles. The line required on our chart for this speed would be about as high as St. Paul's Cathedral. But these speeds fall far short of those of certain heavenly bodies with which we are familiar, such as the meteors, some of which are travelling at 160,000 miles an hour, and the recent comet, which probably exceeded this speed one part of its journey round the sun; whereas the fastest speed which man has, up to the present, been able to produce, even in a projectile, amounts to between 2000 and 3000 miles an hour (the Krupp 10·7 centimetre having a velocity of 3291 metres per second, and a 6-inch Vickers, 3100 metres per second). The highest projectile speeds we have attained are thus only about one-tenth of the speed at which Jules Verne fired M. Barbicane and his friends off, in order to overcome the earth's gravity and reach the moon, since the speed he required was 12,000 yards per second, or 24,000 miles per hour. Such an idea we are quite justified in thinking absurd, but we might have been justified in thinking many of the things absurd which Jules Verne wrote about, only forty years ago, and which have since come to pass. Take "Round the World in Eighty Days." In that case it cost Phineas Fogg 19,000*l.* to take himself and his servant round the world in eighty days. A telephone inquiry of Messrs. Cook an hour or two ago elicited the fact that anyone present can start to-morrow morning and go round the world, with a servant, in less than half the above time, and for less than one-fiftieth of the above sum.

Thus though, impelled by instinct, man will ever continue to strive to increase his speeds of travelling, and with the refinement of machinery and invention doubtless succeed in doing so, it may be safely said that, notwithstanding the still increasing upward angle on some of the speed lines of the charts I have shown to-night, this rate of increase will before long begin to take place at a continually diminishing rate. Such feats as the journey from Paris to London within the hour may be regarded as quite a feasible engineering proposition in the future, though possibly a tube will be used for the purpose, without the employment of wheels, and with a modification of the pneumatic system of that great genius Brunell. We should, however, in doing this journey, be only travelling at half the rate we are actually moving at this spot round the earth's axis, while to do it at the rate we are travelling round the sun, we should only occupy a quarter of a minute. This latter speed, apart from the fact that it is getting very near the point at which meteors fuse with the friction of the earth's atmosphere, seems to be quite outside the limit of the possibilities of artificial locomotion by man, but who can tell how far we shall go towards it!

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—It is proposed to confer the degree of Doctor of Science, *honoris causa*, upon Dr. T. W. Richards, professor of chemistry in the University of Harvard.

On Thursday, May 11, a Grace will be offered to the Senate proposing that the Most Reverend St. C. G. A. Donaldson, D.D., of Trinity College, Lord Archbishop of Brisbane, be appointed as the representative of the University at the inaugural ceremony of the Queensland University to be held at Brisbane on June 1.

The special board for biology and geology has nominated Mr. E. S. Goodrich, fellow of Merton College, Oxford, to use the University table at Naples for one month.

Mr. A. R. Hinks will deliver a lecture on Monday, May 8, at 2.30 p.m., on "Recent Progress in the Measurement of the Earth."

On Friday, April 28, a meeting was held in Trinity College to consider the formation of a Cambridge University Eugenics Society to promote the study of heredity in its bearings on racial and social questions. The Dean of St. Paul's presided. It was resolved to form such a society, and the following officers were elected:—*President*, Prof. Seward, F.R.S.; *council*, the Rev. the President of Queens', Mr. Horace Darwin, Prof. Punnett, Mr. L. Doncaster, Mr. W. C. D. Whetham, Mr. J. M. Keynes, Mr. R. A. Fisher, Mr. C. S. Stock, Mr. R. W. Pyne, Mr. G. K. M. MacMullan, and Mr. E. P. Stapleton

OXFORD.—The Halley Lecture for 1911 will be delivered in the examination schools on Monday, May 22, at 8.30 p.m., by Prof. H. H. Turner, F.R.S., the Savilian professor of astronomy. Subject:—"The Movements of the Stars."

A COURSE of eight lectures will be delivered by Dr. W. M. Bayliss, F.R.S., on "The Mechanism of Oxidation in Plants and Animals," at University College, on Fridays at 4.30 p.m., beginning on May 5. These lectures are open free to all internal students of the University of London and to such other persons as are specially admitted.

DR. H. N. ALCOCK has been appointed to the chair of physiology in McGill University, Montreal, Canada. Dr. Alcock holds at present the post of lecturer on physiology

to the St. Mary's Hospital Medical School, and is also examiner in physiology to the Royal College of Physicians and to the National University of Ireland. He has published numerous papers on physiological subjects, and is the joint author of a text-book of experimental physiology.

MR. IVOR BACK, assistant surgeon to St. George's Hospital, lecturer on and teacher of operative surgery in the Medical School, St. George's Hospital, and Prof. D. H. Macgregor, professor of economics in the University of Leeds, have been elected to A.K. travelling fellowships. Mr. E. A. Benions, fellow and lecturer of St. John's College, Cambridge, has been elected to the fellowship rendered vacant by the resignation of Prof. I. Gollancz in December last.

THE Berlin correspondent of *The Morning Post* states that the Senate of the City of Hamburg has passed a resolution recommending that the Colonial Institute established there some years ago to train men for the Colonial Service shall be developed into an independent institution. This is regarded as the first official step in the movement to found a university in Hamburg. The city already devotes 100,000*l.* annually towards the cost of its scientific institutions, and the project evidently is to merge the latter into one university, though this word is as yet avoided.

PROF. H. E. ARMSTRONG's old students at the Central Technical College have arranged to mark their appreciation of the services he has rendered to science, industry, and education for upwards of a quarter of a century, by entertaining him at a banquet to be held at the Hotel Cecil, at 7 p.m. on Saturday, May 13. It has further been suggested that either an illuminated address or an album signed by his old students should be presented to him as a memento of the occasion. The gathering promises to be an unusually large one, and will include many of Prof. Armstrong's friends as well as old students. The chairman of the committee is Prof. W. J. Pope, F.R.S., and the vice-chairman, Mr. Maurice Solomon. Applications for tickets should be sent to one of the honorary secretaries, Mr. F. F. Renwick, Norland House, Avenue Road, Brentwood, Essex, or Mr. G. W. Tripp, 58 Little Heath, Charlton, Kent.

IT is stated in *The Pioneer Mail* that efforts are being made by the promoters of the proposed University of India and the Hindu University to amalgamate the two schemes and to work jointly rather than separately. The suggestion is that the University should be known as the University of Benares. In the beginning the University would only be an examining body like the Government universities in India, but the promoters trust that it will later on become a teaching body, and so fulfil the true ideal of university life. It is estimated that with the amalgamation of the two proposed universities the total funds available would come to 50 lakhs. It is further suggested that the King should be asked to lay the foundation of the Muslim University and the University of Benares after the Delhi Durbar.

ATTENTION has been directed already in these columns to the movement which has been inaugurated to secure the more efficient education of Europeans and Eurasians in India. An influentially signed appeal to the people of this country for a fund for this object of not less than 250,000*l.* appeared in *The Times* of May 1. An All-India Committee, representing the schools for Europeans and Eurasians established in India by the various religious organisations, has been formed, and it proposes with the fund to be raised:—(i.) to provide adequate salaries for teachers; (ii.) to increase the number of qualified teachers; (iii.) to provide facilities in India for training teachers; (iv.) to bring out qualified teachers to India until the training colleges to be founded shall have made such a course unnecessary; (v.) to provide opportunities for university education for promising students; (vi.) to improve the curricula of existing schools, especially in respect of science and manual training; (vii.) to found scholarships to assist deserving students at different stages of their education. A gift of 50,000*l.* has been received, and another gift of 5000*l.* has been contributed to the general fund in England. Further contributions may be sent to Sir Capel Wolseley, Bt., 157, 158, St. Stephen's House, Westminster, S.W., hon. treasurer of the fund.

ON April 5 the Governor of Bombay, Sir G. Clarke, laid the foundation-stone of the Central Science Institute and the Cowasjee Jehangir Hall in Bombay. In the course of his address, which was reported in *The Pioneer Mail*, the Governor said the mill owner and merchant want men accustomed to accurate thinking and capable of bringing practical consideration to bear upon realities. To both, the possessor of literary culture imperfectly assimilated is of no value, as he lacks some essential qualifications even if his literary attainments were more solid. Both look forward to the developments of the natural resources of India and the consequent creation of industries which await the diffusion of practical science among Indians. The example of Japan is frequently held up to the people of India, but the moral is not grasped. The Japanese instinctively absorbed western science and proceeded to turn it to account, and as soon as they could stand alone they showed that they could rival their European instructors in carrying on scientific progress. In India, scientific habit of thought is rare. Even in Bombay, where malaria could easily be stamped out, the proved results of harbouring the mosquito have not sufficed to carry conviction in many cases, and the spread of infection continues. Direct and indirect need of scientific training face the people of India at every turn. A patient investigator is required who will solve for India problems upon which great industries depend, problems many of which are purely Indian. A constructive power is wanted which depends upon training, that deals with forces and with facts, not with abstract speculation. The need is felt every day of the full recognition of the reign of law in the natural world and of the inexorable relations between cause and effect now widely ignored. An antidote to mere book learning is wanted, a faculty which can concentrate itself upon the practical side of the questions of the day and can discern fallacies of rhetoric, preferring action to talk and practical achievement to visions. All this and much more can be conferred upon India only by sound scientific training widely diffused.

SOCIETIES AND ACADEMIES.

LONDON.

Mathematical Society, April 27.—Dr. H. F. Baker president, in the chair.—Lieut.-Colonel A. **Cunningham**: The number of primes of given linear forms.—H. **Hilton**: The properties of certain linear homogeneous substitutions.—W. P. **Milne**: A symmetrical method of generating cubic curves by apolar pencils.—Prof. M. J. M. **Hill**: The proofs of the properties of Riemann's surfaces discovered by Lüroth and Clebsch.—G. N. **Watson**: The solution of the homogeneous linear difference equation of the second order (second paper).—G. B. **Mathews**: A cartesian theory of complex geometrical elements of space.

Zoological Society, April 25.—Dr. S. F. Harmer, F.R.S, vice-president, in the chair.—Dr. W. **Nicoll**: Three new trematodes from reptiles, from material received from the society's prosectorium. The specimens were interesting as forming an important addition to our knowledge of the large variety of forms which inhabited the air-passages and anterior coil of the alimentary canal of reptiles and batrachians.—Dr. R. T. **Leiper**: Some parasitic nematodes from Tropical Africa. The author gave a brief description of a number of new genera. The paper was based on helminthic material he had collected during a visit to East Africa, Uganda, and the Sudan in 1907, and on material sent to him by members of the Colonial Medical Service.—Oldfield **Thomas**: Mammals collected in southern Shen-si, central China, by Mr. Malcolm Anderson, for the Duke of Bedford's exploration of eastern Asia. The region explored was in the Great Pe-ling (or Tsin-ling) range, that divides northern from southern China, many of the specimens coming from the sacred mountain Tai-pei-san, where several of the most interesting forms were obtained. Of these, by far the most striking was a new species of takin (Budorcas), readily distinguishable by its uniform golden buffy colour from the Sze-chuen species (*B. tibetanus*). In the adult of this fine animal the coloration was wholly buffy, the darkening of the ears, dorsal line, hinder back and limbs found in

B. tibetanus being absent, and there was scarcely a trace even of the dark facial patch so prominent in that animal. The new species was proposed to be called *Budorcas bedfordi*, and female No. 2190 was selected as the type. In all, the collection contained 160 specimens, referable to thirty species.

PARIS.

Academy of Sciences, April 18.—M. Armand Gautier in the chair.—The president announced the death of Jean Bosscha, correspondant in the section of physics.—Ph. **van Tieghem**: The place of the Triuraceæ in the class of Monocotyledons. The author is of opinion that this order should be suppressed, reducing the class of the Monocotyledons to two orders only.—Paul **Sabatier** and A. **Mailhe**: The catalytic esterification of the alcohols by the fatty acids: the case of formic acid. Titanium oxide is preferable to thorium oxide as a catalytic agent when working at lower temperatures, such as are required when formic acid is used. With this oxide the esterification limit of 65 per cent. is reached at 150° C., an excess of the alcohol being employed.—C. **Bratu**: The exponential integral equation.—Maurice **Fréchet**: The notion of the differential.—M. **d'Ocagne**: A nomogram for the determination of the spaces described as a function of the time whilst a ship passes from a velocity V_0 to velocity V_1.—H. **Laroso**: The problem of the cable limited in two directions.—M. **Dussaud**: New uses for low voltage bulbs. Sixteen lamps (10 volts, 1 ampere) are fixed on a rotating disc in such a manner that each lamp receives 20 volts and 1·5 ampere during a fraction of a second. With the expenditure of 30 watts a light apparently steady is obtained equivalent to 10,000 candles, or the same light as an arc consuming 6000 watts.—Guillaume **de Fontenay**: The photographic reproduction of documents by reflection.—L. **Moreau** and E. **Vinet**: The elimination of lead arsenate from grapes in the process of wine-making.—Em. **Bourquelot** and M. **Bridel**: The action of invertin on the polysaccharides derived from levulose.—P. **Sisley** and Ch. **Porcher**: The elimination of colouring matters from the animal organism. All the observations lead to the conclusion that the microbial flora takes part in the chemical processes of reduction of the azoic colouring matters.—Hermann **von Ihering**: The history of the terrestrial fauna of the Brazilian forests.—Armand **Renier**: The discovery in the Belgian Westphalian of imprints of *Calamostachys Ludwigi*.—François **Favre**: The relation between the partitions of *Oppelia* Lias.

DIARY OF SOCIETIES.

THURSDAY, MAY 4.

ROYAL SOCIETY, at 4, Election of Fellows; at 4.30.—Motor Localisation in the Brain of the Gibbon correlated with a Histological Examination: Dr. F. W. Mott, F.R.S., Dr. E. Schuster, and Prof. C. S. Sherrington, F.R.S.—Some Phenomena of Regeneration in Sycon, with a Note on the Structure of its Collar-cells: J. S. Huxley.—Cancerous Ancestry and the Incidence of Cancer in Mice: Dr. J. A. Murray.—Immunisation by means of Bacterial Endotoxins: Dr. R. T. Hewlett.—On a Method of Disintegrating Bacterial and other Organic Cells: J. E. Barnard and Dr. R. T. Hewlett.

ROYAL INSTITUTION, at 3.—The Optical Properties of Metallic Vapours: Prof. R. W. Wood.

LINNEAN SOCIETY, at 8.—On John Vaughan Thompson and his Polyzoa, and on Vaunthompsonia, a Genus of Sympoda: Rev. T. R. R. Stebbing, F.R.S.—On Polytrema and some Allied Genera: Prof. Sidney J. Hickson, F.R.S.—Observations on some New and Little-known British Rhizopods: J. M. Brown.—The British Museum Collection of Blattidæ enclosed in Amber: R. Shelford.—Freshwater Algæ collected in the South Orkneys by Mr. R. N. R. Brown: Dr. F. E. Fritsch.

RÖNTGEN SOCIETY, at 8.15.—The Use of Radium in Malignant Growths: C. W. Mansell Moullin.—Rapid Radiography: Ed. S. Worrall.

FRIDAY, MAY 5.

ROYAL INSTITUTION, at 9.—New Organic Compounds of Nitrogen: Prof. M. O. Forster, F.R.S.

GEOLOGISTS' ASSOCIATION, at 8.—The Special Features of Alpine Scenery and the part played by Ice in their Origin: Prof. E. J. Garwood.

MONDAY, MAY 8.

ROYAL SOCIETY OF ARTS, at 8.—Rock Crystal: its Structure and Uses (Lecture II.): Dr. A. E. H. Tutton, F.R.S.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Foundation and Development of British Guiana from Unpublished Documents: J. A. J. de Villiers.

VICTORIA INSTITUTE, at 4.30.—A Life's Contribution to the Harmony of Christianity, Philosophy, and Science: Prof. F. F. Roget.

TUESDAY, MAY 9.

ROYAL INSTITUTION at 3.—The Institute of France: J. E. C. Bodley.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Some Saxon Bones from Folkestone: F. G. Parsons.—Further Notes on French Dolmens: A. L. Lewis.

ZOOLOGICAL SOCIETY, at 8.30.—On the Palatability of some British Insects. (Experiments made in the Society's Gardens with Arthropods (chiefly Insects) and Molluscs, and Notes on the significance of Mimetic resemblances): R. I. Pocock.—Contributions to the Morphology of the Group Neritoidea of Aspidobranch Gastropods. Part II. The Helicinidæ: Prof. G. C. Bourne, F.R.S.—On the Distribution in the Pacific of the Avian Family Megapodidæ: J. J. Lister, F.R.S.

WEDNESDAY, MAY 10.

ROYAL SOCIETY OF ARTS, at 8.—Beet Sugar Factories: Hal Williams.

GEOLOGICAL SOCIETY, at 8.—The Lower Carboniferous Succession in the North-west of England: Prof. E. J. Garwood.—Palæontological and Lithological Sequence in the Lower Carboniferous of Burrington Combe: Prof. S. H. Reynolds and Dr. A. Vaughan.

THURSDAY, MAY 11.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: On a Method of making Visible the Paths of Ionising Particles through a Gas: C. T. R. Wilson, F.R.S.—The Vertical Temperature Distribution in the Atmosphere over England, and some remarks on the General and Local Circulation: W. H. Dines, F.R.S.—On some Mineral Constituents of a Dusty Atmosphere: Prof. W. N. Hartley, F.R.S.—The Path of an Electron in Combined Radial Magnetic and Electric Fields: Dr. H. S. Allen.—On the Absolute Measurement of Light—a Proposal for an Ultimate Light Standard: Dr. R. A. Houston.—On Harmonic Expansions: Prof. A. C. Dixon, F.R.S.

ROYAL INSTITUTION, at 3.—The Optical Properties of Metallic Vapours: Prof. R. W. Wood.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Driving of Winding Engines by Induction Motors: H. J. S. Heather.

MATHEMATICAL SOCIETY, at 5.30.—Exhibition of a Model of a Deformable Octahedron: G. T. Bennett.—The Scattering of Light by a Large Conducting Sphere (Second Paper): J. W. Nicholson.

FRIDAY, MAY 12.

ROYAL INSTITUTION, at 9—Biology and the Kinematograph: Prof. W. Stirling.

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.—Some Remarks on the Nomenclature of the Veneridæ: Dr. W. H. Dall.—Description of a New Species of Conus from South Africa: G. B. Sowerby.—A Modification in the Form of a Shell (*Siphonaria Algesiræ*) apparently due to Locality: Rev. A. H. Cooke.

PHYSICAL SOCIETY, at 8.—Stream Lines Past the Elliptic Cylinder and Magnetic Interpretation: Sir George Greenhill and Col. R. E. Hippisley.—The Method of Constant Rate of Change of Flux as a Standard for Determining Magnetisation Curves of Iron: J. T. Morris and T. H. Langford.—Demonstration of an Electric Thermo Regulator: Prof. H. L. Callendar.

CONTENTS.

THURSDAY, MAY 11, 1911.

THE RADIUM TREATMENT OF DISEASE.

Radium: its Physics and Therapeutics. By Dr. D. Turner. Pp. x+86. (London: Baillière, Tindall, and Cox, 1911.) Price 5*s.* net.

THIS is a small manual suitable for medical men, giving in a concise form an account of the physical phenomena of radio-activity and the therapeutic uses of radium. For the physical part of the book the writings of Profs. Rutherford and Soddy have been largely used, and for the therapeutic chapters reference has been made to the works of Drs. Wickham, Degrais, and Dominici. In addition, the author records his own observations founded upon a five years' experience of the use of radium as a therapeutic agent. The book is illustrated by a number of plates, including portraits of Prof. and Mme. Curie as frontispiece, and portraits showing various diseases before and after treatment by radium. These include rodent ulcer, nævus, port-wine stain, warts, papilloma, and spring catarrh of the eye.

The opening chapters deal with the physics of radium. They give a concise account of the conclusions to which physicists have come—without discussion. The characteristic effects of radio-activity are enumerated, including the power of affecting photographic plates, of producing fluorescence, of ionising the air, of producing heat and various chemical changes. The alpha, beta, and gamma rays are described, the beta and gamma rays being compared with the kathode and X-rays. In dealing with the nature of the gamma rays, the author writes as follows:—

"The nature of the gamma ray is disputed; at first considered, owing to their magnetic non-deflectibility, to be a pulse or wave motion in the ether, there are now philosophers who regard them as discrete particles, but electrically neutral (positive and negative united). The question, then, is not settled. At any rate, the gamma rays are always found in company with the beta, much as the kathode ray and X-ray go together. If the gamma ray is proved to be a particle instead of a wave motion, we may have to revise our views as to the nature of the X-ray."

The author might have gone further and said that we *shall* have to revise our views as to the nature of the X-ray, for the arguments in favour of regarding gamma rays as material particles refer even more forcibly to the X-rays. The methods of containing radium for therapeutic application are of great importance, the pure salt being so valuable (1 mg. at present costing 18*l.*) that the greatest care must be taken to prevent loss. An impure salt is usually employed, being mixed with barium salts, from which it is very difficult to separate. The bromide and chloride are hygroscopic and soluble, and must be kept in an air-tight receptacle. The radium is contained, for therapeutic purposes, either in (*a*) sealed glass tubes, (*b*) ebonite capsules, or (*c*) mixed with varnish and spread out on pieces of cloth or metal.

The alpha particles are so readily absorbed that they are not available for treatment by any of these methods, even the layer of varnish in the method (*c*) being sufficient to stop the alpha particles. For the treatment of superficial conditions the more readily absorbed soft beta rays are used, a comparatively short exposure being given. For a subcutaneous condition, where the skin is to be spared, a screen of aluminium of ½ mm. thickness, or a silver screen of one-fifth of a millimetre is interposed, and a longer exposure given. For deeply-seated diseases a lead screen, varying in thickness from one-fifth to one millimetre, is interposed, and a prolonged exposure is given. In this case only the hard beta and the gamma rays will get through. When these metallic screens are used, account must be taken of the fact that the metals give out secondary rays, and that these might conceivably injure the skin. For this reason it is recommended that when a metal screen be used, a thin envelope of some non-metallic substance be placed next to the skin to cut off the secondary rays.

Radium emanation has been used therapeutically in various ways by inhalation, injection, in baths, and medicinally. Some natural waters are radio-active (Wiesbaden, Bath, &c.), and their efficacy may be in part due to this. Possibly the greater efficacy of mineral waters taken at their source, as compared with the same waters bottled and taken at home, may be explained by the decay of their radio-activity. The author refers to the present writer's method of using radium emanation enclosed in glass tubes; he points out that this use of the emanation is not, properly speaking, a use of the emanation itself, but only of its rays and of those of the active deposit, for none of the emanation can escape. It is not in any sense comparable to the use of the emanation by injection or other introduction directly into contact with the tissues. In the latter case the emanation tends to diffuse itself throughout the tissues. Wickham and Degrais have made extensive use of water rendered radio-active or actually containing dissolved radium bromide, and of emulsions of insoluble salts of radium in paraffin and vaseline for injection into tumours or beneath them, with the object of preventing their spreading deeply. Various properties of the emanation when used in any of these manners have been described. Thus it is said to increase the activity of digestive and other ferments of the body, to possess specific powers of dissolving urates; ferments which form and destroy uric acid being rendered more active by its use.

The efficacy of radium treatment is said to depend primarily on a selective destructive power, and it has been universally recognised that the rays possessing this selective action are the gamma rays and the hard beta rays, while the alpha particles are said to be universally destructive, destroying both the healthy and the diseased tissues. In the case of radium emanation or radio-active solutions, the whole of the radiation is available, and since the energy of the alpha particles is more than one hundred times as great as that of the beta and gamma together, it is clear that we are dealing here almost entirely with alpha radiation, for the effect of the beta and gamma radiation is relatively so small as to be negligible. No account is taken of this in the present book, but it

is surely of great importance; and if the special actions ascribed to radio-active solutions circulating in the body be borne out by future investigators, it is certain that we shall have to revise our assumption of the universal destructive action of the alpha particles. If we are able to do so, we may well find radium to be a far more valuable therapeutic agent than we have hitherto suspected.

After dealing with the treatment of non-malignant diseases, and with rodent ulcers which are locally malignant and yield readily to the action of radium, the true malignant growths are discussed, and a number of cases described in detail. Temporary benefit is experienced in a large proportion of the cases, the tumours become smaller, while the patient is relieved of much pain. A cure is occasionally obtained, but every case of malignant tumour that can be dealt with by the surgeon should be extirpated. Subsequent treatment with radium may be of the greatest value in destroying any cancerous cells that have escaped removal by the surgeon, and so the recurrence of the disease may be prevented.

Various rheumatic conditions have been treated with some success by radio-active earths. Comparing radium treatment with treatment by Röntgen rays, the chief difference is that the gamma rays of radium are far more penetrating than the X-rays, their effects being manifest on the tissues at a depth ten times as great as that of X-rays. Hence they are to be preferred for deep-seated affections. Radium rays are perfectly "constant" in quantity and quality, whereas X-rays are constantly varying in both these attributes. Hence a dose of radium rays can be measured with a precision that is wanting in the case of X-rays. Radium can be placed in natural cavities or buried in tumours, and left for an indefinite period, giving off its radiation all the time. The quality of the scars left after radium treatment is usually exceedingly good, and is certainly better, as a rule, than the scars left after X-ray treatment. Radium, again, is readily portable from patient to patient. The chief disadvantage of the use of radium is its extremely high price and the consequent risk of loss by breakage or accident. The chief advantage of X-rays over radium is the large area to which the X-rays can be applied.

In reviewing the present state of our knowledge of the therapeutic effects of radium, the feeling reached is that we are making our applications empirically in the hope of lighting, almost by accident, on some property of value in the cure of diseases which have hitherto baffled the physician's skill.

A. C. JORDAN.

ELEMENTARY ZOOLOGY.

An Introduction to Zoology. By Prof. R. W. Hegner. Pp. xii+350. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 8*s*. net.

THERE are some interesting distinctive features in this new introduction to zoology. Only a few types are studied (all of them Invertebrates); they are discussed so as to illustrate the principles of the science; the morphological aspect is not specially emphasised, but is coordinated with the physiological aspect (which, of course, includes the study of inter-relations and behaviour). From a mapping out of the subdivisions of the science (which admits of much improvement), the author passes to the characteristics of living organisms (where the autonomy of biology seems too easily surrendered to the mechanists), thence to the cell, and to the Protozoa. After an introduction to the Metazoa, which makes the significance of the transition admirably clear and introduces some exceedingly useful original diagrams, the book goes on to Hydra and other Cœlenterates, Unsegmented Worms, the Earthworn and Annelids, the Crayfish and Arthropods, the Honey Bee (which is admirably treated), and bees in general. Then follows a chapter on the history of zoology (entitled "Historical Zoology"), and the book ends with a terse consideration of the factors in evolution and related questions. There is a very useful bibliography, and a glossary.

The author shows a keen educative instinct (though the pemmican of the chapter on evolution is questionable); there is a marked freshness and individuality of treatment, and the assistance of a number of experts, who have read particular chapters, has secured an enviable freedom from mistakes.

Having expressed our admiration of the outlook and workmanship of Prof. Hegner's book, we may direct attention to what appear to us to be blemishes. (*a*) Since no complete physico-chemical re-description of any vital activity has as yet been given, it seems to us a great pity to give young students a prejudice in favour of mechanistic theories. (*b*) Being indifferent to the curricula of American Universities, we cannot reconcile ourselves to an introduction to zoology which practically (and advisedly, of course) ignores the Vertebrates. Especially in a book which is so praiseworthy in its recognition of the animal mind, kept by most "zoologies" at a distance, does it not seem a pity not to have included some Vertebrate with a "big brain" if only to contrast it with the bee's, which is on a different evolution tack altogether? (*c*) It is probably beyond the reach of human endeavour to write a text-book of zoology without mistakes, and it is with a full and lively sense of our own fallibility that we ask Prof. Hegner to justify his statement that an anus is present in Ctenophora. We are not very sure about the cœlom of Nemathelminthes either, but "morphology is not specially emphasised" in this book. Besides, what have first-year students to do with cœloms? (*d*) In looking up the glossary to find what "evolution" meant, we found it was "a theory of development" (see p. 291). But this definition is obviously meant to be the counterpart of that of epigenesis which is given a few lines higher up, whereas p. 291 deals with evolution in the ordinary sense. In a definition given of heredity—a very doubtful one to our thinking—a reference is given to a work in which the definition cited was within inverted commas, and obviously not that of the author of the book referred to. But excepting (*a*) and (*b*) these are small blemishes in a work which it has been a pleasure to read, and which deserves a career of much usefulness.

FOREST FIRES.

Incendies en Forêt. By A. Jacquot. Translated by C. E. C. Fischer. Pp. xv+278. (Calcutta: Superintendent Government Printing, India, 1910.) Price 14 annas, or 1*s.* 3*d.*

THE title of this book, "Incendies en Forêt," is somewhat misleading, as it is in the main a general treatise on the valuation of forest property, and forest fires are only partially treated, in so far as their occurrence necessitates a correct mode of appraisement of the damages caused by them.

The first chapter deals with French law in relation to the punishment of incendiaries, and the legal duties of forest officers. Very little is said about the important subject of the prevention of forest fires. We learn, however, that in France fire is only dreaded in the pine forests of the Landes, and in the broad-leaved forests of districts like the Maures and Esterel, where an arid climate prevails. In Provence the compulsory preventive measures are the maintenance of open rides along the borders of the forest, and the clearing away of brushwood in belts four yards wide on each side of the roads and paths throughout the forest. In the Maures and Esterel, but not elsewhere, the railway companies are obliged by law to clear, at their own expense, belts ten to fifty yards wide on both sides of the permanent way. These fire-lines are too narrow to arrest the progress of fire, but serve as bases from which counter-fires can be started.

The bulk of the book deals with the valuation of forests at all ages and of all kinds, a difficult subject, treated carefully and with great detail. The author advocates what he styles the positive mode of valuation. The value of the land itself is estimated by comparison with similar land near at hand, and not by theoretical computations of its timber-producing capacity. The standing crop of merchantable trees is valued as they would be by a timber merchant, namely, by actual measurement of their volume and the price they would fetch in the local market. Young stock, of no actual sale value, is reckoned by discounting at the moment its estimated value at the time when it would be ripe for felling.

Many interesting facts and experiments are mentioned, especially with regard to thinning, which are worth the attention of British foresters. The author shows that thinnings properly executed in coppice—a practice never attempted in England—increase the final yield 50 per cent., and amply repay the small cost of the operation. He declaims against the dense stands of mature trees, which are common in high forests in Germany, alleging that these, although they show more stems, produce a less volume of timber. Thinning is much more drastic in French pine woods than in those of Germany. Pines are light-demanding trees, and heavy thinning secures to each individual the best conditions of light and nutrition, both height and girth increments being stimulated. Moreover, the thinnings yield a considerable revenue, often surpassing in value the final crop, and as this is available early, the rate of interest on the capital at stake is materially increased. Thinning is also necessary, where wind is dreaded, as it strengthens the root systems of the trees that are left. In Germany, it is usual to remove only the dead, decaying, and suppressed stems, whereas in France some of the dominant trees, though in full vigour, are removed. It is often believed that growth in height is stimulated by dense crops, whereas it has been proved by experiments that not only does thinning increase the diameter of the trees left standing, but it also increases their actual height, and improves the form of the stem, which becomes more cylindrical, with an enlarged canopy of foliage. The importance of dense woods at the outset is acknowledged by all, as by their shade the stems are cleaned of their branches, and timber free from knots is produced; but in the later stages of growth there is no doubt of the advantage of the system of judicious repeated thinnings. For oak and beech the effect is the same as for pine.

The disastrous effects of fire upon the soil of the forest is well illustrated by the author, who also enters at some length into the part played by the forest in lessening hailstorms in its vicinity, in improving farm crops by its shelter, and in preventing disastrous floods at a distance.

The book is remarkably cheap, only 1*s.* 3*d.*, and one cannot quarrel with the frequent misprints (*Cf.* p. 17, pendunculate for pedunculate, and holme for holm), and its occasional curious phraseology. It should be of great service in India, and can be read with profit by landowners and foresters in England. It is provided with eighteen pages of useful interest tables.

LIVING MATTER AND ITS FUNCTIONS.

The Evolution and Function of Living Purposive Matter. By N. C. Macnamara. (International Scientific Series.) Pp. xi+298. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1910.) Price 5*s.*

THE object of this book is to trace and explain the evolution of the functions of those elements of living matter which are essential for the manifestation of purposive, instinctive, and psychical phenomena. The book is divided into two parts; in the first the evidence is given which the author believes proves the gradual evolution of purposive action in protoplasm in the various classes of the animal kingdom, in the second the soundness of these conclusions is put to the test by giving in outline the leading characteristics displayed by the Irish Celts of County Clare—a long line of individuals who lived under conditions well adapted to show the power which their inherited qualities exercised on the actions of many successive generations and on the destinies of the race.

The author believes that protoplasm, even in the lowest living forms, exhibits characteristics which indicate the possession of purposive elements, and that these undergo evolution *pari passu* with those elements which constitute the structural parts of the organism. The author holds that even among the

Protozoa the response to stimuli exhibited by their protoplasm is not simply one of reaction to external stimuli, but is of such a nature that a *purposive* function seems to be postulated, and that protoplasm, even in very lowly forms, as undoubtedly is the case in higher ones, is able to store impressions—possesses, in fact, the rudiments of a memory. From the undifferentiated condition, the next step forward is the development of a rudimentary nervous system, such as occurs in the sponges, then the development of well-marked nervous tissue, its aggregation into ganglionic masses, and eventually the formation of a definite though simple nervous system is traced through the invertebrates, and, finally, the progressive evolution of a nervous system through the vertebrates, culminating in man with his elaborate psychical processes.

Although some would hold that the response of protoplasm to external stimuli is simply one of reaction, we think that the author's view of purposive action in addition is borne out by the facts cited, and that this is inherent in protoplasm, just as the tendency to variation appears to be. With regard to the second part of the book, we are not in a position to criticise its historical accuracy, but it makes interesting reading. The emotional and instinctive qualities displayed by the Irish Celts depends, according to the author, on their hereditary characters rather than on experience and on intellectual acquirements. The book is pleasant and instructive reading, and though here and there not altogether free from error, on the whole is a simple and well-developed exposition of the subject of which it treats.

ANIMAL PSYCHOLOGY.

(1) *L'Evolution de la Mémoire.* By Henri Piéron. Pp. 360. (Paris: Ernest Flammarion, 1910.) Price 3.50 francs.

(2) *Vorlesungen über Tierpsychologie.* By Prof. Karl Camillo Schneider. Pp. xii+310. (Leipzig: W. Engelmann, 1909.) Price 8 marks.

(1) M. PIÉRON'S book is a new addition to that excellent and deservedly famous series, the "Bibliothèque de Philosophie scientifique," and is quite worthy of its place. Its subject is, to say the least, a difficult one, being dependent on the careful interpretation of vast quantities of scattered observations and researches made by students of comparative psychology during quite recent years; but M. Piéron has produced out of this material, some of which is furnished by researches of his own, a volume which is not only compact and thoroughly sound, but also readable.

In an excellent introduction, he criticises certain definitions of memory that have been held in the past, and shows by the help of numerous and interesting examples the continuity, the complete lack of hiatus, in the succession of phenomena commencing with the inorganic memory shown in viscosity, hysteresis, &c., through biological memory, heredity, adaptation, &c., to psychological memory, which is frequently alone allowed the designation memory. The presence of consciousness in psychological memory is important, but not of that essential significance which the more metaphysically-minded among the psychologists are so fond of attributing to it. This is quite clearly shown in researches on the memorising of nonsense syllables (Ebbinghaus) where the curve representing the number of repetitions necessary for completely learning series of varying lengths is found to belong to the same type, to have the same mathematical equation, as that representing monomolecular autocatalytic reactions in chemistry, viz., $\log x = Kt + b$.

The contrast, in fact, is not between subhuman and human memory, but one between memory as it is for the individual himself as he enjoys it in consciousness, and memory as it manifests itself objectively both in himself and in his fellow-man.

The author proceeds to consider the phenomena more in detail, commencing with an interesting description of the "persistances rythmiques" displayed by both plants and animals. In the case of the latter, the best examples are given by marine animals, which live on the seashore and reproduce in their organic functions the rhythm of the tides. The rhythm persists when the animals are removed to a new, non-rhythmical environment, although an observer has found that this is not the case with young individuals that have not experienced the tidal rhythm. Piéron has some interesting comments and criticisms to make on the whole problem.

There follows a clear and concise account of the modern experimental methods of research employed to investigate the processes of adaptation and the formation of habits in animals, and the important researches of Thorndike, Hobhouse, Yerkes, and others are usefully summarised. A chapter on "sensory memory," full of experimentally determined results, completes the part of the volume allotted to subhuman psychology.

The last hundred pages of the book deal with specifically human memory, and summarise in small space an enormous number of experimental investigations. The author points out that the laws of rate of learning and forgetting admit of identical mathematical expression for animals and for men, for the different forms of sensorial and motor memory, &c. The curves correspond to the same general mathematical formula, viz., $y = A/K - B^x$. The non-correspondence of memory and intelligence is noted, and pathological modifications are adequately treated. With a useful chapter on the utilisation of memory, and a conclusion, written in more speculative mood, the book ends.

(2) Prof. Schneider gives in his series of published lectures a very full and decidedly original account of the subject-matter of animal psychology. Regarding the physiological mechanism of the nervous system as capable of producing summation of stimuli only, he finds himself forced to assume an active and efficient "Psyche" to explain most of the phenomena of his science. "Die Psyche assoziiert die einzelnen Eindrücke, die dabei ihre Selbständigheit wahren (Assoziationsorgan), während das Gehirn sie sum-

miert und dabei die einzelnen in ihrer Sondernatur vernichtet (Summationsorgan)" (p. 292). Final causes are postulated. "Ohne Berücksichtigung von Finalia ist ein Verständnis auch der einfachsten Amöbenhandlung unmöglich." His account of instinct, therefore, is through and through teleological. The ends pursued are not to be explained from experience, on one hand, nor are they explicable in terms of organisation as a product of evolution. They can only be accounted for in terms of an "Allgemeinbewusstsein," or "Weltvernunft," an absolute consciousness. Kant and Hartmann are referred to more than once, nor is Hegel omitted. Those men of science to whom metaphysics is anathema, and those (a class comprising much the same people) to whom it is a *terra incognita*, will reject much of the book as unsound. For others the book will be found full of suggestions and new points of view.

WILLIAM BROWN.

SCALE MOSSES.

The Liverworts, British and Foreign. By the Right Hon. Sir Edward Fry, G.C.B., with the assistance of Agnes Fry. Pp. viii+74. (London: Witherby and Co., 1911.) Price 2*s.* 6*d.* net.

IT is a pleasure to welcome the little volume on liverworts, to which scale mosses, as well as the more familiar Thallose forms, like Marchantia, belong. Sir Edward Fry has long been known as one who takes a keen interest in mosses, and this new little book on an allied group of plants will appeal to those amateurs who like to know something at first hand of the less easily studied objects of nature. In truth, the liverworts are fascinating plants, for they stand at the parting of the ways where the higher forms branch off from the lower series of primitive groups. They are, however, not easy to study, for they need a keen eye to detect them, and they are, many of them, very difficult to identify.

The authors have done good service in giving a popular and attractive account of the family. The variety of forms, no less than the suggestive differences in their organisation, pointing as it does towards higher vegetative development, will commend the group as a whole to the attention of many who may have avoided it on account of the difficulties which have to be surmounted in making a first acquaintance with the plants composing it.

When the book is critically examined there are not unnaturally points in which one may differ from the authors. The affinity between Calobryum and Monoclea is really artificial, and they are not generally regarded as closely related. Recent work indicates that the former is more naturally placed near Haplomitrium, whilst a considerable difference of opinion exists as regards Monoclea, some considering it as near the Marchantiaceæ, others as belonging to the Jungermanniaceæ in the wider sense.

As regards the origin of elaters, probably the Riccia-Corsinia series affords a better clue than the more specialised Anthocerotaceæ, but it may perhaps be argued that this is, after all, rather a matter of opinion than of proven conclusion. We feel inclined, however, to take exception to the comparison between the stomata of the grass-like sporophyte of Anthoceros and those of the thallus of Marchantia, which belongs to the other—the gametophyte—stage in the life-history. The similarity between the two organs is very slight, and although they perform the same function the mode of origin is quite different in the two cases.

But these are small matters in a book which is written for the amateur rather than for the professed botanist, though the latter will also find it worth reading. There are a few misprints which might be corrected—one of them, Trichcolea for Trichocolea, occurs several times—when a new edition is called for. In the meantime, we can congratulate the authors on having written an interesting little book on a difficult series of plants.

REFRACTORY MATERIALS AND PRODUCTS.

Fabrication et Emploi des Matériaux et Produits réfractaires utilisés dans l'Industrie. By Prof. A. Granger. Pp. iv+378. (Paris Ch. Béranger, 1910.) Price 15 francs.

THE scientific study of firebricks, furnace blocks, crucibles, and other refractory products is one of increasing importance. The progress of metallurgy, of glass-making, of pottery—even the development of the domestic firegrate—demands scientific, as opposed to rule-of-thumb, knowledge of refractory materials and how they may be best applied to the requirements of different industries. Although many excellent refractory products are made in these islands, the scientific study of the subject as a whole has received but little attention as compared with that given to it in Germany, France, and the United States. A few years ago Dr. J. W. Mellor, of the Pottery Laboratory at Stoke-upon-Trent, endeavoured to set up a committee for the study and standardisation of firebrick and refractory materials, and his work is now being carried on, we believe, by a committee of the Iron and Steel Institute, but it appears likely that some considerable time must elapse before we have an English text-book dealing with the subject as fully and as concisely as this French work.

Mr. Granger is well known as the professor of ceramic technology in the school attached to the State porcelain works at Sèvres, and in all his works one recognises the hand of the teacher who finds it necessary to compile a text-book for his students. This is at once the strength and weakness of such a volume. With the usual logical accuracy and perspicacity of a French writer, the author gives an excellent review of his subject. He treats of every variety of refractory material, fireclays, chromite, magnesia, and aluminous products, including the newest materials prepared for electric furnace work.

The book contains a series of excellent illustrations of the various forms of machinery especially adapted for the treatment of fireclays, &c., and the chapter on kilns and methods of firing, which are of extreme

importance in practical work, is excellent. The illustrations of gas-fired kilns, on pp. 81–4, should prove of great value to the English manufacturer, who, so far, has made little use of continental improvements in methods of firing.

The chapter dealing with pyrometry and pyroscopes is also well done, and the discussion of the value of the "Seger" cone is singularly clear and accurate.

We can cordially recommend the work to all who are interested, either as manufacturers or as users of refractory materials, and it would be a still greater pleasure to note the appearance of an English work as comprehensive in scope and plan.

WILLIAM BURTON.

BACTERIOLOGY: GENERAL AND SPECIAL.

(1) *Agricultural Bacteriology, Theoretical and Practical.* By Prof. John Percival. Pp. x+408. (London: Duckworth and Co., 1910.) Price 7s. 6d. net.

(2) *A Text-Book of General Bacteriology.* By Prof. W. J. Frost and Prof. E. F. McCampbell. Pp. xvii+340. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 7s. net.

(3) *Die Eisenbakterien.* By Prof. Hans Molisch. Pp. vi+83. (Jena: Gustav Fischer, 1910.) Price 5 marks.

(4) *The Sources and Modes of Infection.* By Dr. C. V. Chapin. Pp. ix+399. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1910.) Price 12s. 6d. net.

(1) WE have read this book with much interest. The plan of it is well conceived, and it will serve not only as a useful text-book on agricultural bacteriology, but also as an excellent introduction to general bacteriology for those who are non-medical and do not wish to specialise in the medical and pathological side of bacteriology.

In the opening chapters a general account is given of the bacteria, their physiology, morphology, and classification, and the methods employed in isolating, cultivating, and studying them. Fermentation and enzyme action are then briefly discussed, including putrefaction. Next an excellent account is given of the bacteriology of soil, of nitrification and denitrification, and of the fixation of nitrogen, and, finally, the bacteriology of manure, milk, cream, butter, and cheese is dealt with. Considerable space is rightly devoted to milk and milk products, and the subjects of the sources of bacteria in milk, the fermentations occurring in milk, the filtration, cooling, pasteurisation, and sterilisation of milk, milk and its relation to disease, milk standards, cream and cream ripening, the bacterial content, flavour, and defects of butter, and the ripening of cheese are adequately described. A final chapter is devoted to the yeasts and moulds. Throughout the book series of excellent practical exercises for the student to work out are attached to all the sections. A few errors appear which will need correcting in a future edition. The *B. lactis aërogenes* is described on p. 10 as Gram positive, on p. 275 it is correctly stated to be Gram negative; on pp. 46–7, dealing with the neutralisation of culture media, it is stated that most bacteria grow best when the medium contains 1 per cent. of free normal acid; this, however, is true only when phenolphthalein is used as an indicator, and such media are alkaline to litmus. On pp. 96–8 the term "proteose" has been substituted several times for "proteolytic enzyme," entirely obscuring the meaning, and on p. 116 "nitrogen peroxide" appears in place of "hydrogen peroxide." The book is clearly printed, and contains a number of appropriate and well-executed illustrations.

(2) The authors state that there is no work in English on the subject of general bacteriology with the exception of the translation of Fischer's "Vorlesungen," and have attempted to supply this want in the present volume. On the whole the matter is presented in a readable and accurate form. The preliminary chapters dealing with the history of bacteriology might have been somewhat extended with advantage, and the omission of any mention of Lister's work on the lactic fermentation seems unpardonable. The chapters summarising the structure and composition of the bacterial cell and the morphology and classification of the bacteria are excellent. The methods employed in bacteriology and the general physiology of the bacteria are detailed at some length, and in the final portion of the book the biology of specialised groups of bacteria are briefly described. We think the authors have succeeded in their endeavour, and have produced a book which will be of considerable service as a general introduction to bacteriology.

(3) This is a monograph on a group of micro-organisms of considerable biological and practical interest. A majority are thread-forming species, and differ essentially in this respect, and also in the fact that they form conidia, from the true bacteria. They live in waters containing iron and have the capacity of "attracting" the iron from its solution and of depositing it around them as ferric hydroxide, which stains them brownish-red in colour. Ultimately the organisms die, sink to the bottom of the water, and cause the reddish-brown colour so often seen at the bottom of streams and ponds. It has been suggested that some of the iron-ore deposits have been formed by the activity of "iron bacteria" living in the warm waters of an ancient sea. They also cause rusting of iron pipes and conduits and masses of their growth sometimes mechanically obstruct the flow of water in pipes. Prof. Molisch has collected in this monograph the descriptions of the known species; and with the attached bibliographies, illustrations, and plates, and details for their investigation, it forms a valuable survey of the group.

(4) Although this subject is dealt with in works on medicine, epidemiology, and bacteriology, and a special work on it might be considered superfluous, a perusal of its contents has convinced us that Dr. Chapin has compiled an extremely useful summary. The life of disease germs outside the body and the conveyance of infection by contact, fomites, air, food and drink, and insects, are fully considered. An im-

portant chapter deals with "carrier" cases, and considerable stress is laid on this mode of the spread of infective diseases. The limitations to the value of isolation for the prevention of the spread of infectious diseases are critically discussed, and the conclusion is reached that isolation is of far less value than was formerly believed. Bacterial and protozoal diseases are both dealt with, and full references are given to the literature.

R. T. H.

CHEMISTRY FOR MATRICULATION.

(1) *A Class-Book of Chemistry.* By G. C. Donington. Pp. xi+399. (London: Macmillan and Co., Ltd., 1911.) Price 3*s*. 6*d*.

(2) *Chemistry for Matriculation.* By Dr. G. H. Bailey and H. W. Bausor. Pp. viii+548. (London: W. B. Clive, 1910.) Price 5*s*. 6*d*.

(1) MR. DONINGTON'S volume is a very interesting attempt to combine a practical course on modern lines with a descriptive text-book. The arrangement of the matter is distinctly original and has been carefully thought out. Discussion of more abstract topics, such as the atomic theory, Avogadro's hypothesis and valency, is postponed to a late stage in the book, while no chemical formula appears until p. 283. The preference thus given to a more descriptive treatment of the science is all to the good in an introductory class-book of this kind. In the early chapters the author deals very appropriately with the physical operations and physical properties which are used in the purification and characterisation of individual substances, such as solution, crystallisation, distillation, determination of melting points and boiling points, measurement of volume and density of gases. The first topics of a definitely chemical nature to which the reader is introduced are "acids and alkalis," "neutralisation," "rusting" and "burning," "active and inactive constituents of air," "elements and compounds." It must not be supposed that this descriptive treatment involves the suppression of the quantitative aspect of chemical changes. On the contrary, the author contrives in the earlier part of the volume to introduce the pupil by the way to the fundamental quantitative facts of chemistry.

While the general arrangement of the subject-matter is excellent, it may be doubted whether the author attains his object of providing a basis for teaching by research methods. With this in view, each topic is, as far as possible, introduced by the suggestion of experiments to be carried out by the pupil, these leading up to the solution of various problems. The paragraphs, however, in which appropriate experiments are indicated are followed by an authoritative description of all the facts bearing on the question. Various experiments, for instance, relative to the nature and cause of iron rusting are suggested, and the results obtained are supposed to enable the pupil to answer such questions as "Does iron rust in dry air?" "Does water *only* cause iron to rust?" "Is the rusting of iron a chemical or a physical change?" The correct answers, however, are supplied in the descriptive paragraphs which follow, and it is plain that the replies given by the pupil under such conditions cannot be unprejudiced.

The selection of practical exercises is excellent, and the course has stood the test of actual experience. The illustrations include portraits of such pioneers as Priestley, Lavoisier, Davy, and Faraday.

A curious error is the spelling of Avogadro's name throughout as Avagadro.

(2) The second volume under review belongs to the "University Tutorial Series," and is based on Dr. Bailey's earlier work, "The New Matriculation Chemistry." The authors aim at a combination of the heuristic and didactic methods of teaching, and practical exercises for the pupil are accordingly interwoven with the text.

The book begins with an introductory course in which "special care has been devoted to the treatment of the Laws of Constant and Multiple Proportions, Avogadro's Hypothesis, and the meaning and use of Chemical Formulæ and Equations." There is much, however, in the discussion of these topics that is open to criticism. Thus, for instance, Avogadro's hypothesis is described on p. 141 as a "law," the word molecule is used in different senses without any explanation, atomic weights are tabulated and used before the idea of "equivalents" is introduced, and hydrogen is taken as the standard of atomic weights. According to the preface, the book aims at providing a course of fairly detailed study in chemistry, and yet no information is given as to practical methods of deducing atomic weights from equivalents; there is, for instance, no reference to Dulong and Petit's law.

The choice of practical exercises to be performed by the student is not always wise. Dropping a piece of sodium about the size of a pea into water, and demonstrating the low ignition point of benzoline, are experiments which in the hands of beginners might have unpleasant consequences, while such exercises as the preparation of ethylene and the conversion of yellow phosphorus into the red variety are not suitable for the matriculation student.

J. C. P.

OUR BOOK SHELF.

Trattato di Chimica Inorganica generale e applicata all' Industria. By Prof. E. Molinari. Terza edizione. Pp. xvii+924. (Milano: U. Hoepli, 1911.) Price 16 lire.

When the first edition of this work appeared in 1905 its many excellent and novel features were commended in the full review which was published in Nature of February 29 of that year. That these qualities were widely appreciated is shown by the fact that a second edition was called for within a year, and a third edition is now being issued. The present edition contains a very large amount of new matter, above 200 pages having been added to the text, fifty-six of which belong to the general introductory section, and deal with such subjects as mass-action, equilibrium, dissociation, and the phase rule. That the revision of the special section has kept pace with the march of modern industrial development is shown by the very thorough alterations which have been made

in the text, owing to the introduction of new processes, for example, under such headings as the manufacture of liquid carbon dioxide, steel, cements, superphosphates, the fixation of atmospheric nitrogen, &c.

The revision here has been thorough, and many new illustrations, mainly photographs, have been added. The older statistical data, which formed so novel a feature of an elementary treatise of this kind, have been brought up to date. It is pleasing to note that the few misstatements pointed out in the review of the first edition have been rectified. A few misprints of names still occur, *e.g.* Rooseboom for Roozeboom (p. 870), "Lothian, Bell," (as two names) for Lothian Bell (p. 876), Gulber for Guldberg (p. 127), but such misprints are more or less inevitable in view of the very large number of proper names employed, and is not a serious blemish. The work is undoubtedly written by one with a full knowledge of his subject, and will prove useful to a large public, especially to chemical students, engineers, or others interested in the later developments of inorganic chemical industry; in it theory and practice are admirably blended. W. A. D.

Dizionario di Merceologia e di Chimica applicata. by Prof. V. Villavecchia. Terza edizione. Vol. i., A–M. Pp. xii+1558. (Milan: U. Hoepli, 1911.) Price 15 lire.

THE present volume is the third edition of a dictionary of commercial articles, produced in all the various branches of applied chemistry—in the widest sense of the term—ranging from such natural products as minerals and metals, fruits and seeds, oils and fats, through all the branches of applied chemistry upward to the most refined chemical, pharmaceutical, and alimentary preparations. Each article represents a concise monograph on the subject of which it treats. In addition to the Italian synonyms, the French, German, English, and Spanish equivalents are given. Each monograph details the origin, the description, and preparation for the market of the article; it describes the commercial qualities, characters, properties, composition, the adulterants frequently found therein, the most characteristic tests for purity, and the uses of each article. Then follow statistical data, information about market values, and, finally, data concerning specifically Italian conditions, such as import duties and imposts, and references to the Italian pharmacopœia.

The reviewer has selected at random a number of subjects with which he is specially familiar, and has found the information concise, trustworthy, and ably presented. This work must perforce interest the Italian student in the first instance. The fact that the present volume of 1558 pages, from Abelmosco (musk seeds) to Mussena (Massena), appears in its third, much enlarged edition, testifies to its usefulness to the Italian reader.

Annual and Biennial Garden Plants: Their Value and Uses, with Full Instructions for their Cultivation. By A. E. Speer. Pp. xx+256. (London: John Murray, 1911.) Price 7*s.* 6*d.* net.

THERE appears to be no lull in the demand for books on gardening if one may judge from the voluminous output of this class of article. It would seem scarcely possible nowadays for anyone not to be able to grow flowers, so clear are the directions and particulars given in numerous manuals. The book before us deals entirely with annual and biennial plants in the form of a glorified nurseryman catalogue. By dedescribing it in this way, however, it is not sought to detract from the merits of the work, though it may be remarked in passing that the numerous illustrations, six of which are in colour, are so far inferior to those in the catalogues of our leading seedsmen that they might have been omitted with advantage.

The few pages of introduction give with admirable conciseness the essentials of garden craft for the particular class of plants of which the book treats. The rest of the book is a descriptive catalogue, arranged in alphabetical order, of the various species and varieties of annual and biennial garden plants. The author is to be congratulated on having given in nearly all cases the country of origin and date or introduction of the various plants mentioned, though in this connection the fact that *Tropaeolum minus* was introduced from Peru in 1596 might have been recorded, as it is one of the earliest known introductions to this country from South America. He is also careful to give the natural order of each plant and synonyms, as well as the derivation of the generic name in every case, so that for these features alone Mr. Speer's book deserves a place on the shelf of every garden-lover's library.

Full details as to the procedure to be adopted in the sowing of seeds and subsequent treatment of the seedlings are given at the end of the account of each genus.

Paints for Steel Structures. By Houston Lowe. Fifth edition, revised. Pp. 115. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1910.) Price 4*s.* 6*d.* net.

THIS is a new edition of Mr. Lowe's book, and gives a popular description of the present-day knowledge and experience as to the painting of iron and steel structures. The best method of painting such structures has been for some time attracting the attention of chemists and others in the United States, where a large amount of experimental work has been done, and some very curious and interesting results have been arrived at. Mr. Lowe is familiar with these various experimental tests, and has brought the results together in a convenient and popular form in his little book. There are, of course, a great many interesting chemical problems lying behind the question of the painting and rusting of iron and steel structures, which cannot yet be considered as having been solved, and therefore much that can be said in a book of this kind is tentative. On the other hand, the experience gained by experimental tests, although sometimes difficult to explain scientifically, is of value to the practical man, and guides him as to what it is best to do.

The book, therefore, can be recommended to architects and engineers who have to deal with the painting of iron and steel structures, as they will get a great deal of information in a simple form which will assist them in drawing up specifications for such purposes. A. P. L.

Chemistry of Food and Nutrition. By Prof. H. C. Sherman. Pp. viii+355. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1911.) Price 6*s.* 6*d.* net.

THIS is a useful book; it contains numerous data on the properties, composition, and calorific value of the principal articles of food, and an up-to-date description of the scientific principles on which a dietary is constructed, and how it can be adapted to the varying needs of the organism. The author has a clear way of putting his points, and has exercised much judiciousness in not overwhelming his readers with too many arguments on disputed points; he has carefully selected his authorities, and the quotations he cites are apt and sufficient. On the controversial subject of the amount of protein necessary for an adult in the day he carefully splits the difference between Voit and Chittenden, and places the amount at 75 grams. The book is well worth careful perusal. W. D. H.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Racial Problem in Nubia.

IT has been objected that the sketch of the history of Nubia given in the article on "The Unveiling of Nubia" in NATURE, April 27, p. 283, does not agree in every particular with the accounts given by Mr. Firth in the sixth Bulletin of the Archæological Survey of Nubia, p. 8, and by me at the Sheffield meeting of the British Association and in several lectures during the past year.

It must be remembered, however, that the notice in NATURE was a review of the published account of the results obtained by Dr. Reisner during the first season's work of the Archæological Survey, and it did not come within the scope of the reviewer's task to describe the attempts that have been made during the last three years to throw further light upon the significance of the facts set forth in Dr. Reisner's report.

It may prevent such misunderstanding, however, if a brief statement is made of the bearing of recent investigations upon the meaning of the facts brought to light in Nubia. It is not without significance that the archæologists, studying in Nubia the handiwork of the ancient people, and the anthropologists, as the result of the examination in England of the remains of the Nubians that have been sent over here, have arrived quite independently and without collusion at the same interpretation of the significance of the story the pottery and the bones respectively have to tell.

Mr. Cecil Firth's statement of the views of the archæologists will be found in the sixth Bulletin (*op. cit.*).

The working hypothesis that I set up last summer, when all the facts derived from the study of the human remains were being collated for the first time, is not only borne out by the archæological evidence, but has been found to be in full accordance with all the facts which further detailed study of these ancient Nubian remains has brought to light.

It is now quite clear that in pre-dynastic times there were scattered throughout the Nile Valley, not only in the territory we call Egypt, but also much farther south, many groups of people linked to the pre-dynastic Egyptians by the closest bonds of affinity, and also sharing with them a common cultural inheritance. Until the beginning of the period of the Pyramid-builders no difference can be detected either in the physical characters of the people or their achievements on the northern (Upper Egypt) or the southern (Lower Nubia) side of the First Cataract. But as the marshy territory of Egypt was drained, and the extent of its rich habitable land was thus increased ten-fold, there was a movement of population from the barren country above the First Cataract into the more fertile north.

But when the proto-dynastic Nubians emigrated into Egypt their place in Nubia was taken by the next member of the group of peoples that were scattered serially throughout the Nile Valley like beads on a string. As the result of the first season's work in Nubia, the only obvious explanation of the state of affairs revealed in these Nubian graves of the time of the Ancient Empire—the B-group of the archæologists—was found in the hypothesis that the original population of Nubia became tainted with negro blood and fell away from the high standard of culture and technical skill attained by their forefathers. The facts then available did not justify any other explanation. But in the light of the fuller knowledge now in our possession, it is evident that the B-group people were not the direct descendants of the A-group or pre-dynastic Egyptian population of Nubia, but the next bead on the string; in other words, they were members of the southern community of kindred people, next in order in the Nile Valley south of Nubia; and there is no reason to suppose that they had lost any cunning possessed by their ancestors, but rather that they had not kept pace with their northern brethren in the advance of the latter in the paths of civilisation. The evidence for this view is abundant and manifold in kind. I need mention only one fact here—the almost complete absence, among the human remains of the B-group people, of pure negroes, while the whole population is very definitely more negroid than the Egyptians, can only be explained on the hypothesis that the process of admixture took place farther south.

After the time of the Ancient Empire, the next bead on the string—the C-group of the archæologists—was moved north into Nubia. These Middle Nubians, as we call them, were also obviously akin to the pre-dynastic Egyptians, and their burial customs and pottery were clearly derived from the same source as those of the Egyptians: but it is equally certain that the two populations, the Egyptians and the Middle Nubians, had developed along divergent lines. Moreover, the undoubted specialisation of the physical characters of the people, no less than of their arts and customs, was emphasised by the introduction of an exotic African element into the C-group people. They became more definitely negroid than either the A- or the B-group peoples, and their pottery exhibits, no less clearly than their bones, the influence of the negro.

Mr. Firth summarises the archæological statement in these words:—"The theory tentatively advanced in the second annual report that the C-group people represent a later wave (greatly modified by Negro influences) of the same race which founded the Pre-dynastic culture of Upper Egypt, is based on certain affinities in burial-custom and pottery-making, and requires the confirmation which a careful examination of the physical character of the human remains can alone give." The human remains have supplied this confirmation, and they did so before we were aware of the fact that Mr. Firth was asking for the support of the evidence they afford.

His further statement that "the connection between the B- and C-groups does not seem to be very close and a comparison of the two would suggest an independent origin of the C-group" may seem to suggest that there was a much wider hiatus separating the Middle Nubians (C-group) from the earlier inhabitants of Nubia than there was to divide the two groups (A and B) of the latter the one from the other. There can be no doubt there was a much greater contrast between the C-group culture than separated those of its forerunners in Nubia: but it is equally certain that the B-group people, interposed both in time and locality between the A-group (distinctively Egyptian) and the C-group (distinctively Nubian), were much more strongly influenced culturally by the higher civilisation of the former than by that of the latter. Thus the Archaic Nubian (B-group) culture has the appearance of being the direct offspring of the Archaic Egyptian (A-group), but the people themselves form a unit as distinct from its forerunner (A-group) as it is from its successor (C-group).

There is a considerable mass of evidence to suggest that, just as the B- and C-groups represent successive waves, respectively, *circa* 3000 B.C. and 2000 B.C., which moved northward in the Nile Valley, the early pre-dynastic people in Egypt were largely reinforced, perhaps about 4000 B.C., by a precisely similar wave or rather concentration of the scattered primitive Nilotic people in the most desirable part of the Nile Valley.

In these notes I have attempted to suggest the present trend of our investigations without doing more than merely hinting at one out of a multitude of varied kinds of evidence indicative of the northerly trend of the Hamites in the Nile Valley, leading to a concentration in Egypt.

G. ELLIOT SMITH.

Manchester, April 29.

Inheritance of Row-numbers in Maize Ears.

IT is well known among maize-growers that the number of rows of grain on an ear of maize varies from 8 to 24, or even more, according to the breed; also that in the same breed the number may vary within certain limits, *e.g.* 8, 10, or 12 in some breeds, 12, 14, 16, or 18 in others and 18, 20, 22, or 24 in yet others. In some breeds the range of variation is even greater than I have indicated, while in others it seems to be more closely limited. In some breeds an ear carrying more than 8 rows is considered untrue to type, but I am not aware that any

South African grower has yet succeeded in fixing the number of rows in any breed to such a degree that *no variation* occurs in that respect.

In the course of a series of breeding experiments I am conducting, which are not yet completed, I have met with the following interesting case.

Thirty-three plants of "Arcadia" sugar-maize, each of which bore two well-developed ears, were studied as regards number of rows. On 21 plants the number on the upper ear was different from that on the lower, while on 12 plants the number was the same on each ear. Of the 21 plants on which the number of rows differed on the two ears, 13 had a larger number on the lower than on the upper, while 8 had a smaller number on the lower than on the upper. The distribution of rows was as follows:—

Class	Upper ear	Lower ear	Number of plants	Number of plants in each class
As many rows in lower as in upper	12	12	8	—
	10	10	3	—
	8	8	1	12
More rows in lower than in upper	10	14	1	—
	10	12	6	—
	8	12	3	—
	8	10	3	13
Fewer ears in lower than in upper	12	14	1	—
	12	18	4	—
	10	8	3	8
				33

Summary.

8	8	1	—
	10	3	—
	12	3	7
10	8	3	—
	10	3	—
	12	0	—
	14	1	13
12	8	0	—
	10	4	—
	12	8	—
	14	1	13
			33

The total number of ears producing any given number of rows was as follows:—

Rows	8	10	12	14	
Ears	11	23	30	2	Total 66

The "Arcadia" is a white sugar-maize obtained from a cross between a normally 8-rowed "Black Mexican" and a white flour-corn normally bearing a larger number of rows, but I do not know that either was pure bred, for row numbers and no subsequent selection in this line had been made.

It is generally supposed by maize-growers, in this country at any rate, that the number of rows is a definite, heritable character. Results obtained by crossing two other breeds, an 8-row and an 18-row (each believed to be pure as regards this character), have this year produced irregular results in the F_1 generation, for which I have not yet been able to account. However, the case described above seems to indicate that the development of rows is, within certain limits, a vegetative character depending in part on seasonal conditions and on food supply. This view is strengthened by the fact that this is the first year in which I have noticed 14-row ears in this breed, all the parent ears for two or three generations having been 8-, 10-, or 12-rowed (so far as I am aware). At the same time, there is ample indication that, within certain limits, row-numbers are inherited in the maize plant, but it is doubtful whether any South African strains are yet sufficiently pure-bred for this character to demonstrate the point with absolute certainty.

Absorption Markings in "K" Spectroheliograms.

IN a letter published in NATURE of March 30, Mr. Buss suggests that the evidence derived from some spectroheliograms taken by M. Deslandres at Meudon conflicts with that which I obtained from the Kodaikánal daily series.

There is no such "divergence of evidence" in reality. The dark marking shown on our plates of March 21, 1910, and described as vague and ill-defined, is doubtless much more clearly seen in the plates obtained with the Meudon high-dispersion spectroheliograph, which isolates the central absorption line K_3.

With the dispersion available in the Kodaikánal instrument, the K_3 line is about half the width of the camera slit, and photographs taken with the slit exactly central on K integrate the light of the absorption line and of the side components of the emission line K_2. As the dark flocculi or absorption markings seem to be entirely due to variations in intensity in the narrow absorption line, it is rather a matter for surprise that in our photographs they should be so clearly defined in many cases. In the original negatives taken on March 21, 1910, in addition to the broad, ill-defined shading already mentioned, there are clearly seen all the curious linear markings so beautifully shown in M. Deslandres' K_3 plate of this date, and I can find no appreciable differences in the contours of the markings.

With regard to the disappearance of the enormously extended marking between March 25 and 26, had Mr. Buss read the paragraph in my article referring to this with ordinary attention, he would not have suggested that the absence of the marking on the plate of March 26 was due to imperfect adjustment of the spectroheliograph slits. Very possibly the disappearance shown by our plates was not absolute, and K_3 or Hα plates taken on the same day would have shown the marking, but if so the reduction in intensity compared with the previous day would have been marked.

The theory apparently advocated by Mr. Buss, that the absorption producing these markings takes place above the prominences, receives no support from our visual or photographic observations, and his remarkable observation of a dark flat cloud hovering over the bright prominence at each successive appearance east or west seems to be unique! No trace of so extraordinary a feature can be seen on any of our numerous photographs of this prominence.

J. EVERSHED.

Kodaikánal Observatory, April 18.

Calendar Reform.

MAY I trouble you with one or two observations on the excellent article which appeared in NATURE of April 27.

Referring to the application of the principle of the *dies non*, or the setting aside of a day annually not included in the weekly enumeration, the author of the article says "the week can boast a most ancient lineage uninterrupted by the slightest break." Is this certain? I find Dr. Hale in his "Chronology," vol. i., p. 67, says:—"If the year of the Crucifixion was A.D. 31, as is most likely, it follows from an eclipse of the moon in Pingre's tables, April 25, at 9 afternoon, that the Paschal full moon that year fell on March 27, which in the calculations of Newton, Ferguson and Lamy, and the computation of Bacon is reckoned *Tuesday*," &c. I might adduce other reasons for doubting if the continuity of weeks has been uninterrupted. It must be remembered that for some time, at any rate, throughout the Roman Empire the odd day in leap year was treated as a literal—not merely as a legal—*dies non*, being regarded as part and parcel of the day preceding.

Nevertheless, I agree with the author that prejudice in this matter cannot be disregarded.

But no such objections can be stated to the proposal to apply this principle to the *months*, *i.e.* to treat the 365th and 366th days as without the monthly enumeration, and to equalise so far as possible the lengths of the months so as to give four quarters of 91 days, or 13 exact weeks.

It is hopeless to suggest that the present arrangement of months has any scientific or religious sanction or advantage.

I hope shortly to present to the public more fully the arguments in favour of this really non-contentious part of

the proposal, to which in the first instance I think the reform should be confined.

Astronomers are apt to ask, *Cui bono?* But though the advantages of such a simplification would to them be small, they would be enormous, innumerable, and universal to the lawyer, the statesman, the banker, broker, &c.—indeed, to public business, commerce, and education in all civilised countries.

If without infringing any scientific principle or violating any religious symbolism benefits so general can be conferred so easily, I feel sure that scientific men will not stand in the way. Indeed, many of them are in the forefront of the movement.

What we want is a simply natural and naturally simple scheme. I am afraid that suggested by your correspondent —very ingenious as it is—is for that reason unsuited for general use. ALEX. PHILIP.

The Mary Acre, Brechin, N.B.

FROM Mr. Philip's letter it appears that he, at all events, is conscious of the grave difficulties in the way of interrupting the continuous succession of the days of the week. It would be idle, therefore, to argue this point further, or to insist in greater detail on the importance of what Laplace called "peut-être le monument le plus ancien et le plus incontestable des connaissances humaines" (la semaine).

The date of the Crucifixion depends on questions relating to the Jewish, not the Christian, calendar. Now it seems incredible that the Hebrew communities have failed to maintain the order of the Sabbath without a break. If this be granted, the only deduction to be drawn from Mr. Philip's argument is that the Crucifixion did *not* occur in the year 31; which, indeed, according to the most recent chronological view, is most highly probable.

Mr. Philip's argument in favour of equalising the months will be received with interest when it appears. When, however, it is realised that the suggested change will not give us a fixed calendar, it may be doubted whether this minor adjustment, free from objection as it may be, will be found to have the necessary driving force behind it to secure its adoption. H. C. P.

A Zenith Rainbow.

AN interesting rainbow was visible from the Bruges-Ostend canal here at 4.30 p.m. on April 17, in fair weather, almost due west.

The sight at once evoked the expression that the bow was inverted. It was clearly visible for several minutes, and subtended an arc of about 20°.

On shielding the eye from the direct light of the sun, this arc was seen to extend much farther, and formed part of a circle with the zenith as apparent centre, the radius of the circle being estimated from 10° to 15°.

The inside of the bow was violet, the colour following the usual order to red; the intermediate colours were, however, not characterised by the sharpness often seen in the ordinary rainbow.

The state of the sky at the time was misty near the horizon, but otherwise brilliant with high fleecy clouds, with a light wind from N.N.W.

The bow was backed by a thin broken cloud, which presented a "curtain" formation as far as the angle of the sun.

No rain was observed to fall at the time or during the day. No primary or secondary bow was visible, which, among other things, excludes the idea of the bow observed being a tertiary one.

It would be interesting to know whether this type of bow is of frequent occurrence. K. C. KREYER.

7 rue des Lions, Bruges, Belgium, April 18.

IT appears from Mr. Kreyer's description that the phenomenon observed was the upper arc of contact of the halo of 46° radius. The altitude of the sun was about 24° at the time, so that the height of the point of contact would be about 70°, and the centre of the arc, accepting your correspondent's estimate of 10° or 15° radius, would be at an altitude of 80° to 85°. The phenomenon is described by Pernter as the most beautiful of all halo phenomena, and it occurs often when no trace of the 46° halo is visible; the colours, with the exception of the violet, are definite and brilliant, with the red towards the sun. The violet seen by your correspondent is more rarely present. The cloud with "curtain" formation was probably cirro-stratus, and would be formed by the ice crystals which give rise to halo-phenomena.

The bow observed is not of frequent occurrence (about seventy had been observed up to 1883), and it is interesting to have a record of it. E. GOLD.

Meteorological Office, South Kensington, London, S.W., April 27.

Daylight Saving!

THE following aspect of the Daylight Saving Bill does not appear yet to have been noticed.

A man who is accustomed to rise at 9 a.m., lunch at 1.30, dine at 7.30, and go to bed at 11.30 will naturally object to turning out of bed an hour earlier on a dull, grey, cold April morning. So, when the clocks are put forward, he will consider that the change is only nominal, and will continue to follow the old hours, rising at 10, lunching at 2.30, dining at 8.30, and going to bed at 12.30. When, however, the clocks are put back the weather is getting bad, and the pleasantest part of the day is after the blinds have been drawn and the gas lit; he will be glad of the extra hour's sleep in the dark morning, and the increased fireside comfort in the evening, and will be so accustomed to regard 10 o'clock as the time for getting up, 2.30 as lunch time, 8.30 as dinner time, and 12.30 as the time for going to bed, that he will certainly not want to go back to the old clock reckoning. Thus "daylight saving" will mean a saving of an hour's daylight in the dark winter months and a gain of an hour's gaslight.

"THE VOICE OF THE SLUGGARD."

DAYLIGHT AND DARKNESS.

WHATEVER may be thought of Mr. Willett's so-called daylight-saving scheme, it is impossible not to admire the persistence with which he pursues the idea, and secures support for it from city corporations, town councils, chambers of commerce, members of Parliament, and other people who are attracted by the advantages offered, and do not realise how unscientific the scheme is, or the gravity of the objections to the adoption of a variable standard of time-reckoning. We do not believe for an instant that the Government is likely to give facilities for legislation on the lines of the Summer Season Time Bill, however sanguine the promoters of the Bill may be As, however, a meeting at which the Lord Mayor presided, and the Home Secretary spoke, was held at the Guildhall on May 3, it is worth while to consider again some aspects of the proposals usually overlooked.

The promoters of the Bill have circulated a mass of literature, in which the advantages are emphasised and the objections disregarded. Among these communications is an article contributed to *Die Woche* by Dr. E. von Engel of Berlin, who supports warmly the proposition of accommodating the standard meridian of Greenwich to that of Berlin or Mid-Europe. We have no doubt he is perfectly sincere in his recommendation. At the same time, the advantages of making the hours of business in England coincide with those in Germany is entirely in favour of the latter country.

In consequence of this renewed earnestness and vigour of the daylight-saving movement, it is desirable to express, concisely and decisively, some fundamental objections to a scheme which can be made to present so much that is agreeable. This is the more necessary because there is a feeling that scientific men are inclined to display a selfish regard for their own convenience, and a contemptuous indifference to

national requirements and economy. It is needless to say that such a view completely misrepresents the character of the scientific objection to the scheme. Let us admit, as fully as the most ardent of the supporters of Mr. Willett's scheme could wish, that the acceptance of his proposed legislation will do all that he demands for it: that it will give London 154 more daylight-using hours in the year, that it will reduce the lighting expenses in all industrial operations, that it will improve the health of the nation and be productive of other advantages. It is still incumbent upon the promoters to show that the machinery which they propose is the best adapted to the end in view, and that it will be effective. Our contention is that they have sought to effect the amendment they desire in an objectionable manner. Our lives, duties, business, and pleasures are not uniformly distributed throughout the hours of daylight. Then let us have a more systematic arrangement. What should be aimed at is a modification of our habits on judicious lines. It should be the business and the effort of Mr. Willett and his friends to cultivate a more enlightened public opinion, to persuade people to adopt more rational customs. He has tried to get a desirable result by a wrong method; we might say, by a disingenuous method.

Of course, it may be argued, as Dr. von Engel does, that "No society, however powerful, would be able to induce a universal movement for early rising for increasing our enjoyment of the sunlight." If not, why not? What has been the determining factor by which the conduct of life has been continually shifted later in the day? It is not impossible that the preference for the afternoon has been brought about by the necessity or convenience of regulating life not by light, but by heat. The heat meridian does not coincide with the light meridian, but is some two hours or more after it, and the day is arranged apparently so as to make available the greatest amount of heat. Mr. Willett asks us to disregard this effect. He does not seem to see, or at least does not admit, what is perfectly obvious to all who have given the matter sufficient consideration, that if more light is utilised in the morning, there is also a lower temperature to be encountered. To have to burn a fire in the early morning would be a very decided set-off to the use of less artificial light at night. But on this view we do not insist. We are content to make the point, that heat as well as light should be considered, and that its importance in the comfort of life cannot be neglected, as is shown by the social arrangements that obtain in other countries of Europe, as well as in the Tropics. But perhaps the promoters of the scheme for periodically changing the standard meridian contemplate also a seasonal variation of the thermometer scale. It would be just as reasonable for Parliament to enact that, in certain months, a temperature of, say, 60° should be called 70°, as it would be to agree that for a certain part of the year 6.0 o'clock should become 7.0 o'clock.

In his speech at the Guildhall, Mr. Churchill referred to some points upon which we have a few words to say. He mentioned that the agricultural population of the country already make full use of daylight hours in the various seasons, and that thousands of firms and offices (he might have included the Board of Education) have different working hours in summer and winter. A not inconsiderable number of people thus solve the problem in the most reasonable way by adapting their habits so that the best use is made of daylight. This would seem to provide an argument for urging similar action upon other sections of the community, but scarcely furnishes a reason for compulsory alteration of the clock upon days prescribed by Act of Parliament. It is only in a great city like London that individuals whose hours of work and leisure vary with the seasons can be said to suffer any difficulty or inconvenience because, as Mr. Churchill said, they are "out of contact with the customary time-table of the nation." There is no general time-table of life and labour followed in the United Kingdom as a whole. The "customary time-table" of London differs as regards evening meals and amusements from that of nearly all other cities in the kingdom, being an hour or more later than is usual in most provincial towns. If custom is to be considered in the scheme for the division of daylight and darkness, then London will require the clocks to be advanced by two hours to be placed in the same position as most places in the provinces where the clocks would be put forward for one hour.

It is also forgotten by the promoters of the scheme that the daylight hours of London and other places in the same latitude differ considerably from those of places farther north. At Aberdeen, Dundee, and Edinburgh, for instance, lighting-up time for vehicles in the present month is about 35 minutes later than in London, and next month it will be three-quarters of an hour later, that is, about 10.0 p.m. Scotland has, in fact, a natural extension of the daylight hours in the summer months without any need for legislation. At Edinburgh and all places north of it there are not sufficient hours of darkness in May, June, and July for the normal eight hours of sleep required by men or women, and there would be no advantage in advancing the clocks by an hour from the third Sunday in April to the third Sunday in September. The 154 hours "more daylight" which Mr. Churchill says would be secured by the scheme "to the whole people of these islands," are already possessed by the people of Scotland between April and September. Why not suggest, therefore, that for certain months of the year the latitude of Edinburgh shall be the latitude of all other places south of it in the United Kingdom, instead of proposing that the longitude of Berlin shall be the longitude of Greenwich?

Another point referred to by Mr. Churchill was the ease with which the change of nine minutes from Paris to Greenwich time was effected recently in France. It is difficult to understand how this action can be held to afford any support to the scheme of "daylight saving." Our own view is that, as France has now adopted the Greenwich meridian as its standard for time-reckoning, it would be an unfriendly and injudicious act for us to abandon Greenwich time for German time during an arbitrary period of the year. France has now come into line with the international system of time-reckoning based on standard meridians beginning with the meridian of Greenwich and extending round the whole civilised world. These meridians are permanent standards at present, but if the principle of the daylight-saving scheme were accepted they would oscillate east and west on different dates, and hopeless confusion would be introduced in the place of a scientific system.

The fact that it is easy to advance one's watch by an hour when entering the zone where Mid-European time is kept, and to put it back an hour when leaving the zone, provides no argument for the alteration of the time of the United Kingdom twice a year. When you move fifteen degrees east you really do reach a longitude at which the time, as indicated by the sun's position, is an hour in advance of Greenwich time. Noon occurs nearly an hour earlier at Berlin than at Greenwich, whatever

standards of time are adopted, so it is natural to adapt one's watch to the new conditions when reaching Germany. By the daylight-saving scheme, 11.0 Greenwich time would be called 12.0 noon during the summer season; that is to say, the sun would be considered to have reached its highest point for the day an hour before it actually does so. Of course, we remember that there is a difference between apparent time and mean time, but the variation of the equation of time does not effect the affairs of everyday life. When, however, it is proposed that Parliament should grant powers to enable the people of the United Kingdom to pretend that during summer months noon at Greenwich corresponds to noon in the neighbourhood of Berlin, it is time the absurdity of the scheme was exposed. The scheme is unworthy of the dignity of a great nation, and if it were made compulsory by legislation, it would be a monument to national flaccidity. We cannot think that the Government will lend its support to proposals which involve more international consequences than the promoters are aware of, and would make us the laughing-stock of the enlightened people of the world.

THE NEW ENCYCLOPAEDIA OF SPORT.[1]

FROM a biological point of view two articles in this issue are especially noteworthy, namely, one on the Arabian horse, by the well-known breeder, Mr. W. Scawen Blunt, and one on grouse disease, by Dr. Shipley. The former stands as it was in the first edition, the author stating that he has practically nothing to add or alter. Its special interest lies in the fact that the author still maintains the theory that the Arab horse, in place of being a comparatively late importation, originally existed in a wild condition in the comparatively desert districts of Nejd and the central plateaus of Yemen. On the other hand, such historical evidence as exists does not indicate that the natives of Arabia were in possession of tame horses at a very early period, and this seems to weigh considerably against the idea of the former existence in the country of a wild race.

The article on grouse disease, to which Dr. H. B. Fantham contributes the section on the coccidiosis of young birds, has been written specially for the present edition, and is therefore thoroughly up to date, although the author is careful to add that many of the inferences and conclusions referred to must be regarded as more or less provisional. This contribution, which is well and profusely illustrated, is thoroughly worthy of its author, but since Dr. Shipley's investigations into grouse disease have been already reported in NATURE, further mention is unnecessary.

The other articles on natural history subjects display that pleasing variety of treatment to which allusion was made in my review of the first volume. For instance, whereas Mr. Bryden, in the article "Deer" (which appears to have been compiled from the "Deer of All Lands"), treats his subject almost exclusively from a zoological point of view, the writers of "Elephant" confine themselves mainly or entirely to the sporting aspect of their theme, making no reference to the local races of the African species. On the other hand, in the article "Giraffe," Mr. Bryden does record most of the local forms of that species. Need of revision in the article last mentioned is evident from the repetition of the old statement (which was not true previous to the discovery of the okapi) that "the giraffe forms a distinct family of its own." Neither is Mr. Selous quite faultless when writing of the African elephant, since he repeats the old error of this species being "somewhat less in bulk and stature than either the mastodon or the mammoth." Nomenclature is also, as in the first volume, distinctly erratic, Mr. Bryden, in the article "Deer," denominating the Chilian guemal *Mazama bisulca*, whereas Mr. Hesketh Prichard, in the article "Guemal," calls it *Xenelaphus bisulcus*.

Tora Hartebeest and Grant's Gazelles. From "The Encyclopædia of Sport."

That the editor has endeavoured to bring the biological articles up to date is, however, quite evident, as, in addition to the already mentioned article on grouse disease, there is one, by Mr. Bryden, on the African forest-hog (Hylochœrus), a genus originally described in NATURE. In this effect he

[1] The Encyclopædia of Sport and Games. Edited by the Earl of Suffolk and Berkshire. A new and enlarged edition. Vol. ii. Crocodile Shooting—Hound Breeding. Pp. viii+448. (London: W. Heinemann, 1191.) Price 10s. 6d. net (abroad 12s. 6d. net).

may be said, on the whole, to have been fairly successful, for, in spite of slips and inconsistencies like those just referred to, the average sportsman will find practically all the information to be expected from a work of this nature in regard to most of the animals of which he may be in search, and as the work is essentially one for the sportsman, this is really all that can be legitimately demanded.

From first to last the volume is thoroughly well illustrated, both as regards plates in colour and text figures, some of the latter, as exemplified by the one herewith reproduced, being really exquisite.

As regards subjects other than natural history, the articles, so far as I am capable of judging, are all that they should be, and as most of them are written by experts, they bear the imprimatur of authority. Of those in which I am personally much interested mention may be made of Mr. Rawdon Lee's "Dogs," which contains precisely the sort of information suitable to those who are not specialists in canine matters. If the all-round lover of sport, in the widest sense of the word, is not thoroughly well satisfied with the volume as a whole he must be very hard indeed to please. R. L.

WHEATS AND FLOURS.[1]

REPRESENTATIONS having been made to the Local Government Board by various medical officers of health and public analysts on the growth of the practice of bleaching flour, and stress having been laid on the prohibition of bleaching in the United States of America, Dr. Hamill received instructions from the Board to make inquiries as to how far the practice obtains and to what extent, if at all, it is justifiable. In this report, after indicating the sources of supply, he describes the milling of wheat and grading of flour; then, after indicating what are the factors determining the quality of flour, he proceeds to discuss bleaching processes and their effect.

In roller milling the production of flour is a gradual operation. The wheat passes through a series of fluted, chilled, iron rollers, the product from each pair being sifted before passing to the next; at each stage the fragments of endosperm, as they pass through, are further reduced, and the flour separated out. It is possible for the miller either to collect in one portion the whole of the flour produced, the mixture obtained being termed a "straight run flour"; or he may separate it into two or more portions, the one being derived from the first two or three pairs, the other from the last pair, of rollers. Flour is arbitrarily graded into "whites" or "patents," representing the product from the first few rollers, and "households," representing the rest of the flour; a further subdivision is made when required. There is a difference in price of as much as 5*s*. or 6*s*. per sack of 280 lb. between the highest and lowest grades.

Millers in this country have to deal with wheats coming from all parts of the world, and some of them acquire great skill in so blending and milling the wheats at their disposal as to produce a flour of absolutely uniform behaviour in the bakehouse throughout the year; this is a matter of the very greatest importance to the baker, who has learnt to appraise the market value of flour from its baking qualities and appearance. For many years past the baker has had to satisfy the demand for a very white loaf, especially on the part of the operative classes.

Dr. Hamill might with advantage have considered this point in greater detail; the demand arises apparently in part from prejudice, dating from a period when cheap bread was very much adulterated and dark in colour; it is in part based on the fact that the whitest bread, as a rule, is the lightest in texture and the most digestible. Colour in bread is probably more a question of optics than due to the original colour of the flour—a yellow, strong flour will often make a whiter loaf than a weak, very white flour. The baker attaches importance not merely to colour, but to freedom from specks of offal or dirt. Stone milling has been almost superseded by the more complicated process of roller milling, because the latter permits of the more or less complete removal of bran and other undesired parts of the grain. As Dr. Hamill points out:—

"In stone milling a large, if not the greater, part of the germ is lost in the offal; only a portion finds its way into the finished flour.

"In both stone and roller milling it is possible to obtain a yield of flour representing anything between about 70 and 100 per cent. of the wheat milled, according to the amount of offal included in the flour. As a rule, the greater the amount of offal in the flour—*i.e.* the greater the percentage yield of flour obtained from the wheat—the darker is the loaf which it will produce. The colour of the loaf, however, depends not only upon the amount of offal which the flour contains, but upon the milling process adopted (stone or roller milling) and upon the colour of the wheat used (red or white). For these reasons different flours containing the same percentage (above 70 per cent.) of the total wheat may yield loaves varying very considerably in colour."

The question of the relative food value of different wheats or of the flour from different parts of the berry in no way enters into the consideration of its market value.

The bleaching of flour is effected commercially with nitrogen peroxide; it appears to be impossible to detect a bleached flour by mere inspection. Flour which has been badly dressed, containing particles of offal, is unsuitable for bleaching, as this only makes the specks more conspicuous.

Dr. Hamill concludes that bleaching produces no effect upon the baking qualities of flour. It improves the colour of the whole output of the mill and represents a pecuniary gain, since it gives the miller a larger percentage of high-grade flour. It is of assistance in maintaining uniformity in the appearance of flour, but at the same time it enables the miller to use cheaper wheats (*not necessarily of lower food value*). There is no evidence that bleaching enables good flour to be made from unsound wheat.

Flours are classed as strong or weak, according as they will produce large well-risen loaves or not. This property is in some way connected with the character of the protein of the flour, and it has been the subject of a great deal of experimental work within recent years. It is a well-known fact that the properties of colloidal substances, to which class the gluten of flour belongs, are profoundly modified by small quantities of electrolytes, and it has been found that the treatment of weak wheat during milling with small quantities of phosphates causes the flour obtained to be "stronger" than it would otherwise be. As a consequence, it is possible to make from weak British wheat a strong flour, the bread from which has the rich flavour characteristic of our flours. Seeing that bread of the type demanded throughout the country cannot be made without a considerable proportion of a strong flour, it would seem justifiable to conclude that the new invention will enable a larger proportion of British flour to be used in our bread, much to the advantage of the community—incidentally it should increase the value of British flour which

[1] Reports to the Local Government Board.
(1) On the Bleaching of Flour and the addition of the so-called 'Improvers" to Flour: by Dr. J. M. Hamill.
(2) On the Chemical Changes produced in Flour by Bleaching: by Dr. G. W. Monier-Williams.
(3.) On the presence of Calcium Sulphate in Baking Powder and Self-Raising Flour: by Dr. J. M. Hamill.

to-day, on account of its "weakness," only commands bottom prices. Legislation in the direction suggested would thus put British wheat at a disadvantage.

Dr. Hamill does not accept this view, basing his objection partly on the ground that it is not desirable to make any additions to flour, partly on the fact that an originally low-grade weak flour is substituted for a high-grade one; finally, on the fact that since strong American flours contain more protein than weak British flours the food value of the bread is diminished. Here it is necessary to join issue with him. Bread is eaten as a source of carbohydrate and as a diluent to the concentrated fat and protein foods and not as a source of protein. Whether it contains half a per cent. more or less of protein is quite immaterial to the consumer.

It was clear to those who took part in the visit to Canada of the British Association that strong wheats will sooner or later have to give way to weak wheats wherever the two come into direct competition, on account of the much higher crop yields given by the latter. As a consequence, the character of our bread will change unless science in the meantime enables us to produce strong flour from a weak wheat. To cramp progress in this direction at the very outset would appear to be absurd.

It is at times stated on very inferior evidence that bleached flour is injurious to health; Dr. Harden's authoritative statement to the contrary which is recorded in an appendix to the report should settle this question finally.

The report of Dr. Monier-Williams on the chemical changes produced in flour by bleaching is full of valuable and suggestive matter. At the same time very many of his results are open to technical criticism, especially those of the experiments dealing with enzymes. It is obvious that much work remains to be done.

It is clear that the issues considered in the report are of great public importance, but the questions raised are so difficult and of such complexity that it is impossible to arrive at any final opinion on the evidence at present available. It is obviously necessary that the whole subject should be submitted to discussion from the chemical, the physiological, and the practical side, including the agriculturist, as well as the miller and baker. Dr. Hamill shows a very strong bias in the direction of forbidding any treatment whatsoever of flour, although he is unable to produce convincing evidence in support of his conclusions; seeing that his experience is very limited, it is to be hoped that the subject will be remitted to competent observers for full discussion before any steps are taken to introduce restrictive legislation.

Since the above was written, the members of the National Association of British and Irish Millers at a general meeting have adopted a resolution to the effect that wheaten flour sold as such without any qualifying designation should be the unbleached and untreated produce of properly cleaned and 'conditioned' wheat only." They ask the Government to appoint a Board of Reference, consisting of properly qualified experts, to consider thoroughly the whole question of bleaching and the addition of foreign substances to flour.

ORIENTAL SILVERWORK.[1]

MR. LING ROTH, who, in dealing with obscure chapters of anthropology and art, such as Tasmanians or Dayaks, or the brasswork of Benin, has already proved himself a good compiler, has now, in describing Malay and Chinese silver work, found a subject well suited to his powers. Few people, he remarks, have ever heard of Malav silverwork; South Kensington has only half a dozen specimens. The objects illustrated in this volume come from private collections made by officers who have served among the Malays, Messrs. Cecil and Leonard Wray, W. A. Luning, and Dr. C. Hose.

This scarcity of material is due to at least two causes. In the first place, so far as the Malay Peninsula is concerned, this phase of art is practically dead. The old rajahs and sultans, like the nawabs

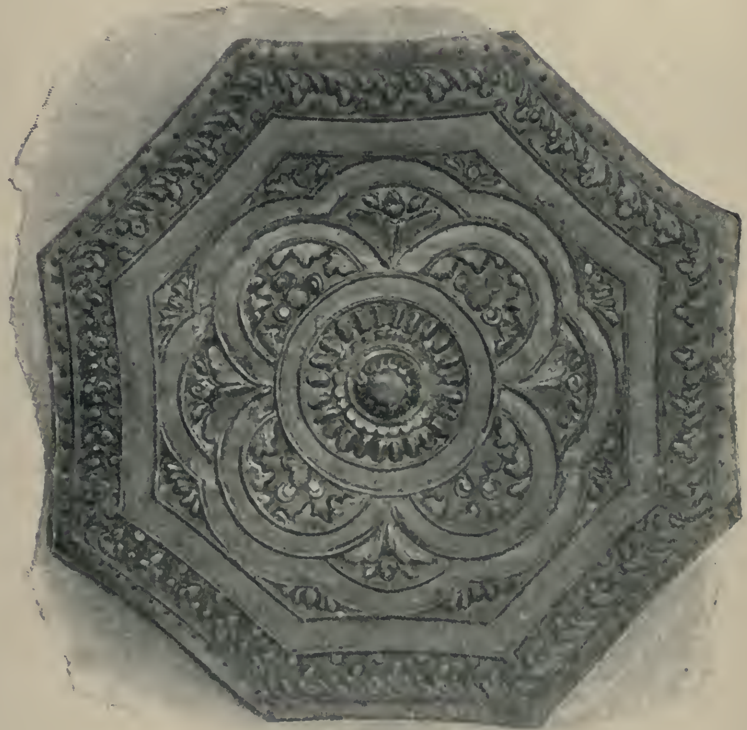

Fig. 1. Buntal (Octagonal Pillow-end Plate), diameter 4½ inches. Lotus pattern at centre. From "Oriental Silverwork, Malay and Chinese."

of Oudh and other Indian princes, amidst their ill-organised households and troops of retainers, used to keep in their service gold- and silversmiths, who worked only for their masters, and produced nothing for the market. With new tastes and wants suggested by contact with foreign culture, this condition of things has passed away. It must be said, however, that among the Malays the decay of the local crafts cannot be attributed to the introduction of European trumpery, though this seems to be the case among the branch of this people in Borneo. In the second place, Malays have a traditional respect for their old art products, and will not sell them except under extreme pressure of circumstances. In this connection Mr. Ling Roth might well have quoted the interesting account by Mr. W. W. Skeat of the magical powers ascribed to the regalia in Malay native

[1] Oriental Silverwork, Malay and Chinese. With over 250 original illustrations, a Handbook for Connoisseurs, Collectors, Students and Silversmiths. By H. Ling Roth. Pp. iv+300. (London: Truslove and Hanson, Ltd., 1910.) Price 21s. net.

courts, a feeling which has possibly extended to art work in the precious metals and has had the effect of checking its dispersal.

The problems of the origin and affinities of this school of art work have not been fully dealt with by the author, and the material available is scarcely sufficient to form the basis of a comprehensive examination. The Peninsula is inhabited by a very mixed population, and it has been the meeting-ground of more than one ancient civilisation. Of these the most powerful is clearly China, which now supplies numerous emigrants who form an important ethnical element. To the west lies India, to the east Java and Siam. Probably all these have contributed something to the general stock of form and design. But in addition there is undoubtedly much that is indigenous.

As regards decoration, we find nothing which can be traced to architectural forms, and little which is specially religious. The introduction of Islam, which places a rigid taboo on delineation of the human form, has had far-reaching effects, and the motifs have necessarily been largely drawn from local vegetable life. These, again, have undergone considerable modification, partly resulting from the the natural tendency in all such art to become conventional, and partly under direct Chinese pressure. The lotus design which frequently appears in the patterns, may have come from either China or India, and further study of the ornamentation will probably show that more has come from India than Mr. Ling Roth is at present prepared to admit.

The examples which he illustrates are chiefly small objects—boxes for holding tobacco, betel, lime, salves, or unguents, bowls and saucers, and the curious end-pieces attached to pillows, which, like many of the other objects, are ostentatiously paraded at wedding processions (Fig. 1).

The methods of manufacture, which are fully described by Mr. L. Wray, represent what is known in European art as repoussé, a thin plate of silver being placed on a lump of softened gum-resin and worked from the back by a series of punches. Graving is little used, and the results attained show considerable artistic skill. As is usual in Oriental art, the craftsman uses no fixed design and much is due to his taste and invention.

This book may be safely recommended to students of Oriental metal work, and to art classes, particularly at centres where the study of silver and gold plate is specialised, and designers in other branches of art productions may find useful suggestions in the excellent photographs with which it is illustrated.

NOTES.

In *The Daily Mail* of Monday last, Sir Ernest Shackleton made an urgent appeal to the British nation on behalf of the Australasian Antarctic Expedition, which, it is hoped, will start in June under the command of Dr. Douglas Mawson. In his letter Sir Ernest Shackleton points out that Australasia has done much for south polar expeditions which have started from this country, and he asks for help, "from this side of the line and from Australians and New Zealanders who are gathering in London for the Coronation," towards the sum of 12,000*l.* needed to purchase a suitable ship, which has been selected by Dr. Mawson, and to enable the expedition to start in June. The Royal Geographical Society has already subscribed 500*l.*, as in the case of Captain Scott's expedition, and a committee has been formed in Australia to assist the explorers. As the result of the appeal, and the steps taken by *The Daily Mail* to bring it under the notice of people interested in exploration, the sum of nearly 9000*l.* had been subscribed by Wednesday morning, and there is little doubt that the whole amount required will be provided. Dr. Mawson proposes to take a monoplane with him for use during the expedition.

A COMMITTEE of the Geological Society has been formed to secure the means of providing a memorial to the late Prof. T. Rupert Jones, F.R.S., in aid of his widow and daughters. The late Prof. Jones was never in receipt of more than a very moderate income, and receiving only a small pension upon his retirement thirty years ago from the post of professor of geology in the Royal Military College, Sandhurst, he was unable to make any suitable provision for his family at his death, when his pension ceased. During his long life Prof. Jones was an ardent geologist and palæontologist, and the author of nearly 200 separate papers or other works, some of which were mentioned in our obituary notice published in NATURE for April 27 (p. 287). Subscriptions towards the proposed memorial may be sent to Prof. W. W. Watts, F.R.S., president of the Geological Society, Hillside, Langley Park, Sutton, Surrey, who has consented to act as treasurer to the fund. It is to be hoped that the committee's appeal will meet with a ready and generous response.

THE council of the Pharmaceutical Society has elected the following honorary members in recognition of their distinguished scientific work:—Prof. W. E. Dixon, F.R.S., professor of pharmacology, King's College, London; Dr. Adolph Engler, director, Botanical Museum, Berlin; Prof. Percy F. Frankland, F.R.S., president of the Chemical Society; M. Eugène Léger, late president Société de Pharmacie de Paris; pharmacien en Chef de l'Hôpital St. Louis, Paris; Lieut.-Colonel D. Prain, C.I.E., F.R.S., director of Royal Gardens, Kew; and Dr. Ludwig Radlkofer, professor of botany, University of Munich.

ON Tuesday next, May 16, Prof. F. W. Mott will begin a course of two lectures at the Royal Institution on "The Brain and the Hand"; on May 18 Dr. W. N. Shaw will deliver the first of two lectures on "Air and the Flying Machine": (1) "The Structure of the Atmosphere and the Texture of Air Currents," (2) "Conditions of Safety for Floaters and Fliers"; and on Saturday, May 20, Mr. W. P. Pycraft will commence a course of two lectures on "Phases of Bird Life": (1) "Flight," (2) "Migration." The Friday evening discourse on May 19 will be delivered by Prof. R. W. Wood on "Recent Experiments with Invisible Light," and on May 26 by Prof. Gilbert Murray on "The Greek Chorus as an Art Form."

THE provisional programme of the International Congress in Naval Architecture and Marine Engineering, to be held in connection with the jubilee of the Institution of Naval Architects in July, has been issued. On Monday, July 3, there will be a reception at the Royal United Service Institution. On Tuesday, July 4, the International Congress will be opened by H.R.H. the Duke of Connaught, K.G. The three following days, July 5, 6, and 7, will be devoted to the reading and discussion of papers contributed by Admiral Sir Cyprian Bridge, G.C.B., Sir Andrew Noble, Bart., K.C.B., Sir William H. White, K.C.B., Sir Philip Watts, K.C.B., the Hon. C. A. Parsons, C.B., Mr. S. W. Barnaby, Dr. S. J. P. Thearle, Mr. C. E. Ellis, Colonel G. Russo (*Italy*), Admiral Kondo, (*Japan*), Mr. Uchida (*Japan*), Count Shiba (*Japan*), Prof. Terano (*Japan*), Konsul Dr. O. Schlick (*Germany*),

Geheimrat Prof. Flamm (*Germany*), Prof. A. Rateau (*France*), and Mr. J. Johnson (*Sweden*). On Thursday, July 6, there will be a visit to the National Physical Laboratory to inspect the national experimental tank, and in the evening a banquet to the delegates and representatives.

THE death, at a very advanced age, of Miss C. C. Hopley, daughter of the late Mr. E. Hopley, of Lewes, a naval surgeon, has been recently announced. As regards natural history, the deceased lady, who took special interest in reptiles, of which she kept various specimens as pets, was best known as the author of a popular work on snakes, published in 1882. American birds likewise attracted her attention, and during the Civil War, when she was travelling to collect materials for a work on this subject, she was arrested and imprisoned as a British spy. Miss Hopley was for a number of years a contributor to *The Globe*, many natural history articles in that journal having been apparently written by her pen.

THE authorities of the British Museum are to be congratulated on having acquired, at an almost nominal price, the valuable collection of specimens illustrating the religion of Polynesia, which was long in the possession of the London Mission Society. Many of the specimens are unique, and it would now be quite impossible to form such a collection. Among the most remarkable objects are the great tapering idol of the national god of Raratonga, kept swathed in blue and white matting; Tangaroa, the supreme god of Polynesia, a wooden figure with small human-like objects sprouting from his eyes, mouth, and other parts of his body, typifying his creative power; and a head-dress of black feathers, which completes a mourning costume already owned by the museum. It would have been nothing short of a calamity if a collection of this kind had been dispersed, and the council of the London Mission Society, which has for some time entrusted the objects to the British Museum for exhibition, is to be commended for its liberality in transferring the collection to the nation.

IN reference to the proposal to appropriate a large portion of the ground at the back of the Natural History Museum to purposes other than those of that institution, it is pointed out in the April number of *The Museums Journal* that the Government does not appear to realise the imperative need for expansion which must occur at no distant date if the museum is to do its work properly and keep abreast of the times. Such expansion, it is added, will by no means be confined to galleries and rooms for the exhibition and storage of specimens, but must embrace rooms and buildings in which scientific work in connection with the collections is carried on. Indeed, this latter item will probably be found to be the more urgent of the two. "Nowadays, any museum worthy of the name requires libraries, laboratories, workshops, studios, and so forth, and these often occupy a larger area than the exhibited collections of the museum. The ground that lies between the Natural History Museum and the Science Museum might very well prove none too large for either of these museums alone."

APROPOS of the article on "Standard Bread" which appeared in the last issue of NATURE, Dr. Leonard Hill, F.R.S., publishes a note in *The British Medical Journal* of May 6 on the nutritive value of white and of standard bread. Young tame rats were fed for three weeks some on white and some on standard bread, and for a second three weeks some on white and some on standard flour. Two lots of twenty-five rats each were used and kept in identical conditions; at the start the total weight of each lot was approximately the same. The results were astonishing; ten of the white flour and bread lot died against five of the standard. Taking fifteen survivors of each lot, the standard has a percentage gain in weight of $27\frac{1}{2}$, against twelve for the white in the last three weeks, and at the end nearly all the latter are losing weight, and are less lively and less sleek than the standard. Another lot fed on white flour *plus* an addition of the germ equivalent to that in standard flour, have done as well as on standard flour and bread, suggesting that the germ contains bodies essential for growth or activating enzymes engaged in the digestion of wheat proteins.

IN the House of Commons on May 3, Mr. E. Edwards asked the Secretary of State for the Home Department whether any arrangements were being made to continue the experiments with coal dust which had been carried on during the last three years by representatives of the coal owners and others at Altofts Colliery and elsewhere; and whether the Government were prepared to undertake the control and responsibility of the experiments, in view of their great importance to the mining population in the direction of the prevention of coal-dust explosions. In reply, Mr. Churchill stated that it has been decided to continue the experiments referred to under the supervision of the Home Office, and that the Treasury has sanctioned the considerable expenditure that will be necessary for the purpose. The Mining Association has offered to place at the disposal of the Government for the purposes of the experiments the plant and instrument now in use at Altofts, an offer which has been accepted, and arrangements are being made for starting work as soon as possible on a new site. Mr. Churchill has appointed an expert committee to be directly in charge of the experiments, the members being Sir Henry Cunynghame, K.C.B., Mr. R. A. S. Redmayne, Captain Desborough, Prof. H. B. Dixon, F.R.S., and Mr. W. Cuthbert Blackett. He has also requested the members of the Royal Commission on Mines and of the Coal Dust Committee of the Mining Association, under whose supervision the previous series of experiments was conducted, to act as a consultative committee in connection with the experiments.

MR. J. A. J. DE VILLIERS described the foundation and development of British Guiana before the Royal Geographical Society on May 8. Starting with the first settlement in the early part of the seventeenth century, he traced the gradual growth and development of the colony in the hands of the Dutch for some two hundred years. From 1803 the country became British property, and in 1834 Robert Schomburgk, who had been sent out by the Royal Geographical Society, commenced his travels and explorations which enabled him to lay down boundaries provisional at that time, but which were substantially followed and accepted by the arbitration tribunal in Paris in 1899. The whole subject is an interesting and instructive contribution to colonial history.

Miss Olive MacLeod, who, with Mr. and Mrs. P. A. Talbot, has been exploring the country round Lake Chad for several months, returned to England on Tuesday. The expedition passed up the Niger and Benue Rivers by steamer and canoes through Southern and Northern Nigeria, and then traversed the North Kamerun. French Ubangi was reached in October last. A splendid reception was accorded to the party by the Lamido at Lere. The mysterious falls on the Mao Kahi were located, and have been named Les Chutes MacLeod. After mapping this

part of the river, the party went through the Tuburi Lakes and down the Logone to Fort Lamy. The expedition then proceeded down the Shari to Lake Chad, which was crossed, in Kotoko canoes, from the Shari to Saiyorum. Close studies were made of the various peoples visited, especially of the little-known tribes of French Central Africa and the Badumn of Lake Chad. A large collection of objects of ethnological interest was made, especially of musical instruments, while typical examples of music were taken down. A botanical collection of several thousand specimens has been sent to the British Museum, as also a number of birds, beasts, and reptiles. A route-sketch was made across Lake Chad, and a survey by plane-table and theodolite from Maifoni to Kano.

In a curious paper contributed to the Journal of the Royal Society of Arts for April 21, Prof. H. Chatley discusses Chinese natural philosophy and magic. He endeavours to trace a close analogy between the system advocated by the sage Ch'u Hsi, who lived in the twelfth century of our era, and the discoveries of Sir W. Crookes and Sir J. J. Thomson. Discussing the part played by gambling in magic, he remarks:—"The use of cards is said to be derived from the Turot cards, which were originally employed for occult purposes. The legend which ascribes the invention of cards to the purpose of amusing a mad king does not seem at all a sufficient explanation, and there is, in addition, the fact that cards of a kind existed before the said king. In further support of this idea, the well-known practice of telling fortunes by cards may probably be regarded as a survival of a regular form of divination by such means. It seems, in fact, that card-playing for stakes is a mere development of a ceremony in which individuals consulting the oracle decided to abide by its pronouncements as to the holding of disputed property."

Mr. Dean C. Worcester, Secretary of the Interior under the Government of the Philippine Islands, in an interesting and well-illustrated article contributed to the March issue of *The National Geographic Magazine*, describes the methods by which the American authorities have succeeded in gaining control over, and to some extent civilising, the pagan tribes of northern Luzon. During his tour the officer in charge of the district collects representatives of tribes which are normally in a state of war, and secures peace and the cessation of head-hunting by promoting athletic contests, which are most popular among these savages. They are encouraged to compete in their tribal dances, and the games most popular are running, wrestling, the tug-of-war, and climbing the greased pole. He thus sums up the results of this policy:—"We have been able to get results in dealing with wild men by following the simple policy of always giving them a square deal; by not punishing them for a given course of action unless they had had ample warning that such action would be followed by punishment; by never failing to punish them when, *after due warning*, they have misbehaved; by making friends with them again whenever they were ready to be friendly; and by finding an outlet for their superabundant animal spirits in rough but innocent field sports."

The second number of the Annals of the Cyprus Natural History Society, for 1910, contains a short summary of the more interesting animals observed in the island during the year. A list of Cyprus birds (290 spp.) was published in the first number, and it is proposed to issue shortly lists of the mammals and Lepidoptera.

According to the Indian *Pioneer Mail*, the Bombay Natural History Society is appealing for a sum of 2000*l*. with the object of starting a zoological survey of British India. At present about 8000 rupees have been subscribed, and with this in hand the society has started one collector; but as the services of Mr. Shortridge, who was recently invalided home from New Guinea, are available, it is desired that these should be secured, although this cannot be done without a large increase in the subscription list. It is pointed out that a brief glance at Blanford's "Mammals of India" will show how much remains to be done even in that section of the zoology of the country. Later information states that the sum promised has reached about 10,000 rupees.

In vol. vi., part i., of the Records of the British Museum, Dr. Annandale describes a cirriped of the parasitic group Rhizocephala taken on a crab, *Sesarma thelxinoe*, from a stream 700 feet above sea-level in the Andamans, near Port Blair. The specimen, which is believed to be the only example of the group hitherto obtained from fresh water, is made the type of a new genus and species, under the name of *Sesarmaxenos monticola*. It is pointed out that the crab on which the parasite was found belongs to a group the members of which usually breed in brackish water, if not in the sea, and it is therefore possible that the Andamanese species may periodically visit the ocean to spawn, and that the parasite may have become attached to the type specimen during such a sojourn. "Nevertheless, the fact that the latter contains larvæ in the brood-pouch while living at an altitude of 700 feet entitles it to be included in the fauna of the Indian Empire, and suggests that it is able to flourish in jungle-streams, even if it also occurs in the sea."

In an article contributed to the May number of *Cassell's Magazine*, entitled "The Vandalism of Collectors," Mr. S. L. Bensusan directs attention to the evil effects on the British fauna produced by the recent expansion of nature-study. For it is pointed out that a considerable proportion of those who cultivate this pursuit are not content with acting the part of observers, but join the ranks of regular collectors. This entails a large destruction of birds and their eggs (probably to a great extent illegal), as well as a prodigious slaughter of butterflies and moths, to say nothing of the reckless uprooting of wild flowers. Game-preservers and game-keepers also receive a share of blame, although it is admitted that the latter are worse than the former. In conclusion, the author observes that it would have been better for the wild life of the country if the cult of nature-study had developed side by side with a fuller recognition of the claim of the wild fauna and flora to protection, or with definite legal restrictions on the taking of specimens for private purposes.

At the conclusion of his presidential address to the Quekett Microscopical Club, on some problems of evolution in the simplest forms of life, as reported in the Journal of that body for April, Prof. E. A. Minchin expressed the opinion that in the case of the Protista syngamy is the factor which checks variation among individuals exposed to slightly different external conditions. With such restraining influence a species would tend to break up into different races and strains, either as the result of varying environment or from an innate tendency to divergence. Syngamy, on the other hand, tends to reduce individual differences to a common level. If this be correct, and if it be also true that there is no syngamy among them, it follows that real species do not exist among bacteria, the

members of which must be regarded as strains, without the stability of a species, and liable to modification in any direction by environmental influence. Hence he thinks it "evident that the passage from the bacterial to the cellular grade was perhaps the most important advance in the evolution of living beings. The acquisition of the cellular type of structure was the starting-point for the evolution, not only of the higher groups of the Protista, such as the Protozoa and unicellar plants, but through them of the whole visible everyday world of animals and plants, in all of which the cell is the unit of structure, and which consist primarily of aggregates of cells."

MR. A. R. NICHOLS records (Fisheries Ireland Sci. Invest., 1910, i.) 101 species of Polyzoa from the coast of Ireland, twenty-three of which have not been recorded previously from that coast, and six are apparently new to the British list. Mr. W. M. Tattersall (ii.) describes and figures, from the north-east Atlantic slope, six species of Mysidæ, of which a preliminary diagnosis only had been published, and also defines two new species and two new genera. Four bottom-living species are added to the British and Irish list, two of which were known previously only from the west coast of Greenland. Mr. R. Southern (iii.) contributes observations on certain pelagic Polychæta of the coasts of Ireland, and records *Vanadis formosa*, *Greefia celox*, Callizona (three species), Tomopteris (four species), Travisiopsis (two species), and Sagitella (two species), all of which, except two of the species of Tomopteris, do not appear to have been previously recorded from the British marine area. All these pelagic species live in warm and comparatively highly saline waters of the European branch of the Gulf Stream drift, and are carried therein towards the west coast of Ireland, but only rarely do they cross the 200-fathom line.

THE *procès-verbaux* of the council and sections of the International Marine Investigations, the meetings of which were held in Copenhagen at the end of September last, contain interesting references to observations completed and in progress. Prof. D'Arcy Thompson criticised the investigations on the age and growth of herring as determined from the scales, holding that the number of rings exhibited was subject to individual variation, and did not necessarily give a correct determination of the age of the fish. Prof. Heincke maintained that the method of age-determination by the scale-rings was scientifically sound, and Dr. Hjort stated the reasons for his belief in the trustworthiness of this method, remarking that herring examined in all months of the year showed rings which varied exactly according to the time of the year. Dr. Heincke contributed a summary of the present condition of certain aspects of the investigations on plaice. The spawning conditions of plaice are now well known, various more or less separated spawning places having been found in the southern and northern North Sea, the Kattegat, the Belt, and the Baltic, closely correlated with which are different local races, of which six or seven are distinguished, namely, those associated with the regions just mentioned and others with Iceland and the Barents Sea. Those of the Baltic and Barents Sea are slow-growing races, while those of the North Sea and Iceland are quick-growing races. The recognition of these differences is of great importance in connection with the questions of over-fishing and the plaice-production of different regions of the sea.

PRESENTING in the *Bulletin du Jardin Impériale Botanique*, St. Petersburg (vol. xi., part i.), a list of fungi collected within the government of Samara, Mr. N. N. Woronichin comments upon a new species of Physalospora taken on fruits of Caragana and certain allied species that grow parasitically on species of Astragalus.

ON account of the marked sensitivity of the apex of the coleoptile or first green leaf, oat seedlings are frequently employed for heliotropic experiments, and it has been stated that an incision made in the coleoptile, whatever its orientation, does not prevent the transmission of a stimulus. While offering evidence modifying this statement to the extent that an incision on the posterior side may inhibit the transmission, Mr. P. B. Jensen describes experiments in the *Bulletin de l'Académie Royale des Sciences et les Lettres de Danemark* (No. 1) in which he cut right through the coleoptile, replaced it, and then obtained proof of transmission in the case of stimuli induced by light and also by gravity.

FOREST Bulletin No. 1 of 1911, issued by the Government of India, gives an account of tests of the calorific values of fifty-six specimens of Indian woods carried out by Mr. Puran Singh, Forest Chemist to the Government. The Lewis Thomson calorimeter was used, one kilogram of the wood being burnt in oxygen. The results for thoroughly dried woods lie between 4000 and 5000 kilogram calories per kilogram of wood for the whole of the samples tested. For air-dried wood, which contains about 15 per cent. of water, the calorific power lies between 3500 and 4300 kilogram calories per kilogram of wood. Charcoal prepared from the woods has an average power of 7000 kilogram calories per kilogram.

SYSTEMATIC articles in the *Kew Bulletin* (No. 3) consist of a long series of diagnoses of new tropical African species of Loranthus already enumerated in the "Flora of Tropical Africa," a note on Spatholirion by Mr. S. T. Dunn, and a critical opinion by Mr. T. A. Sprague on the exact status of two saxifrages known as *lingulata* and *lantoscana*, according to which the latter should be regarded merely as a variety of the former. A notable instance of invasion of our southern shores by an alien brown alga, *Colpomenia sinuosa*, is described by Mr. A. D. Cotton. The alga thrives best in sheltered situations, and makes its growth principally in the autumn; persisting through the winter, it produces spores in spring and disappears in summer. On the authority of Lieut.-Colonel A. F. Appleton, a discrimination of the ordinary Transvaal grasses is provided; outside the species of Eragrostis, Panicum, and others well known, *Anthistiria imberbis* and *Chloris virgata* are recommended as fodder plants.

A GENERAL index has been issued for the Journal of the Board of Agriculture in two volumes, dealing with the two periods 1894–1904 and 1904–11. Since the Journal started in 1894, it has maintained a high standard, and has published many articles of permanent value. All these are rendered much more available, now that the general index has appeared, than they were before.

WE are in receipt of the Madras Agricultural Calendar, April, 1911, to March, 1912, issued by the Agricultural College and Research Institute, Coimbatore, containing a number of articles intended for the large and the small agriculturist. In the nature of things, the college is able to play a much more paternal part in the life of the community than would be possible elsewhere, and this publication shows clearly how very extensive are the ramifications of an Indian agricultural department.

THE seasonal distribution of egg production has formed the subject of a biometrical study by Drs. Pearl and Surface, the results of which are published in Bulletin 110

of the United States Department of Agriculture Bureau of Animal Industry. Four cycles were found in the year, the winter period, November to March, wherein egg production is essentially a non-natural (*i.e.* a forced or stimulated) process, the spring period, March to June, this being the natural laying period of the fowl, and two later periods, June to September and September to October. The third period represents in part a natural continuance of the normal breeding period, and in part a stimulated process; it is terminated by the moult, the characteristic feature of the fourth period.

The Harper Adams Agricultural College has recently issued two reports, one dealing with the experiments carried out in the counties of Staffordshire and Shropshire. Numerous field trials are reported in various centres, dealing with the effects of the various artificial manures alone and in various admixtures on the common crops. Some of the proportions are a little difficult to understand; one of the mixtures, for instance, being composed of 1½ cwt. of one constituent, 3⅛ cwt. of another, and 1⅝ cwt. of a third. Unfortunately no soil analyses are given, nor are there any meteorological data for the various centres, so that discussion of the results is not possible. At the college itself, work has been continued on the "wart" disease of potatoes caused by the fungus *Synchitrium endobioticum*, Percival, not the least interesting feature of which is that certain varieties of potato are immune, whilst others, in the same conditions, are attacked.

In *La Géographie* (No. 3, 1911), M. N. Villate gives an account of his recent journeys from Tidikelt to the Niger by the Ahaggar, and adds to our accurate knowledge of the French Sahara. His object was to extend the network of astronomically determined positions, and he succeeded in obtaining the latitude and longitude of forty-nine points. Equal altitudes of stars were observed for latitude and chronometer correction; longitudes were obtained when practicable by occultation of stars, and chronometer watches furnished a means of determining the difference of longitude between neighbouring points on the route. Observations were also made of the magnetic declination, inclination, and horizontal force at some thirty-five to forty points from Biskra in the north to Gao on the Niger in the south. In consequence of changes which were found to have taken place in the magnetic moment of the magnets during the journey, values of the horizontal force can only be given to three places of decimals of C.G.S. units.

Miss Georgina King has reprinted several newspaper articles in a pamphlet entitled "The Mineral Wealth of New South Wales and other Lands and Countries" (Sydney: Brooks and Co.), with some additional matter and a personal introduction. Her main contention is that the ore-deposits were connected with volcanic activity, which was especially prevalent in Tertiary times. Man, however, is said to have existed in Australia in "the early Tertiary period," and to have acquired a wandering propensity from the mental shocks then received. Glossopteris is said to be in Europe exclusively a Mesozoic plant. Waterspouts over oceans are attributed to "upheavals of subsided metamorphic matter." We can understand the writer's assertion that geologists in Australia have objected to the publication of such papers in scientific journals; but we can scarcely believe, as is alleged, that their motive was a fervent desire to issue the results under their own names.

The Italian Seismological Society has issued a volume of notices of the earthquakes observed in Italy during the year 1907. The volume is compiled by Dr. G. Martinelli, assistant in the R. Ufficio Centrale di Meteorologia e Geodinamico at Rome, and forms the appendix to the fourteenth volume (for 1910) of the *Bollettino* of the Seismological Society. Twenty years ago, such notices were contained in a few sheets of the *Bollettino Meteorico* of the central office. When the Seismological Society was founded in 1895, they were issued in detachments with each part of the *Bollettino*. Published, as they now are for the first time, in a separate volume of nearly six hundred pages, we can form some idea of the magnitude and value of the work, for the editing of which Dr. Martinelli is responsible. Among the most interesting of the notices are those on the Calabrian earthquake of October 23, 1907. These form the foundation of the report that will shortly be issued by the Government Commission on this violent, if somewhat restricted, shock.

The monthly meteorological chart of the North Atlantic, published by the Meteorological Committee for May (first issue), includes useful synoptic weather charts of that ocean for April 6–12 (commencing with the day following the blizzard experienced in this country). They show that during nearly the whole of the period in question there was an area of high barometric pressure outside our north and north-west coasts, and that it extended at times to the mid-Atlantic. This distribution of pressure explains the severe weather over England and France, which was accompanied by frequent showers of snow and sleet. As the central part of the anticyclone extended southward the weather became finer. The chart of the Indian Ocean for the same month contains an interesting communication on phosphorescent seas from Admiral Tydeman, of the R. Netherlands Navy (see Nature, March 16). We note that the chart has been further improved, and extended to the eastward.

A new method of producing the line spectra of a metal, which promises to facilitate greatly the study of the subject, is described by Dr. G. Gehlhoff in the *Verhandlungen* of the German Physical Society for March 30. It makes use of the fact that the inactive gases, helium, argon, &c., are spectroscopically extremely sensitive to impurities, their lines disappearing from the positive glow of the vacuum tube if small quantities of air or water vapour are present. A small quantity of the purified metal to be investigated is introduced into one of the ordinary spectral tubes, and the tube washed out with, and finally filled with, helium. On passing the discharge the tube may or may not give the lines of the metal in the positive glow, but on heating it, a temperature can always be found at which the lines appear, and a higher temperature at which the helium lines disappear completely. These temperatures are respectively, for cæsium, 50° and 70° C.; for sodium and potassium, 80° and 140° C.; while for mercury the temperature of the room is sufficient to produce the lines of the metal.

The March number of the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale* contains the first instalment of a lecture on the electrification of railways, delivered before the society in November last by M. de Valbreuze. After giving a short history of the slow progress of electrification previous to 1905, and its rapid extension since that date, the author describes the principal features of the systems at present in use under the heads:—Direct current 500–700 volt systems, triphase systems, monophase systems, and direct current high-pressure

systems. As the article is well illustrated and deals to a large extent with installations less well known in this country, it will prove of great value to those who wish to get a bird's-eye view of the present state of the problem of electrification of railways. Subsequent articles will deal more in detail with the conditions under which electric traction is advantageous, and the relative merits of the various systems.

We learn from an illustrated article in *The Engineer* for April 28 that the 9,000,000-gallon water tank, constructed by Messrs. Clayton, Son and Co., of Leeds, for the water supply of Calcutta, is now finished. This tank is 321 feet square and is 16 feet in depth. The height from the top of the tank to ground level is 110 feet; the tank is supported by a large number of braced steel columns. The tank is divided into four compartments by cross frames, each of which can be used independently, so that one or more compartments can be put out of service for cleaning or repairs without interrupting the service from the others. The tank is constructed of steel plates ⅜ inch in thickness and is thoroughly stiffened. The tank is roofed in, the roof overhanging the tank by 12 inches. Plates and brass wire gauze are fitted in order to prevent birds, &c., from gaining access to the tank. The tank had to be made absolutely watertight by the terms of the contract, and this has been carried out successfully.

The Cambridge University Press has published separately, price 3*s*., the exercises from Dr. C. Davison's "Algebra for Secondary Schools," which was reviewed in Nature on November 19, 1908 (vol. lxxix., p. 65).

Messrs. Witherby and Co. have in the press and will shortly publish an illustrated travel book, entitled "Through South Westland," by Miss A. M. Moreland, being a chronicle of a ride through a district in New Zealand which is little known to the outside world.

The latest ornithological catalogue of Messrs. John Wheldon and Co., 38 Great Queen Street, London, W.C., which has been received, is conveniently arranged under countries. It includes particulars of the books from the library of an eminent ornithologist lately deceased, and selections from several other important libraries. The catalogue gives details of 1450 books and papers.

The Royal Insurance Company, Ltd., of Liverpool, has issued the eighth edition of "Records of Sports." Among its new features may be mentioned the section dealing with aviation, which provides full information, up to the end of 1910, of notable performances and other events in connection with aviation. The details provided in connection with many sports have been greatly amplified. Copies of this interesting book of reference may be obtained, so long as the supply lasts, by applying to the manager of the company at 1 North John Street, Liverpool.

Erratum.—In the abstract of a paper read before the Royal Society of Edinburgh, printed in Nature of April 6, p. 200, second column, line 8 from bottom, the ^{n} in the formula $y^{n}(x+a)$ was omitted. The formula was printed exactly as it was in the type-written copy supplied by the reporter, and the error was unfortunately not noticed by him in proof.

OUR ASTRONOMICAL COLUMN.

Meteoric Fireballs and Meteors.—On April 30, at 11.58 p.m., the Rev. T. E. R. Phillips, of Ashtead, Surrey, saw a fine meteor about three times as brilliant as Jupiter. It was directed from Virgo, and disappeared in 206° + 14°, only the end course of about 3 degrees being observed.

On May 2, at 10.53, Mr. J. H. Elgie, of Leeds, saw a fine meteor equal to Venus descending from 2° above β Serpentis to 4° above β Libræ.

On May 4, at 8.52 p.m., Mr. S. A. Wilson, of Reigate, Surrey, witnessed the flight of a magnificent meteor from the Polar star to a few degrees below Capella. Its light was estimated as three times the apparent lustre of Venus. It left a long train in its wake, and moved with fairly slow speed. The radiant point was probably in the eastern sky at about 247° + 2°, as there is a very active shower of bright meteors from this point in May, and the direction of the fireball of May 4 is nearly conformable with this stream.

Mr. F. T. Naish, of Bristol, watched the eastern sky on May 4, 14h. to 15h., and saw eight fairly bright meteors. Three of these were conspicuous from their streaky trains and very long flights, and they were directed from the radiant point of Halley's comet. The paths intersected at 338° − 2°. The shower of Aquarids supposed to be associated with the famous comet referred to has certainly returned this year, though not in special abundance according to the reports already received.

The Total Eclipse of the Sun.—Major Hills, secretary of the Joint Permanent Eclipse Committee, has, according to *The Times* of May 5, received a telegram from Father Cortie stating that thick cirrus clouds persisted at totality, but photographs of the corona and spectrum were obtained; the corona was characteristic of the minimum sun-spot period.

A telegram received by the Astronomer Royal from Mr. Worthington, who was also stationed at Vavau, reads:—"Splendid photos, inner and outer corona, one and a half degrees."

A later communication states that Mr. C. L. Wragge, formerly meteorologist to the Queensland Government, saw the eclipse under excellent conditions at Lifuka, Friendly Islands. Hydrogen prominences were wonderfully distinct, and, apparently, a four-vaned corona was seen extending some distance from the moon's disc.

Spark Spectra of Calcium and Hydrogen in a Magnetic Field.—Some results possibly of great importance in the study of solar physics are published by M. Hemsalech in the *Comptes rendus* for April 24 (vol. clii., No. 17, p. 1086).

M. Hemsalech finds that when a spark is passed perpendicularly to the lines of force in a strong magnetic field, the enhanced lines in the spectrum of the spark behave differently from the arc lines. When the spark passes between calcium poles, in a field of from 4000 to 6000 C.G.S., it is violently projected in a sheaf at right angles to the lines of force, and a spectroscopic examination of this sheaf shows that the line at λ 4227 is as long as H and K; the spectroscope is pointed parallel to the lines of force. When the spark is passed in a strong transverse current of air, without a magnetic field, the 4227 line is much longer than H and K.

But when the spark is passed, in the magnetic field, in an atmosphere of hydrogen, a remarkable change takes place, for whereas the respective heights of the H and K lines were 22·6 and 23·7 cm., the 4227 line was only 16·3 cm.; the heights of the hydrogen lines were Hα 21·4, Hβ 20·0, Hγ 18·8, and Hδ 16·3 cm. The spark lines at λ 3706 and λ 3737, in the vicinity of the poles, are also higher than the arc lines λ 4283 and λ 4455. In an atmosphere of oxygen, however, the 4227 line is as long as H and K, and if a weaker current, 800 C.G.S., is employed, it becomes longer and stronger than they.

M. Hemsalech tentatively suggests an analogy with the solar conditions. A mass of hydrogen atoms carrying electric charges, and travelling parallel to the solar surface, might, in the magnetic field around a spot, become violently projected, as in the laboratory, and carry with it to as great or a greater height the calcium vapour so abundant in the solar atmosphere; this could not happen immediately over a spot nucleus, for there the lines of force are perpendicular to the solar surface.

The Solar Constant.—Messrs. Abbot and F. E. Fowle, jun., discuss the value, during recent years, of the solar constant of radiation in No. 3, vol. xxxiii., of *The Astro-*

physical Journal. Two outstanding questions regarding the work are now settled. The first was the true pyrheliometric scale, which, as pointed out in these columns on April 20, they have now decided upon. The second was that of carrying the energy-spectrum observations further into the ultra-violet, with the prospect of increasing the values of the constant previously given, and this has now been done. During this work it was discovered that a region containing considerable energy in the ultra-violet was neglected in the 1905–6 observations, but a special investigation shows that there is no need to raise the value of the solar constant obtained for that period; the published coefficients of atmospheric transmission for 1905–6 are, however, all about 1·4 per cent. too low.

The values of the constant derived from the 1905–9 Mount Wilson results indicate a range of solar variability within a range of 8 per cent., which does not appear to be accidental, and the agreement of the results obtained at different altitudes discounts the probability of this variation having an atmospheric origin. The mean value of the solar constant obtained for the period 1905–9 was 1·922 calories (15° C.) per square centimetre per minute, and this is probably correct within 1 per cent. The most likely explanation of the 8 per cent. variation is that there are really variations of 0·03 stellar magnitude in the solar radiation outside our atmosphere.

PHOTOGRAPHIC OBSERVATIONS OF SOLAR PROMINENCES.—Valuable additions to our knowledge concerning the sun's atmospheric disturbances are likely to accrue from the systematic study of the spectroheliograms showing solar prominences. The results of such a study are published in No. 2, vol. xxxiii., of *The Astrophysical Journal* by Mr. G. Abetti and Miss R. E. Smith, who have reduced a large number of spectroheliograms taken at the Mount Wilson Observatory, and compared the prominences with those shown on photographs taken at the Yerkes Observatory and with those observed visually at Catania. The comparison of the Hα and the calcium-light photographs *inter se* and with the Catania hydrogen observations reveals several points of interest. Among these it would appear that the calcium vapours rise to greater heights than those of hydrogen, a feature shown both in the measures of heights and of areas. The mean height (56″) of the Mount Wilson calcium prominences is about 7″ greater than the mean height of the hydrogen prominences observed there and at Catania. It would also appear that the calcium prominences have a slightly different distribution from those of hydrogen. Results for the period 1906–8 are tabulated and plotted, and one or two special cases of interrelation with disturbed areas are discussed.

THE MOVEMENT OF STARS OF THE ORION TYPE.—In a paper published in the *Bulletin de l'Acad. roy. de Belgique* in 1910, Dr. Stroobaut directed attention to the different values obtained for the sun's velocity through space when it was derived from the radial velocities of Orion stars from when it was derived from the velocities of other stars; since then Profs. Frost and Kapteyn, using different coordinates for the apex, have disclosed a similar difference. Dr. Stroobaut has recalculated his values with their value for the apex, and finds that his new results show practically the same difference as theirs. He obtains for the solar velocity 19·25 km. when using all stars, and 21·8 km. for the Orion-type stars; the latter is divided into 16·0 km. in the region of the apex and 26·2 km. near the antapex (*Bull. de l'Acad. roy. de Belgique*, No. 1, p. 30).

EPHEMERIS FOR ENCKE'S COMET NEAR PERIHELION, 1911.—In No. 39 of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo* Dr. Backlund discusses the orbit of Encke's comet during recent years, and tabulates the several perturbations it has suffered since its apparition in 1898; these are very small. He also gives a revised set of elements, from which he has prepared an ephemeris covering the period of perihelion passage and extending from July 1 to September 21; the return is not a favourable one for observations.

THE CATANIA OBSERVATIONS OF SUN-SPOTS AND FACULÆ, 1910.—Prof. Riccò's annual tabulated summary (1910) of the spots and faculæ observed at the Catania Observatory appears in No. 3, vol. xl., of the *Memorie di Astrofisica ed Astronomia.* The values for the year show that the solar activity is still declining. The mean daily frequency of spots was 1·7, and on 104 days (35 per cent.) no spots were recorded.

THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THE Royal Photographic Society is holding its annual exhibition in the spring instead of the autumn this year, and in the hall of the Prince's Skating Club, Knightsbridge. The exhibition is open now and closes on the last day of this month. Queen Alexandra has graciously contributed sixteen of her own photographs, and surrounding these there is a very large collection of portraits of King Edward VII. As these date from about 1853, they may be studied both as a pictorial history of our late King, and also as representative of the development of photographic portraiture from the early days of the collodion plate. Entomologists and microscopists will be pleased to see a fine portrait of Mr. Fred. Enock, by Furley Louis, in the same gallery.

There is a large collection of autochromes, with here and there among them colour transparencies by other analogous processes. By daylight they are excellently shown, and indicate that the number of those who employ these processes for the photography of colour is rapidly increasing, and that the general results are far more successful than they were a year or two ago. Sir W. J. Herschel and Mr. J. H. Gear both show photographs of rainbows, which are very different from the poor representations that the best of monochrome photography can render of them. There is some notable photomicrographic work in colour, especially various minerals and crystals shown between crossed Nicols, and among Prof. Waymouth Reid's collection there are a few examples of high-power pathological work.

The general natural history section is not very extensive, but includes several "life-histories" of moths, butterflies, tadpoles, and, by Mr. William Farren, a series of twelve prints illustrating the nesting period of the nightjar. The "Great American Egret," by Mr. Hugh C. Knowles, and "Gannet going down wind," by Mr. Oliver G. Pike, are of special interest at the present time.

The scientific section is larger than it has been lately. This branch of the subject can never be adequately represented, because only a small proportion of the scientific work done is suitable for an exhibition, but this year the society has been successful in getting together an excellent collection. High-power photomicrography is well represented. Dr. T. W. Butcher's *Navicula Smithii* and *Coscinodiscus asteromphalus*, and Dr. Duncan J. Reid's Trypanosomes are specially noteworthy. Mr. Charles R. Darling shows a series of photographs of drop formation taken comparatively slowly, with exposures of one-tenth of a second instead of, as heretofore, in a few millionths of a second. The drops are of aniline oil in water. Among the radiographs, the series by Dr. Thurston Holland represents probably the finest work at present possible in this direction. Ten lantern slides of a normal stomach, taken by Dr. F. Haenisch with a Rœntgen-cinematographic apparatus, show the peristaltic wave moving down the great curvature. Prof. Zeeman contributes an illustration of his recent work on the effects of a magnetic field on the absorption sodium spectrum lines, and Prof. R. W. Wood sends some of his photographs of landscapes taken with the infra-red radiations. Dr. George H. Rodman shows photomicrographs of the pollen cells of fifty different flowers, and also a series of stereo-photomicrographs of natural history and botanical subjects, which represent some small objects, such as diatoms, in a realistic way that is very rarely seen.

Among the astronomical exhibits that will be studied with interest are fifty transparencies by Dr. Max Wolf, of Heidelberg, of various comets and nebulæ with their spectra, photographed under different optical conditions, and an extensive series of photographs of planets and comets and their spectra, lent by the Lowell Observatory. Of the many other noteworthy subjects we can only refer to illustrations of rotary photogravure in its applications to newspaper illustration and three-colour printing, shown by Mr. A. J. Newton, the principal of the London County Council School of Photo-engraving.

GEOLOGICAL WORK IN BRITISH LANDS.[1]

III.—IN CANADA.

THE Geological Survey Branch of the Canadian Department of Mines has a large amount of pioneer work before it. In a publication numbered 1097, issued in 1910, Mr. J. Keele describes his reconnaissance across the Mackenzie Mountains in Yukon and North-West Territories, involving much personal risk and often dependence on hunting for a supply of food. The country that he explored along its rivers lies between the Mackenzie Mountains, a part of the Rocky Mountain axis, and the St. Elias Range. The valley bottoms are practically free from frost during June, July, and August; but the temperature varies from well below zero in January to 90° F. during the almost continuous daylight of June. Cambrian, Silurian, Devonian, Triassic, and Cretaceous strata have been recognised, and Mr. R. G. McConnell has described a basin of Cainozoic rocks, including basalt. Granite, intruded in local "stocks or pillars" (p. 41) into old sediments, is responsible for Mount Sheldon and other upstanding peaks of the Mackenzie Mountains (Fig. 1). The map accompanying the memoir, like the illustrations, is a fresh contribution to geography.

FIG. 1.—Mount Sheldon, Mackenzie Mts., a granite mass intruded into Palæozoic sediments.

Mr. W. McInnes reports (No. 1008) on a part of the North-West Territories drained by the Winisk and Attawapiskat Rivers, with a large map on the scale of one inch to eight miles, geologically coloured along the rivers traversed. Topographical surveys were made during journeys by canoe. This region, lying north of the Ontario border, has no great relief; the Archæan plateau has been smoothed by glaciation, and much of the lowland is covered with boulder-clay, in which the streams now cut characteristic vertical cliffs. Post-glacial marine clays, with *Pecten islandicus*, *Mya truncata*, and *Mytilus edulis*, those widely spread molluscs of the north, occur in the valley of the Winisk, presumably representing an inflow from Hudson Bay. Lists of living land and fresh-water shells are given on pp. 52 and 53, and will be sought for here only by those zoologists who know the observant outlook of the Canadian Department of Mines. Its Memoir 14-N, by the by, is devoted to new species of marine shells dredged off Vancouver Island. In a report bound up with that on the Winisk area, Mr. A. Wilson describes a traverse from Lac Seul to Cat Lake, across an unexplored area of 15,000 square miles in extent, to the west of that examined by Mr. McInnes. The rocks consist of amphibolites and mica-schists, penetrated by granitoid gneisses on the south, the latter containing inclusions of amphibolites. Here, as so often happens, the schistose rocks, with their metamorphosed basic associates of igneous origin, are the oldest recognised in the district.

Mr. W. H. Collins's account (No. 1059) of the geology between Lake Nipigon and Clay Lake, Ontario, is remarkable for its clear acceptance (p. 52, &c.) of the intrusive relation, over wide areas, of the Laurentian to the Keewatin and Huronian series. Inclusions of the latter in the gneisses, far away from any junction of the two types of material, are used as an argument for the former extension of a schistose mantle over the whole area. It may be confidently stated that in our islands such inclusions would be often treated under the mysterious title of "basic segregations."

The Survey now (1910) issues a definite series of publications styled Memoirs, No. 1 being by Mr. A. Wilson on the geology of the Nipigon Basin. In Lake Nipigon we are glad to note the occurrence of Murchiston, Geikie, and Kelvin Islands, all constructed of firm crystalline rock. These are parts of the great and almost horizontal sheets of diabase which cover a wide area, and which remind one of similar occurrences in the Karroo systems of South Africa. After a full discussion, the author concludes that the capping diabase in his area represents a lava that flowed over a land-surface of great extent, to which it is unconformable, and from which, at certain points, it has gathered boulders (p. 94). The sedimentary series of shales, sandstones, and dolomites, in which the igneous sheets are intercalated, are at present classed as Keeweenawan, but Mr. Wilson thinks (p. 71) that they may be younger than even the Potsdam series farther east. The gneisses that occur below the Huronian series include basic types that "probably represent highly metamorphosed portions of the cover, or rather are new rocks whose constituents in part were derived from the cover, and in part from the granite magma" (p. 57). Many features of the surface that might have been attributed to glacial erosion are found to pass under the diabase sheets, and the author regards the ice in this area as comparatively unimportant from a moulding point of view.

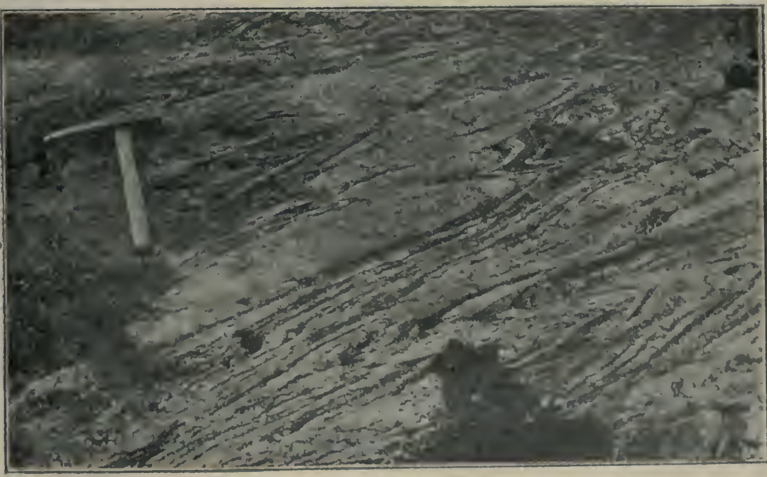

FIG. 2.—Gneiss formed from red granite and amphibolite, with contortion due to flow, and a tendency to produce a second direction of banding. Near More Falls, Ontario.

Mr. D. Cairnes, in Memoir 5, writes on the coal district of the Lewes and Nordenskiöld Rivers, the latter

[1] The second article appeared in NATURE of April 27 (p. 292).

being a tributary of the former, and both draining ultimately into the Yukon. The coals are of Jurasso-Cretaceous age. The physiography and natural history of the district are described, and the summer months are said to be delightful. The drift-filled valley floors, set with little lakes, are likely to attract stock-raisers and even cultivators.

Messrs. F. D. Adams and A. E. Barlow furnish an important memoir of some 400 pages (No. 6, price 30 cents) on the Haliburton and Bancroft areas of Ontario. This region is part of a great elevated plain, dissected into moderate and rolling hills, and formed of Laurentian granite-gneisses, with inclusions of amphibolite. The authors give conclusive reasons for regarding the latter masses as derived from the roof or walls of the granite batholith; the blocks fell into the magma, and partook of its subsequent movements (p. 121). Frequently they become streaked out, until strongly banded and even contorted gneisses are produced (Fig. 2); but the authors hesitate (p. 123) to urge that all the grey gneiss of the district has originated in this composite way. The amphibolites, even on a large scale, are traced to the contact-alteration of limestones by the granite, with perhaps some intermingling from the igneous magma. This is, of course, what has been urged in many other areas; but the broad exposures in these undulating Canadian lands offer unusual opportunities for demonstration. Many other types of crystalline rock are described, including syenites with corundum, and the whole memoir is one of immense interest to the petrographer. The corundum is worked commercially (p. 371).

Mr. J. Dresser describes St. Bruno Mountain, in Quebec, in Memoir 7, a mass of ultrabasic igneous rock intruded into Ordovician rocks, probably in Devonian times. Mr. D. Dowling deals, in Memoir 8-E, with the promising field of Cretaceous and Cainozoic coals at Edmonton, on the Saskatchewan, in the north-west.

Memoir 3 is a quarto by Mr. L. M. Lambe on Palæoniscid fishes from the Albert Shales of New Brunswick. The author correlates these beds (p. 14) with the Scotch Calciferous Sandstone. He figures, among other specimens, the types that were described by C. T. Jackson, without illustrations, in 1851.

Mr. C. D. Walcott (Smithsonian Miscell. Collections, vol. liii., No. 7, 1910) has carried his studies of Cambrian stratigraphy into the Bow River Valley, Alberta, Canada, a highly picturesque and mountainous region, where he finds that the basal Cambrian beds rest unconformably on unaltered pre-Cambrian shales and sandstones.

Perhaps we may mention here, in conclusion, a paper by Mr. R. Guppy, published in Canada (Trans. Canadian Institute, vol. viii., p. 373), on "The Geological Connections of the Caribean Region." Mr. Guppy, writing from Trinidad, discusses deep-water Cainozoic beds in Jamaica and other islands, and argues for a former "land connection between the Caribean and North Africa and a sea connection between the Caribean Sea and the Pacific." Both these probably passed away at the close of Miocene times. Mr. Guppy has a way of abolishing double letters in generic names, which may be American, but is hardly fair to their originators.

G. A. J. C.

PRESSURE IN STELLAR ATMOSPHERES

WITHIN the last fifteen years the spectroscopic equipment applied to the study of both laboratory and celestial investigation has been very materially modified both in dispersive power and design. In the early 'nineties there were very few of the 21·5-feet Rowland concave grating spectrographs in regular commission for terrestrial research, and it is probably safe to say that no stellar spectrographs were in use giving direct spectra comparable in dispersion with Rowland's solar spectrum.

The transference of Dr. G. E. Hale's sphere of labours from the Yerkes Observatory to the new solar observatory on the summit of Mount Wilson, Pasadena, California, in 1905, however, marks an important epoch in the progress of spectroscopy, as from that time may be dated the successful application of high dispersive spectrography to the problems of celestial and terrestrial identification, both chemical and physical. Many of the beautiful discoveries have already been noted as they were announced: the photography of sun-spot spectra on a sufficiently large scale to serve as a standard map for future reference, the magnetic field accompanying the sun-spot vortices, the detailed laws of solar rotation, all giving an enormous mass of detailed evidence from which fruitful discussions may be profitably initiated. In the examination of certain of the solar photographs numerous peculiarities were noticed in the relative wave-lengths of the lines, indicating the operation of a definite law. Some time previously Halm had announced (*Astronomische Nachrichten*, Bd. 173, p. 273, 1907) that certain iron lines were relatively displaced to the *red* at the sun's limb compared with their position at the sun's centre. In 1910 Hale and Adams described the results of a long series of determinations of these minute displacements made with the spectrograph attached to the tower telescope of the solar observatory (*Astrophys. Journ.*, vol. xxxi., p. 30, 1910). After eliminating all the known differences owing to rotation and orbital motion, they found from an examination of 470 lines between λ 3741 and λ 6573 that the residual displacements could be classified to a certain extent. Thus the hydrogen lines, calcium (H, K, 4227), sodium D, and magnesium *b* lines showed no appreciable displacements, and this was also the case with the lines the intensities of which were greatly strengthened at the limb of the sun. The lines of titanium, vanadium, and scandium show considerably smaller displacements than the lines of iron and nickel.

The elements of high atomic weight, such as lanthanum, cerium, in general exhibited very small displacements.

The *enhanced* lines, as a class, showed decidedly *larger* shifts than the corresponding *arc* lines.

All these facts point to the suggestion that they are caused by the varying pressure in different parts of the sun's atmosphere, and it will thus be readily seen how, by a careful study of these interrelations and the laboratory variations known to exist under different modes of treatment, we may find it possible to arrive at a satisfactory explanation of the mechanism of the solar atmosphere.

Now to the astrophysicist the sun is simply our nearest star, presenting to us special facilities for local selective examination by reason of the fact of its having a disc of appreciable diameter, and furnishing abundance of light. When the problem is extended to the case of stellar atmospheres the difficulties are at once greatly increased.

It was to afford the means of attacking this question in an efficient manner that Dr. Hale planned the installation of a very high dispersion spectrograph to be used with the new reflecting telescope of 60 inches aperture which has been so perfectly designed, constructed, and adjusted into working trim by Prof. G. W. Ritchey. With the new spectrograph, the spectra of several of the brighter stars have been successfully photographed, and from a preliminary study of those of α Canis Majoris (Sirius), α Canis Minoris (Procyon), and α Böotis (Arcturus), Mr. W. S. Adams has been enabled to come to some interesting conclusions respecting the conditions existing in the atmospheres of these stars (*Astrophys. Journ.*, vol. xxxiii., p. 64, 1911; Contributions from the Mount Wilson Solar Observatory No. 50).

By means of subsidiary mirrors, the equatorial reflector is employed in the *coudé* form, the light being reflected down and through the hollow polar axis to the slit of the spectrograph. The equivalent focal length of the combination of mirrors is 150 feet (45·7 metres), giving an aperture ratio of 1 : 30.

For convenience of manipulation and constancy of temperature, the spectrograph was arranged vertically downwards in an underground pit. The spectrograph is of the Littrow or auto-collimation type, consisting of a lens of 15·2 cm. aperture and 5·5 metres focal length, used in conjunction with a dense flint-glass prism of 63° angle, and a plane mirror to send the light back through the prism, thus giving the equivalent dispersion of two prisms. The large scale of the dispersion thus provided will be evident from the approximate linear equivalents, given as follows:

At λ 4300, 1 mm. on photographic plate = 1·4 A.
,, 5000, ,, ,, ,, ,, = 2·4 A.
,, 6500, ,, ,, ,, ,, = 6·2 A.

Satisfactory definition is obtained throughout the whole length (43 cm.) of the plate used in the spectrograph camera. In the more refrangible portions of the spectrum Lumière "Sigma" plates were employed, while from λ 4900 to the red end Seed "Gilt Edge 27" plates sensitised by Wallace's formula were used. For comparison the spectrum of the iron arc was photographed alongside the star spectrum.

Six plates of the spectrum of Sirius (λ 4200 to λ 6600), four of the spectrum of Procyon (λ 4200 to λ 4900), and nine plates of the spectrum of Arcturus (λ 4300 to λ 6600) were available for measurement, and the chief object in the study of these spectra has been to test the possibility of detecting any differences of displacement for the different lines, and thereby obtain some idea of the effective pressure in the atmospheres of the stars. In Sirius the number of lines available for measurement was comparatively small; in the case of Procyon and Arcturus the selection of lines was similar to those used in the investigation of similar displacements of the lines in the spectrum of the sun's limb.

The enhanced metallic lines, it will be remembered, show as a class most definitely larger shifts at the sun's limb than the ordinary arc lines. Now in the spectrum of Sirius the enhanced lines form a prominent feature, while the arc lines are few. In Procyon the enhanced lines are less prominent, while the arc lines have become more pronounced. In Arcturus the enhanced lines are almost evanescent, while the arc lines, which are associated with the spectrum of sun-spots, are very strongly developed. Mr. Adams gives a table showing in summary form the main results of the inquiry, from which it is seen that in all cases the enhanced lines show a decided displacement to the red relative to the arc lines. Giving the displacements as radial velocities in kilometres, we may summarise the results as:—

Sirius: Enhanced—Arc Lines = +0·90 km. = +0·014 A
Procyon: ,, ,, ,, = +0·58 ,, = +0·009
Arcturus: ,, ,, ,, = +0·08 ,, = +0·001

The behaviour of the prominent lines in Arcturus is so definite that a special discussion is given of them. A large proportion of the lines of titanium, vanadium, and calcium are greatly strengthened, the enhanced lines decidedly weakened, and those of iron and chromium either strengthened or weakened according to their temperature gradation. The lines of nickel appear to be more prominent in the star spectrum than in sun-spots. The following table summarises this discussion:—

Element	Displacement Å	Equivalent Velocity km.
H	−0·020	−1·2
Ca	−0·017	−0·70
Mg	−0·011	−0·68
V	−0·006	−0·24
Ti	−0·006	−0·23
Ni	−0·006	−0·22
Fe	+0·006	+0·25

The shifts evidently suggest definite grouping of similar elements. The iron lines show a shift towards the red compared with all the other elements examined.

Such is the material Mr. Adams provides for his investigations. In the absence of any other known probable cause, he considers pressure as the principal agent causing these systematic displacements in stellar spectra. The laboratory experimental results of Humphreys and others gave as an average shift for the arc lines of iron 0·0025 Å per atmosphere of pressure. At the sun's limb the enhanced lines in the more refrangible portion of the spectrum were found to be shifted approximately 50 per cent. more than the arc lines, and recent work by Mr. Gale on the spectrum of titanium indicates that the enhanced lines of this substance are also shifted more than the arc lines at the same pressure. Assuming, then, that a similar relationship exists between the enhanced and arc lines of other elements, this affords a means of estimating the gravitational pressures in the atmospheres of stars the spectra of which show these displacements. Thus, as seen in the table quoted above, the enhanced lines in the spectrum of Sirius are shifted towards the red relative to the arc lines by 0·014 Å. This would correspond to a pressure of 12 atmospheres in excess of that existing in the sun's reversing layer. Similar reasoning in the case of Procyon indicates a pressure of 7 atmospheres over that of the sun's reversing layer. These results appear to be in accord with the modern view of regarding stars of the Sirian type as possessing no true photosphere, being simply a mass of gas increasing in density towards the centre without any surface of discontinuity or condensation. In such a star the light coming from great depths would most probably be visible from outside, and indications of great pressure would then be expected. In Procyon the spectrum indicates a transition stage between Sirius and the sun, and the pressure is shown intermediate also. It should be noted here, however, that one of the most important cases investigated by Humphreys in his work on pressure effects is directly opposed to the above conclusions. He found that in the case of calcium the blue *g* line was shifted by pressure about *twice* as much as the H and K violet lines. Now the behaviour of these lines in the laboratory, and also in the spectrum of the solar chromosphere, indicates that H and K are typical *enhanced* lines, while 4226 (*g*) is a very typical *arc* line. The differential pressure effect on the enhanced and arc lines of strontium was exactly similar to that of calcium, viz. the enhanced lines were shifted *less* than the arc lines. Unfortunately for this discussion, Humphreys only employed the arc spectrum in his pressure investigation, so that the general behaviour of the enhanced lines of other substances than calcium and strontium cannot be inferred from his results.

Passing on to the conditions of pressure in Arcturus, it is pointed out that the facts indicate the existence of a well-formed photosphere, the light from which proceeds from relatively low-pressure areas at moderate depths. The results for the lines of different elements indicated in the table are similar to those found for the solar lines. Thus in the sun hydrogen rises to very great heights, calcium and magnesium also being high-level substances. Titanium is also relatively high-level, but iron is distinctly a low-level element. In Arcturus the displacements indicate exactly such an arrangement, and it is thus concluded that the lines of H, Ca, Mg, Ti, &c., are subject to less pressure than those of iron, and therefore that the gases producing them lie at a higher average level.

CHARLES P. BUTLER.

RECENT INVESTIGATIONS ON SOIL FERTILITY.

FOR some years past the United States Department of Agriculture Bureau of Soils has maintained that infertility might, and not unfrequently does, arise from the presence in the soil of toxic organic substances that have been excreted from the roots of plants. This view has been opposed on two grounds: it is not evident that plants do normally excrete poisonous substances; and if such substances are present there is no proof that they would act as poisons in the soil, which possesses a remarkable power of withdrawing dissolved substances from solution. Not long ago Scheiner isolated dihydroxystearic acid from a considerable number of unproductive soils, and now, in conjunction with J. J. Skinner,[1] he has examined its behaviour to plants in water cultures. In all cases its effect was toxic, but the toxicity was much reduced when fertilisers were added to the solution, and was at a minimum when the fertilising constituents were present in the ratio most favourable to plant growth. Several incidental questions were also cleared up dealing with water cultures—perhaps the most difficult of all experiments to interpret—and the paper contains a great number of data bearing on the subject. The behaviour of this acid in the soil is not touched upon, and very wisely no attempt is made to argue from a water culture to a soil. It is, however, a distinct step in advance that an acid has been isolated from certain soils and identified, and shown to be poisonous in water culture. The results may well be connected with the known fact that, in absence of lime, soil becomes acid and loses fertility, which can only be restored by addition of lime or chalk.

[1] Bulletin 70, Bureau of Soils, U.S. Department of Agriculture.

So great is the part played by bacteria in determining fertility, that a great amount of attention is being paid in most soil laboratories to their various actions. The fixation of nitrogen is of perennial fascination, and is still far from being solved. Certain bacteria, notably azotobacter, can take up gaseous nitrogen and synthesise protein, nuclein, &c., without any materials save only sugar and various mineral salts. The organisms occur in most soils, and it is only necessary to inoculate small quantities of soil into a solution containing the sugar, phosphates, potassium and other salts, but no nitrogen compounds, for development to take place and nitrogen fixation to occur. The chemistry of the process is unknown; investigation, so far, has been confined almost entirely to morphological work and to the effect of various conditions on the process. Messrs. C. Hoffmann and B. W. Hammer, of the University of Wisconsin Agricultural Experiment Station, have recently (Research Bulletin 12) repeated and extended some of these observations. They find the best sugars are mannite and lactose, but it is not desirable to have too much. Similarly, there is no advantage in having too much calcium carbonate, although some is needed. In one respect these authors differ from previous investigators; on analysing the dry azotobacter cells they obtained a protein content of 17·75 per cent. only, against 80 per cent. found by Gerlach and Vogel and 70·6 per cent. by Stoklasa. The cause of the difference is not clear, but may perhaps be ascribed to the slime that invariably surrounds the organism without being an integral part of it, and that is only removed with great difficulty.

How far azotobacter is active in the soil is difficult to determine, because there is an opposite process, the liberation of gaseous nitrogen from protein, and also, under anaerobic conditions, from nitrates, also brought about by bacteria. But it has been shown by Koch that the addition of sugar to soil some months before the seed was sown led to an increase in crop by increasing nitrogen fixation, although if applied direct to the crop it produced harmful results. These facts are attracting much attention in sugar-producing countries, and it has been shown that waste molasses, which cannot profitably be sold, gives useful increases in crop when applied as manure some weeks before planting, especially on light soils. S. S. Peck, of the Hawaiian Sugar Planters' Experiment Station (Bulletin 34), has studied the two changes, nitrogen fixation and denitrification, and confirms the general results already obtained; molasses applied before planting stimulates nitrogen fixation, but applied to the growing plant it does harm by causing loss of nitrate or diminished nitrification.

He also confirms some recent work of Russell and Hutchinson, and finds that numbers of protozoa harmful to bacteria occur in soil—he found amœbæ, paramecium, and others—all of which can be destroyed by moderate heat or antiseptics like carbon disulphide. Partial sterilisation of the soil is being studied in several directions. *The Journal of Agriculture of South Australia* states that farmers there have long recognised the advantage of burning the stubbles, and thus heating the soil; investigations are in hand at the Roseworthy Agricultural College to study the problem from this new point of view. An apparatus for soil sterilisation suitable for gardeners is described in *The Journal of the Department of Agriculture of Victoria*, which is similar in principle to some that are working in England. *The Scientific American* recently gave an account of methods proposed in the United States.

Although nitrates are invaluable in the soil, an excess is injurious, because it causes plasmolysis. Dr. Headden, of the Colorado Agricultural College Experiment Station (Bulletins 155 and 160), reports analyses of soils in Colorado containing such excessive amounts of nitrates that they were sterile. He thinks their formation can be explained only as due to bacteria; he supposed that nitrogen fixation has gone on to an excessive degree, and has thus led to disastrous consequences. Further work on these soils will be awaited with interest.

The factors determining soil fertility are slowly being disentangled, but they are far from being fully known, and therefore investigations of cases of infertility are of considerable scientific interest, besides being of technical importance. Such a case is afforded by the scouring pastures of Somerset, now being studied by C. T. Gimingham, of the University of Bristol. Pastures in certain districts of the Lower Lias formation cause diarrhœa or "scouring" in cattle fed on them. No obvious explanation is forthcoming, no poisonous weeds are found, nor does the provision of a pure water supply obviate the trouble. Mr. Gimingham has, in *The Journal of the Board of Agriculture* (No. 7), collected the main facts, and adduces strong evidence to show that the physical condition of the soil is the determining factor, the peculiar conditions obtaining on the Lower Lias, but not on the adjacent alluvium and Inferior Oolite, being favourable to the factor actually causing the disease. Experimental work on this subject is necessarily slow and tedious, but, in view of its importance, it is much to be hoped that Mr. Gimingham will be able to continue the work on the sound lines on which he has begun.

The phenomena of flocculation and deflocculation in soils have been much investigated, but are far from being worked out. E. E. Free has recently summarised (Journal of the Franklin Institute) the present position of our knowledge, and has shown that a marked influence is exercised by impurities present in the water in which the suspensions are made for experimental purposes. He considers it probable that in absolutely pure water only a medium degree of permanence would be attained. In his view, any material can be suspended in water, flocculated, and deflocculated, if it can be got in a sufficiently fine state.

E. J. RUSSELL.

MUSEUM WORK IN INDIA AND AFRICA.

ACCORDING to the report of the Natural History Section, the year 1909–10 was an important one in the development of the Indian Museum, Calcutta, as it witnessed not only a reorganisation of the staff of that section, but likewise the passing of an Act to give greater independence to the constituent sections in the matter of scientific and educational work, and also to permit the respective chiefs of the same to become *ex officio* members of the board of trustees. As a result of the new regulations, it will be possible to separate the archæological from the zoological section, and to place the former under the control of the director of the Archæological Survey. Among the additions during the year, attention is directed to the cast of a susu, or river-dolphin, from the Hughli.

The report on the fishes collected by the *Golden Crown* is continued, by Messrs. Annandale and Jenkins, in No. 1 of the third volume of the Memoirs of the Indian Museum, these contributions including a supplementary note on the rays, together with accounts of the Plectognathi, Pediculati, and flat-fishes. As the collection of sharks made by the *Golden Crown* was relatively small, the consideration of that group is postponed. The teleostean collection, on the other hand, is so extensive that its description in an adequate manner will practically mean a revolution in our ideas of the Indian marine fish-fauna. In the present contribution three small and compact groups, to which the additions are comparatively few, have been selected for treatment.

From among nine papers on various groups of invertebrates in the fourth part of vol. v. of the Records of the Indian Museum it must suffice to refer to some interesting information, by Messrs. Henderson and Mathai, on the occurrence of dimorphism in certain fresh-water prawns of the genus Palæmon. In many, if not all, the species two forms of adult males occur, namely, a normal type of relatively large size, with well-developed nipping-claws, and a generally smaller type, with the same claws no bigger than in females. Among certain other decapods in which a similar dimorphism obtains, the two phases are recurrent, and severally represent the breeding and non-breeding conditions; but, so far as the authors of the paper could ascertain, this does not appear to be the case with the Indian Palæmons.

The classification of the anopheline mosquitoes of India forms the subject of No. 5 (it may be noted that "part" and "No." are respectively used in the two issues) of vol. iv. of the serial last quoted. The changes proposed are of a radical character, the author, Major S. P. James, refusing to admit that any of the species are referable to the typical Anopheles. The Indian members of the group

are divisible into two series, respectively characterised by the presence or absence of scales on the abdomen.

To the Annals—which now bear the alternative title of Mededeelingen—of the Transvaal Museum for November, 1910, Mr. J. Hewitt contributes a key to the South African members of four families of lizards, with notes on their distribution. The issue is also noteworthy on account of the inclusion of eight beautifully coloured plates to illustrate Mr. Meyrick's article on Microlepidoptera published in an earlier part.

REPORT OF THE BOARD OF EDUCATION.

THE report of the Board of Education for the year 1909–10, published a few days ago (Cd. 5616, price 8*d.*), contains an instructive statement of the position of elementary, secondary, and technical education in England. One section of the report, dealing with the teaching of science in secondary schools, was reprinted in NATURE of May 4 (p. 326), and we now give an abstract of other portions. The section of the report devoted to elementary education reviews the history and recent development of the provision made for teaching the pupils in public elementary schools, and touches upon certain aspects of the subject of school staffing which have been especially prominent very recently. With this subject we are not particularly concerned in these columns, but the subjoined extracts, relating chiefly to higher education, will interest readers of NATURE.

Establishment of the Universities Branch of the Board.

The Board has recently organised a special branch of its department to deal with the many matters arising from the connection with the work done by the modern universities. Experience had shown that the technological and professional instruction (including the training of teachers for elementary and for secondary schools) given by the universities and aided by grants from the Board, could not be properly dealt with as part of the ordinary administration of the Board as applied to institutions which have less autonomy, responsibility, and prestige than the universities. The universities need the greatest possible degree of freedom in organising and carrying out their important national and international functions, and the Board has for long been convinced that their relations with the universities should be so adjusted as to further this end. In April, 1910, the President accordingly appointed the Board's director of special inquiries and reports, Mr. H. F. Heath, to the office of principal assistant secretary for the new universities branch of the Board. Mr. Heath had a long connection with, and an intimate knowledge of, the modern universities before his appointment to the Board in 1903, and his work in the Board's staff as an advisory rather than an administrative officer since that date marked him out as specially qualified for the new post. Mr. Heath continues to hold his office as director of special inquiries and reports.

The International Commission on the Teaching of Mathematics.

In view of the fact that a meeting of the International Congress of Mathematicians is to be held at Cambridge in 1912, and that an International Commission on the Teaching of Mathematics has been constituted in connection with the educational section of the congress, the office of special inquiries and reports has made arrangements to publish a series of papers dealing with the teaching of mathematics. It is intended that copies of these papers shall be placed at the disposal of the International Commission, and that they shall ultimately form a volume or volumes in the series of special reports on educational subjects.

An advisory committee has further been appointed by the President of the Board to assist in the collection of papers and to advise as to the suitability of the contributions sent in. This committee will also act as the British Subcommission—one of a number of national subcommissions established to assist the International Commission in its work—and is constituted as follows:—Mr. C. E. Ashford, Sir G. H. Darwin, K.C.B., F.R.S., Prof. G. A. Gibson, Mr. C. Godfrey, Sir George Greenhill, F.R.S., Mr. G. H. Hardy, F.R.S., Prof. E. W. Hobson, F.R.S., Mr. C. S. Jackson, Sir Joseph Larmor, M.P., F.R.S., Prof. A. E. H. Love, F.R.S.

Mr. C. S. Jackson is honorary secretary to the British Subcommission.

The Science Museum.

The needs of the Science Museum have been before the Board for some years, and it has recently become possible to take active steps to provide for them. The matter formed the subject of a memorial of great weight, presented just a year ago by a deputation representing the learned societies, the universities, and the technical colleges of the country; and the evidence then put before the Board amply confirmed the view that the science collections are even now of great value to the nation, but that their usefulness is crippled, and their growth prevented, by the inadequacy of the buildings in which they are housed.

The accommodation for these rich collections, which include many inventions that have proved to be pioneers in industrial arts and afford much effective exposition of modern developments of pure and applied science, ought to be in every way worthy of the interests which they serve. What has now to be done to meet this requirement ought to be done on a scale and in a form that will give the Science Museum an assured place among the permanent national institutions of the country. The Board is anxious that the scheme for the future development of this museum should receive adequate consideration before the work is actually put in hand, and it feels that the requirements of the collections in the Museum of Practical Geology in Jermyn Street should be discussed at the same time. In whatever action it may take in this matter, it wishes to assign to the valuable collections in these two museums definite part in the provision of facilities by national museums. A Departmental Committee was therefore appointed in March, 1910, to consider and report upon various questions in regard to the collections. In particular the committee was asked "to advise (*a*) as to the precise educational and other purposes which the collections can best serve in the national interests; (*b*) as to the lines on which the collections should be arranged and developed, and possibly modified, so as more effectively to fulfil these purposes; and (*c*) as to the special characteristics which should be possessed by the new buildings, which it is hoped will shortly be erected on the South Kensington site to house these collections, so as to enable the latter to be classified and exhibited in the manner most fitted to accomplish the purposes they are intended to fulfil." [See NATURE, May 4.]

The committee informed the Board in a preliminary report in July last as to the general conclusions it had then reached on these questions, and in particular as to the nature and extent of the collections and as to the size of the buildings that would be required for such a development of the collections as they contemplated. The Royal Commission for the Exhibition of 1851 has intimated that it is prepared to make a grant of 100,000*l.* from the funds at its disposal towards the erection of a new building for the museum, the balance of the cost of which would be provided from public funds.

Secondary Schools (England).

The total number of schools regarded as eligible for grant during 1909–10 was 841, as compared with 804 during 1908–9. Of these, 325 were controlled by local authorities, 447 were endowed schools or schools of a similar type, 29 were schools belonging to the Girls' Public Day School Trust, and 40 were controlled by Roman Catholic teaching orders. In these schools there were on January 31, 1910, 76,909 boys and 64,649 girls, as compared with 73,273 boys and 62,401 girls on January 31, 1909.

In addition to the 841 schools on the grant list there were 87 other schools recognised by the Board as efficient during 1909–10, being an increase of 5 on the number recognised as efficient during 1908–9. Of these 67 were endowed schools or schools of a similar type, 3 were controlled by Roman Catholic teaching orders, and 17 were private schools. In these schools there were on January 31, 1910, 8215 boys and 7249 girls, as compared with 7117 boys and 7179 girls on October 1, 1908.

Thus during the year 1909–10 there were in England altogether 928 schools recognised by the Board as efficient, educating 85,124 boys and 71,898 girls, as compared with

886 schools in 1908–9 educating 80,390 boys and 69,580 girls.

Length of School Life.

The length of school life is a matter to which the Board attaches very great importance, for if the bulk of the pupils in fact drop out of a secondary school after passing through only a fraction of the school course, it is clear that the secondary school is not fulfilling its aim and is not entitled to State aid. An article of the regulations expressly provides that a school will not be recognised as a secondary school unless (1) an adequate proportion of the pupils remain at least four years in it, and (2) an adequate proportion of the pupils remain in it up to and beyond the age of sixteen.

The average length of school life in schools on the grant list is not yet nearly so high as it should be. Some improvement is being made, but it continues to be slow.

At the end of 1909 the Board took up the cases of thirty-five schools which appeared to have an exceptionally short average school life, and, after a careful investigation of the circumstances of each case, addressed to twenty-six of these schools a warning that continued failure to comply effectively with the Board's requirements would entail removal from the grant list. In many of these cases the Board suggested that an undertaking should be required from the parents of all pupils, on their admission to the school, that they would not be removed without good reason before completing an adequate period of school life; and directed attention to the fact that such an undertaking with a penalty enacted had already been adopted by several school authorities with marked results. The suggestion has, as a rule, been cordially accepted, and is, it is believed, already having good effect; but these and all other cases where there is a tendency for the school life to be abnormally short are being kept under careful observation, and action is being taken where necessary.

Attendance at Evening and similar Schools.

Statistics for 1909–10 with reference to schools and classes intended for those whose ordinary avocation occupies the greater part of their time will be given in the statistical volume for that year, to be issued later in 1911. Reference, however, to Tables 83 and 99 in the 1908–9 statistical volume reveals an increase in the total number of students enrolled in these schools from 751,600 in 1907–8 to 752,356 in 1908–9. These figures show but little progress in popular appreciation of the facilities offered to those desirous of recovering what they have lost of their previous education, or wishing to obtain a wider and firmer grasp of the principles underlying their several callings, whether these be in industries, in commerce, in professions, or in domestic occupations. It is also matter for regret that nearly 20 per cent. of the students enrolled failed to complete the small minimum of attendances required in order to enable grants to be paid towards their instruction.

The average number of hours of instruction received per student in the county boroughs (including London) as a whole was 55. In seven county boroughs this average was under 40; and in 21 others, while more than 40, it was under 50. In 47 it was above 50; in nearly all of these it was under 80, but in 10 county boroughs, situated in Lancashire and Yorkshire, and in one in Cheshire, the average number of hours received per student during the year 1908–9 exceeded 80, in two cases the average being more than 100 hours. In such cases the high average reflects considerable credit on the organisation of the work of further education, and very satisfactory results may fairly be anticipated from the instruction received by the students.

In the administrative counties (excluding London) each student received on an average 48 hours of instruction. In view of the number of short courses of special instruction recognised as eligible for grants in certain rural areas, as well as for other reasons, it is to be expected that the average should be lower in rural than in urban areas. Only in seven cases, however, was the average below 30 hours; in 17 others, while more than 30, it was under 40; in the remaining 37 this average was above 40, and in three of these cases it exceeded 60, in two of them being more than 80.

From these figures it will be seen, on one hand, how meagre is the amount of instruction received by the students in some areas, and, on the other, that even under existing circumstances some students can be induced to give real and continued attention to their further education.

The number of students more than 21 years of age has fallen from 253,677 in 1907–8 to 247,436 in 1908–9.

Technical Institutions.

The total amount of advanced instruction of the kind provided in technical institutions is still disappointingly small. In some of the more important industries, as, for example, engineering, the instruction is largely utilised by students; but in a great many others the supply of students is very small. It is to be deplored that there are several schools in which the well-qualified staffs and the excellent equipment practically stand idle in the day-time through lack of students.

The students enrolled in the 42 technical institutions which were recognised as eligible for grant in 1908–9 numbered 3400, of whom 3010 qualified for grant. Of these latter 1990 took full courses of instruction; 806 were engaged in the work of the first year, 653 in that of the second, 406 in that of the third, and 125 in still more advanced work. There is still a tendency to admit students to technical institutions before they have had an adequate course of general education; 211 students were under 16 years of age at the opening of the session 1908–9.

For the year 1909–10, 49 technical institutions were recognised as eligible for grant, showing an increase of seven over those recognised in the previous year.

Day Technical Classes.

Grants are payable under Article 42 of the regulations to schools and classes which are, as a rule, for students younger than those in the technical institutions. Under this category there are included, however, some classes of a standard equal to that required in a technical institution, but with courses not of sufficient duration to be eligible for grants as technical institutions. Day technical classes vary in their aims, some being preparatory to trades, such as engineering, others providing instruction of a domestic type, others again being for blind or deaf students.

In 1908–9, in England and Wales, day technical classes were recognised as eligible for grant in 103 institutions; and at the 180 courses for which grants were paid, 10,237 students were enrolled, of whom 9636 qualified for grant. Of these courses, 109 were full-time and 71 part-time; 6137 students attending the former, 3499 the latter. Of the full-time courses, 52 were for junior students, of whom 4039 qualified for grant, and 57 courses were for senior students, of whom there were 2102 who also satisfied the conditions of eligibility for grant.

For the year 1909–10, day technical classes were recognised as eligible for grant in 109 institutions.

THE BRITISH SCIENCE GUILD.

THE report of the British Science Guild, presented at the fifth annual meeting, held on April 7, has just been distributed. A few of the subjects dealt with in the report were mentioned in the account of the annual meeting which appeared in NATURE of April 13; and we now reprint the section referring to Government organisation, a summary of the first report of the Canadian committee, and the conclusions and recommendations of the Technical Education Committee. The report of the Canadian committee shows that valuable work in promoting the aims of the Guild is being carried on in the Dominion. We note with interest that among the subjects receiving consideration are the teaching of science in schools, technical education, the conservation of natural resources, and the location of icebergs by their temperature effects—a very important matter to ships navigating in many waters during foggy weather.

The report of the Technical Education Committee, which runs to forty-eight pages, should be read in connection with Lord Haldane's remarks upon technical education at the annual meeting. In the course of his speech, he said:—"With regard to technical education, there is more going on in this country than people realise, and the mistake that has led to the want of recognition of this is the habit people

have of comparing things that are unlike. It is quite true that in higher education and in the application of science to industry Germany has marked features which we do not possess, but evening schools and evening classes connected with universities or technical colleges are things which are little known in Germany as we know them."

Lord Haldane seems himself to have erred in comparing things which are unlike, and the conclusion derived from the comparison is, therefore, misleading. Our evening-class system is admirable, but as the report of the Guild's Technical Education Committee points out, it is to a large extent of the nature of continuation school work, and has no relation to technical education rightly so-called. About three-quarters of a million students attend evening schools and classes, but the average number of hours of instruction received by each student throughout the session is only about fifty, and 20 per cent. of the students fail to complete the small minimum number of attendances required by the Board of Education as qualification for a grant toward the instruction. Moreover, nearly 150,000 students in evening schools and classes are under fifteen years of age. It is obvious that, however excellent this evening-school work may be considered from the point of view of further education, it can be of little assistance to national industries and manufactures which require highly specialised knowledge and research for their development.

The latest report of the Board of Education provides the best reply to the suggestion that we have reason to be satisfied with what is being done for technical education in England. It appears from this report that in the forty-two technical institutions recognised by the Board (and that number includes practically all the technical schools and colleges in which organised courses of relatively advanced instruction are given in the day-time, as well as applied sciences departments of such Universities as Birmingham, Liverpool, Manchester, and Leeds), about 2000 students took full courses of instruction in 1909–10. Of these students only about 400 were engaged in work of the third year, and 125 in still more advanced work. What it comes to, therefore, is that the total number of day students in English polytechnics, technical schools, and colleges is less than in a single German technical university such as that of Charlottenburg or Munich.

But putting comparisons aside, there is surely nothing to be satisfied with in the fact that only 125 students in the technical institutions connected with the Board of Education are doing work beyond that of the third year, considering that the entrance age is sixteen, and in some cases is reduced to fifteen years. No wonder the Board of Education remarks in its report:—"It is to be deplored that there are several schools in which the well-qualified staffs and the excellent equipment practically stand idle in the day-time through lack of students." Details of our position as regards technical education, and suggestions for its improvement, will be found in the report of the Technical Education Committee, printed as an appendix to the report of the Guild. The subjoined extracts from the general report and this appendix are of particular interest.

Government Organisation.

In the appendix to the fourth report several opinions were quoted touching on the need of a better reorganisation of our executive Government. It was pointed out by our president that at present our "executive government is about as disorganised and chaotic an institution as anybody can conceive." "There was too little science in it at the present time. There was hardly a department which did not require the aid of science if it was to be effective."

"I believe that things will not be right until we have a scientific corps under a permanent committee, just as the Defence Committee is under the Prime Minister to-day. I think you should not have a body which consists of officials of the ordinary kind, but one which should consist of the most scientific men, who would go there because they are honoured and paid, and put on the footing on which they deserve to be placed, and are recognised as a body of men who will be at the elbow of the department, and who can organise the scientific work of the State. If we get that, as I hope we shall, I trust that the example of the Government in adopting science will be followed by the municipalities, as I believe it is going to be followed more and more by our manufacturers."

"The creation of the Committee of Imperial Defence carried scientific principles into the sphere of government, and was the first step towards getting military and naval motions into order. We now have a general staff which is a body, not to exercise command, but to give advice in a thoroughly practical fashion and in a fashion which can be enforced. The speculation may be indulged in whether one of the great reforms of government to which we are coming—because we have been driven to it—will not be the creation in an organised fashion of just such a general staff for departments of government, and not merely for the army."

Apart from the question of advisory committees already referred to, there are other parts of our administrative system, or want of system, which have to be considered.

The oldest Government departments were set going in the pre-scientific age. War, diplomacy, and finance were then the chief things considered. The State did not concern itself with commerce and industry, or the health or education of the people, nor had science or art any place in the administration. It was in connection with the Navy that the first scientific services were established, the Royal Observatory for preparing an ephemeris[1] and a survey of the seas to render the navigation of warships more secure.

In most Continental nations, including our own, the scientific education of army and navy officers was insisted upon long before that of civilians; hence the former were necessarily employed in various departments of the State, when the necessity of facing scientific problems arose. Thus our land survey was carried out by the Board of Ordnance.

It was while this state of things existed that the Board of Trade and the Department of Science and Art were established, as a result of the Prince Consort's warnings and pleadings. It was the Board of Ordnance which supplied its well-instructed officers of engineers to these and other public departments as the need for scientific treatment arose, and because fully educated civilians were not available either in the departments or outside them. It is in consequence of these various additions to the State machinery at different times to meet different needs that the "chaotic" condition to which our president has referred has arisen. The new problem raised by the necessity of scientific inquiries to aid the service of the State has not yet been faced.

To take an instance of our administrative system, or want of system, we may refer to our national surveys. Our four national systems of surveys of the surface of the land, of which that surface consists and of what lies underneath it, of the air and of the seas, are at present controlled by four different departments of the State.

The two land surveys, one using the maps prepared by the other, are controlled, one by the Board of Agriculture, the other by the Board of Education. The Meteorological Office, which deals with the air, is under the Treasury, while the hydrographic survey is controlled by the Admiralty.

There is good reason for the last named being under the Admiralty, because to the Admiralty belong the ships which are necessarily used in the work; but there is no reason why the other three surveys should not be administered by one department.

The question arises whether the surveys dealing with the land surface and what lies beneath it should not be brought together, and under the Board of Education, and whether the air survey (the Meteorological Office) should not be transferred from the Treasury to the same department, which already administers the Solar Physics Observatory, in which allied work is carried on. The recent transfer to South Kensington of the Meteorological Office is another argument in favour of this proposal.

To take another instance. The primary, secondary, and technical education of the country is controlled by the Board of Education, while the Treasury is supreme in matters relating to the universities. The situation is as if

[1] Even then, however, according to Sir George Airy, the latitude of the court had more to do with the foundation of the Observatory than the importance of determining the longitude at sea A Royal mistress had reasons for wishing the new departure.

the Secretary of State for War were only concerned with barrack-yard drill, the higher training at Aldershot and Salisbury Plain being in charge of another Minister.

No other civilised Government attempts to deal with general education in two watertight compartments. The present position suggests inquiry which may show that the Board should really be made responsible for the whole of the educational ladder, and not merely for the lower rungs of it. This would take from the Treasury a matter with which, from its constitution and personnel, it is not so fitted to deal as is the Board of Education.

We have already found in two cases, the Meteorological Office is one and university education another, and to these can be added a third, the administration of scientific grants, in which the Treasury, the function of which is to control the expenditure of spending departments, acts as a spending department itself; an Alice in Wonderland arrangement, in which the Chancellor of the Exchequer acts both as judge and jury; there is no Minister in the Cabinet to advise or defend expenditure thus administered, except the one whose chief function is to veto it, and no consultative committee to refer to; to this may doubtless be attributed the small regard paid to the claims on behalf of science and the higher learning generally.

In the matters under review the practice of foreign Governments varies according as science is regarded from the pure or applied standpoint, but the rule most generally acted on is to place the scientific services under the control of the Minister of Public Instruction, who is thus a Minister for Science.

It would appear from the foregoing references to the distribution of the services among departments, that much of the apparent confusion would disappear if certain of them were transferred to the Board of Education. This would be in harmony with Continental practice, and would have the advantage of utilising to the fullest extent the services of an advisory committee, when, following the precedent recently so fully acted on, one is appointed to deal with the scientific services. Another way out of the present chaos is to appoint a Minister of Science.

Although the words "Science and Art" have disappeared from the title of the Board of Education, it still carries on the work of the Science and Art Department, and the more thoroughly it is carried on and developed the better it will be for the nation. It is unfortunate from this point of view that in the controversies which have been carried on of late years in the name of education, the real functions of the Board have become obscured.

If we pass to the question of museums we find the same chaos; this was reported on by the Duke of Devonshire's Commission in 1874. Of these the oldest, the British Museum, including the Natural History Museum with a Geological Department at South Kensington, is administered by trustees; the youngest, the Victoria and Albert Museum and the Science Museum, also at South Kensington, by the Board of Education.

The Board of Education also controls the Geological Museum at Jermyn Street, the Geological Department of the British Museum being, as stated above, at South Kensington.

The above anomalies lie on the fringe of the subject; they are given as examples of the ground to be covered when an inquiry is made.

Conclusions and Recommendations of the Technical Education Committee.

(1) The work of technical education should be organised as a national system. A system of scholarships or bursaries should enable the most promising students to pass from the technical school to the university, or to highly specialised institutions established to promote the scientific and practical study of particular industries. Technical institutions of sufficient standing should be connected with local universities, and others should be assigned work and place in an organic scheme to prevent waste of effort and undesirable competition.

(2) There should be a national Advisory Board for Technical Education and local Advisory Boards should also be appointed; these should include a certain number of teachers as well as representatives of industry and commerce. Greater appreciation of the value of scientific and technical education to industrial progress may thus be secured. The development of specialised institutions closely connected with local industries is always promoted by the appointment of representatives of the leading manufacturers upon the governing bodies of such institutions.

(3) Courses of study and syllabuses leading to national certificates in technical education should be approved by the National Advisory Board. Such work should be of a more advanced character than that for which local bodies may grant certificates, but a national certificate relating to attainment in the specialised knowledge of the district could be established by the local and national Advisory Boards acting jointly.

(4) Evening classes provide a valuable means of combining theoretical studies with actual practice—concurrent training in factory and school—and have done much to qualify strong and capable men for positions of responsibility in commerce and in certain industries. An extension of the opportunities for part-time study in the day is, however, greatly to be desired, and the increase of such classes should do much to advance technical education.

(5) There should be in each district a sufficient number of (*a*) trade preparatory schools for pupils of about twelve to fifteen years of age, such schools to differ from ordinary secondary schools in the large amount of time given to various forms of manual instruction; (*b*) continuation schools for part-time day pupils and for evening pupils. Both (*a*) and (*b*) would be concerned chiefly with the further education of pupils trained in primary schools.

(6) For the comprehensive training required to produce future captains and leaders of industry, whole-time instruction is essential in institutions of advanced type. It is desirable that each institution of this type should add to its curriculum, as far as possible, specialised instruction in a particular subject, or group of subjects, relating to one or more of the principal industries of the district.

(7) The national and municipal expenditure upon education in England in respect of technical, art, evening, and similar schools and classes is about one and a half million pounds per annum: and the number of students above fifteen years is about half a million; so that, neglecting younger pupils, the annual cost is only about 3*l.* per student. As, however, the chief part of the work of most of the schools, whether day or evening, is elementary or of a continuation-school grade, it cannot be classified as technical education; hence the actual expenditure upon technical education properly so called is only a small amount of the total.

(8) In most parts of the country, bursaries or scholarships are provided, by means of which promising pupils in public elementary schools may pass into secondary schools or technical schools, and thence into a technical college or university for more advanced instruction. For work of what may be called a post-graduate standard, however, little provision has been made, though it is of the highest importance. To secure the highest development of industries, highly technical and specialised work must be carried on in suitable institutions by well-qualified students. Increased facilities should therefore be afforded by liberal scholarships or other assistance, to enable such students to enter institutions of this type and maintain themselves while following approved courses of study or research.

Report of the Canadian Committee.

Since the meeting of the organising committee of the British Science Guild in Canada, held in Winnipeg during the meeting of the British Association, the Canadian committee has been established on a firm basis, and some definite work has been undertaken. It is a source of satisfaction to have the sympathy and advice of Lord Strathcona, who kindly consented to become honorary president of the committee this year, owing to the withdrawal of Earl Grey as Governor-General of Canada.

One of the most important questions now being considered by this committee is the teaching of science in the schools. A special subcommittee has been formed, with Dr. C. J. Lynde, Department of Physics at Macdonald College, as chairman. The object of this committee is to gather information as to the facilities for science teaching offered in the various provinces. The committee has in view the following questions:—

What sciences are taught in the schools, and by whom? What qualifications (academic or professional) has the teacher?

Is the instruction assisted by lecture, experiment, and laboratory work?

How far instruction in physics or chemistry encourages scholars to take up a scientific or technical career?

In what way can assistance be given by the universities to the science teachers in the schools?

Whether the giving of one or two lectures by university professors in the schools from time to time, on modern development in science, would be of assistance to the teachers?

Whether special summer courses in elementary science given in the universities would be of help to the science teachers?

Whether there is a modern scientific publication taken regularly by the school, or by the teacher?

Dr. J. W. Robertson, a vice-president of the committee, has been appointed by the Government chairman of the Commission on Technical Education. This commission is entrusted with the duty of thoroughly investigating the needs for technical training all over Canada. It will, in addition, go to the United States and Europe, where the educational systems will be thoroughly investigated. In Dr. Robertson's own words, we state the work of the commission. He said that "the Government had expressed a recognition in a new form of the heritage of Canadians. This recognition is in the form of the conservation of the resources of the country. These cannot be utilised until the people have been educated in this regard, and in their proper development. The best way is that whereby labour can be applied with the least waste, cost, &c. Industrial efficiency is an all-important item in the successful development of Canada. The commission, by investigation and by personal observation, is to secure all the information possible on the industrial life of Canada."

One of the vice-presidents of this committee, Mr. F. H. Sexton, is director of technical education for Nova Scotia. Prof. Sexton's work is proving of the greatest benefit to the province. It is to be hoped that his efforts may be directed to wider fields. Nova Scotia was the pioneer in establishing technical education in America, being the first province in the Dominion to do so, and being two years ahead of Massachusetts, which was the first State of the Union to take this up. Through Prof. Sexton's efforts, there exists in all the colleges a uniform course of study for the first two years' work. Scholars can then do advanced work in the provincial technical college in any branch of engineering they desire. There are a number of night schools, mostly for miners, which are of great benefit. These schools are supported by the Government, and are entirely free. They are not intended to increase the number of men seeking employment, but to increase the efficiency of those already at work.

A commission has been appointed by the Government to study the natural resources of the country. In this important matter the Guild committee is ably represented by the Hon. Sydney Fisher, Minister of Agriculture, one of our vice-presidents.

The Forestry Association in Canada has been actively engaged in educating the people to a better appreciation of the value of conservation. There exists in Canada at the present time vast areas of forest wealth. Each province has its own forestry regulations, and much valuable material has been collected and distributed by the association. It is safe to predict that the paper-making industry will in the near future be controlled in Canada. The destruction by fire is one of the most serious features of our national loss. Through the efforts of the association, however, greater intelligence is being displayed in fire patrol. The people are beginning to realise the need for stricter regulations in the forest regions.

In the matter of parks and playgrounds in the rapidly increasing City of Montreal, one of the members of the committee, Dr. J. G. Adami, F.R.S., has been among the chief workers in securing a Parks Commission, which is to have power to acquire land for parks in and around the city, as well as to investigate the housing of the poor. Dr. Adami has been active, also, in the work for the prevention of tuberculosis, and much good has already resulted from his labours.

The secretary has been devoting much study to the ice conditions of the St. Lawrence River as it affects navigation. A report now being printed by the Department of Marine and Fisheries sets forth the result of the study last year. The Minister of Marine, the Hon. L. P. Brodeur, one of the vice-presidents of the committee, has shown the greatest interest in this work, and has given the secretary every facility for study. Investigations have been carried to the lower St. Lawrence and Gulf in order to determine a matter of vital importance to the St. Lawrence route to be able to determine the influence of icebergs on the temperature of the water. It is a matter of vital importance to our St. Lawrence route to be able to determine the effect of icebergs, and, if possible, devise some means for ships to locate them when navigating in foggy weather. Already an instrument has been devised which is capable of detecting the temperature effect of an iceberg for distances varying from two to seven miles. This year the Minister has so far recognised the importance of the work by detailing a special ship for the temperature tests.

It is hoped that the Canadian committee may be of active help to the British Science Guild by advising it on Canadian questions. Already the Canadian committee has received assistance from the secretary in London on the question of the work of the National Standards Laboratories, for which it desires to express its thanks.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. G. E. Moore has been appointed university lecturer in moral science for five years from October 1, 1911, until September 30, 1916.

Mr. Keith Lucas has been approved by the general board of studies for the degree of Doctor in Science.

On Thursday, May 11, the following Grace will be offered to the Senate:—That the bequest to the University by the late William Chawner, Master of Emmanuel College, be gratefully accepted, and that the Vice-Chancellor be requested to communicate this Grace to Mr. Chawner's executors.

OXFORD.—Further instalments of the scheme of university reform are promised for the present term. On May 16 the preamble of a statute exempting honour students in mathematics or natural science from the requirement of Greek in Responsions will be submitted to Congregation, and on May 23 the first stage will be taken of a statute constituting a new board of finance, the main duties of which will be to review annually the published accounts of the University and colleges, to report thereon to the Hebdomadal Council, and to advise the council generally on matters of financial administration. It is not proposed to abolish the existing board of curators of the University chest, but to continue it, with somewhat limited powers, side by side with the new board of finance.

A member of Congregation has circulated a protest against the proposed exemption of science and mathematical students from compulsory Greek. His main points against the measure are that it will tend to diminish the opportunities given in the smaller grammar schools and new "secondary" schools for the teaching of Greek to boys of pronounced literary gifts, and that it will lead to an undue diversion of endowments in the University and colleges from the literary and historical and philosophical humanities, which he thinks are in some danger of being neglected in other universities and in the country at large, whereas science is in no such danger.

Statutes reconstituting the boards of electors to fourteen mathematical and science professorships in the University passed Congregation on May 9 without opposition.

BIRMINGHAM.—The University is the recipient of a munificent bequest under the will of Mr. John Spencer, of Handsworth, chairman of Messrs. John Spencer, Ltd., tube manufacturers, of Wednesbury. The bequest includes "5000*l*. to the University of Birmingham, to be applied in the advancement of science and in promoting the work-

ing out of scientific problems in any department of science in such a way as the principal and vice-principal shall determine as being wisest and best for the end I have in view, which is to promote discovery and knowledge, believing that this conduces to the good of humanity." In addition to this, the University will ultimately, as residuary legatee, receive the benefit of considerably more than the above amount.

DR. A. E. KENNELLY, of Harvard University, has accepted an invitation of the University of London to come to London for the purpose of delivering a course of advanced lectures, and has chosen as his subject "The Application of Hyperbolic Functions to Electrical Engineering Problems." The course will be given at the Institution of Electrical Engineers at 5.30 on five consecutive days, commencing on Monday, May 29, and tickets of admission may be obtained free by application to the academic registrar of the University of London.

THE leading article in *The Builder* for May 5 deals with the amalgamation of the Society of Architects with the Royal Institute of British Architects. It is a matter of congratulation that a mutually satisfactory basis of amalgamation has been arranged. The unity of action which will result in matters connected with registration and with education cannot fail to be of benefit to the profession. There must be many whose chief interest in obtaining a settlement of the question of registration is based on the hope that it will clear the ground for a thorough reorganisation of our educational methods, without which our architecture must drop behind that of other nations. If the new union will secure this advance, it will justify all the sacrifices that have been made to consummate it.

THE Worshipful Company of Drapers has given to the Battersea Polytechnic the sum of 6000*l.* in order to erect a building to house a department which is to include such branches of science as physiology, hygiene, bacteriology, and also that further work which, for want of a better name, may be termed hygiene or town planning. It is hoped also to include the subject of geology, more particularly in its application to the nature of soils, forms of vegetation, &c. It is expected that important results will arise from the establishment of this new work, and that the department is likely to prove, from the sanitary science point of view, of great service, inasmuch as it will give opportunities for the study and advancement of the principles which in the future must control life, and especially that of the towns. A suitable letter of thanks has been sent to the Drapers' Company for their munificence.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society May 4.—Sir Archibald Geikie, K.C.B. president, in the chair.—Dr. F. W. **Mott,** Edgar **Schuster,** and Prof. C. S. **Sherrington**: Motor localisation in the brain of the Gibbon, correlated with a histological examination. A comparative study of the convolutional pattern of the brains of lemurs and apes led to the expectation that the remarkable use the Gibbon makes of its arms and hands would be found by experiment and histological investigation to be correlated with the remarkable expansion of the cortex cerebri in the precentral region as shown by the development of a broad gyrus extending from the middle of the precentral region to form the second frontal convolution. This development, it was inferred, would push downwards and forwards that portion of the cortex which on stimulation gives rise to eye movements in Macacus. Stimulation experiments by unipolar excitation are given in detail showing the correctness of this deduction; moreover, for the first time the excitable motor cortex is precisely mapped out in this animal. The experimental observations have been correlated with a histological survey of the cortex cerebri in front of the central fissure. Figures are given to show the distribution of two quite distinct types of cortex in the lateral surface of the Gibbon's brain in front of the central fissure corresponding to Campbell's precentral and intermediate precentral types, or to Brodmann's types 4 and 6. The great forward extension of the intermediate precentral area (especially that which may be described as the middle frontal convolutions) forms a most characteristic feature of the Gibbon's brain, and distinguishes it in a very striking way from the Orang and Chimpanzee on the one hand, and Cercopithecus and the Baboon on the other.—J. S. **Huxley**: Some phenomena of regeneration in Sycon, with a note on the structure of its collar-cells. *Production of normal individuals from isolated cells* (as in Wilson's experiments on Monaxonida).—Cells were obtained singly by straining sponges through gauze. They first unite into lumps, all the kinds being confusedly mixed (reunion). Next the dermal cells migrated to the surface to form a flat epithelium round a mass of quiescent collar-cells (reorganisation). Then came redevelopment: spicules arise, monaxons before triradiates; gastral cavity and osculum appear. The spicules form later than in the larva (where, however, they are certainly precocious), and the regenerates failed to fix permanently. Otherwise redevelopment resembled normal post-larval development. None became heterocœlous, though one lived and grew as a functioning sponge for several weeks. The fate of the cells here is *not* a function of their position, for they have to migrate into position before development can proceed. *Behaviour of pure collar-cells.*—If large bits of gastral epithelium are taken, they bend back and round up into perfect hollow spheres with collars directed *outwards*. Similar spheres were formed, but in a different way (with preliminary solid stage), if numerous single cells were taken. Though some lived more than a month, no other tissue was regenerated by them. These spheres have no bearing on phylogeny. Their structure is probably due only to oxygen requirements and to surface tension. Their failure to regenerate other tissue proves nothing against choanoflagellate ancestry; the ancestral cells may have given up their regenerative powers to others, more suited, as has happened elsewhere (*e.g.* Ascidians). *Collar-structure.*—Longitudinal rods do exist in the collar, as described by Bidder.—Dr. J. A. **Murray**: Imperial Cancer Research Fund. Cancerous ancestry and the incidence of cancer in mice. The present paper is in continuation of a previous communication (Roy. Soc. Proc., B, vol. lxxxi., 1909, p. 310). The analysis of the ancestry of 1600 mice bred in the laboratory has permitted their classification in two groups differing considerably in the incidence of cancer. Out of a total of 562 female mice which lived for six months or more, cancer had occurred in the mother, one or other grandmother, or all three in 340, and in them 62 developed cancer of the mamma (18·2 per cent.). In the remaining 222 mice in which cancer was absent from the maternal and grandmaternal ancestors, only 19 developed cancer of the mamma (8·6 per cent.). The group with recent cancerous ancestry is found on analysis to be more severely attacked at all age-periods than the non-cancerous group (cancerous ancestors remote). Detailed analysis of the ancestors enhances the importance of the differences. The differences exceed their standard errors sufficiently to render them significant. The predisposition is apparently not constitutional, but local, and is regarded as only one of the factors in the development of cancer.—Dr. R. Tanner **Hewlett**: Immunisation by means of bacterial endotoxins. The action of bacterial endotoxins in immunising against the corresponding living organisms has been investigated. Guinea-pigs were the animals employed. *Typhoid Endotoxin.*—Series of guinea-pigs were given single injections of the endotoxin, ranging from 0·01 mgrm. to 1·0 mgrm. Five to eleven weeks later the animals were injected with living typhoid culture; considerable protection was obtained, particularly with doses of 0·1 and 1·0 mgrm. The protection afforded by the endotoxin was better, and lasted longer than that conferred by a bacillary typhoid vaccine. *Cholera Endotoxin.*—Six guinea-pigs each received 0·25 mgrm. of the endotoxin, and all survived an injection of living cholera culture given eleven weeks later. *Diphtheria* and *Plague Endotoxins* similarly confer some protection against the living organisms. No immunising substance was obtained from the *Trypanosoma brucei*. The results suggest that bacterial endotoxins may be of considerable value as protective vaccines. The endotoxin solutions maintain their

activity for some weeks at least, probably for a much longer period. A few inoculations of typhoid and diphtheria endotoxins have been performed in the human subject. The inoculations cause some local reaction at the site of inoculation, but little general reaction. (The endotoxin solutions were prepared by the method described in Roy. Soc. Proc., B, vol. lxxxi., 1909, p. 325.)—J. E. **Barnard** and Dr. R. T. **Hewlett**: A method of disintegrating bacterial and other organic cells. Bacterial toxins are of two kinds, extra-cellular and intra-cellular. The former are excreted into the medium, *e.g.* beef broth, on which the organism is cultivated, so that by a process of filtration the organisms can be removed, and the toxin is obtained in the filtrate; but the majority of pathogenic micro-organisms do not excrete their toxins, at least to any extent, and the toxins are retained within and form integral parts of the cells of the organisms. One method of obtaining these toxins is mechanically to disintegrate the bacterial cell, so that the cell contents are expressed, and the apparatus here described accomplishes this. It consists essentially of a containing vessel, in which, by a suitable rotation of steel balls, the organisms are crushed. The principal conditions to be fulfilled in such an appliance are:—Approximately every cell should be brought under the grinding action. Little or no rise of temperature should take place. The disintegration must be carried out in a vessel which is sealed, so that, when dealing with pathogenic organisms, none can escape at any stage of the process. These conditions are, in the main, complied with in the apparatus described. Experiments indicate that by this method the cell-juices are obtained unaltered, and suitable for investigations on the chemical composition and properties of the bacterial proteins and other cell constituents. Also that, after the grinding process has been carried on for a sufficient time, practically no cells remain which can be properly stained by any recognised bacteriological method, and which therefore can be regarded as whole cells containing a normal quantity of cell-juice.

Physical Society, April 28.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Prof. E. **Wilson**: High-tension electrostatic wattmeter. When using the electrometer as a wattmeter it is necessary (in order to secure accuracy) that the voltage impressed upon the quadrants shall not be less than a certain minimum depending upon the voltage to be impressed upon the moving system. When the latter voltage is of the order 10,000, the quadrants require a voltage larger than can economically be provided by a shunt. One is led, therefore, to consider intensifying devices. The "series" or "current" transformer, the secondary winding of which is closed on a non-inductive resistance, can be used to give fairly good results, but it is not accurate at all frequencies, and is dependent upon wave form. The author's quadrature transformer is a very simple piece of apparatus which can be relied upon to give for electrostatic wattmeters an electromotive force which is strictly the differential of the current in the primary winding. When so used it is necessary, for accuracy, at all frequencies and on all wave forms, that the integral of the mains voltage shall be impressed upon the moving system, although for sine curves only the differential need be impressed instead of the integral.—Dr. R. S. **Willows** and T. **Picton**: The behaviour of incandescent lime kathodes. Wehnelt has shown that incandescent lime emits a large number of negative ions; if, therefore, hot lime is used as the kathode, a discharge may be obtained in a vacuum tube with P.D.'s so low as 30 volts. The alteration with time of these kathodes, under continued use, has been investigated and the following results obtained:—(1) When lime is heated on platinum foil, so far from showing fatigue, it actually increases in activity. With P.D.'s greater than the saturation voltage this increase may be nine-fold. At lower voltages a slow but steady increase up to 100 per cent. has been found. The steady activity falls when the lime is cold; the initial activity may greatly increase. (2) When the lime is heated on nickel foil, if the tube carries a heavy discharge, the current increases to a maximum and then decreases. A greatly increased activity is frequently shown after the lime has been cold for some hours. At the lower voltages the same general variations are shown as with platinum. (3) Great irregularity is frequently shown when the current is first started; at this stage other causes than temperature, such as mechanical vibrations, greatly influence the emission of ions.—Dr. S. **Marsh** and W. H. **Nottage**: The formation of dust striations by an electric spark. The formation of dust striations by electric spark has been investigated by many observers. The paper attempts to explain their formation as being due to hydrodynamic forces existing between the dust particles while the wave motion is passing over them. The application of this theory to the striations in a Kundt's tube has been made by Kœnig and Robinson. The wave motion is assumed to be of the spherical progressive type, and expressions are obtained from the intervals between consecutive striæ and the distances of the striæ from origin. Measurements were made of striæ formed on a glass plate with vertical central spark. The agreement between theory and experiment is within the experimental error. Experiments with channels of various shapes were made. Illustrations of the various striæ patterns obtained with small obstacles and reflecting surfaces are given, and the use of these as a convenient means of indicating reflecting interference and diffraction of sound waves is pointed out.—Prof. E. **Wilson** and L. C. **Budd**: Previous magnetic history as affected by temperature.

PARIS.

Academy of Sciences, April 24.—M. Armand Gautier in the chair.—M. **de Forcrand**: The hydrates of potassium fluoride. The results of determinations of the solubilities and heats of solution of the fluorides of the alkalies and the alkaline earths are given. In addition to the hydrate $KF.2H_2O$ already known, the properties of a new hydrate, $KF.4H_2O$, are described.—G. **Tzitzéica**: Certain conjugated networks.—Francesco **Severi**: The simple integrals of the first species attached to an algebraic surface. —Henri **Villat**: The determination of certain discontinuous movements in fluids.—L. **Hartmann**: The mechanism of the permanent deformation in metals submitted to extension. The metal bar under tension is polished on one face, and this repolished at intervals during the gradual increase of the load. The method gives valuable information on the changes taking place in the bar above the elastic limit.— G. A. **Hemsalech**: Some spectral phenomena accompanying the displacement of the spark by a magnetic field. A study of the spectrum of the spark between calcium electrodes in a magnetic field, the metal poles being in an atmosphere of hydrogen. The spectrum obtained approaches that observed in the upper layers of the chromosphere of the sun.—M. **Gutton**: Experiments on the velocity of light in refractive media. In a preceding note the author has described a method for the comparison of the velocities of propagation of Hertzian waves and light in air. The same apparatus has now been applied to the measurement of the ratio of the velocities of light in air and liquids. These results are compared with the indices of refraction determined in the ordinary way, and the differences are shown to be in accord with the theory developed by M. Gouy in his memoirs on the propagation of light in media possessing dispersion.—M. **Guilleminot**: The intensity and quality of the X-rays diffused by aluminium plates of varying thickness (secondary rays).— Georges **Baume** and Georges **Pamfil**: The fusibility curves of gaseous mixtures, combinations of hydrochloric acid and sulphur dioxide with methyl alcohol. With the system methyl alcohol, hydrochloric acid, a clear mixture is shown at the composition corresponding to equal molecules. With sulphur dioxide two compounds are defined, CH_3OH,SO_2 and $2CH_3OH,SO_2$.—L. **Franchet**: The preparation of the black enamel of the Greek potteries by means of natural ferroso-ferric oxide. The black enamel of the ancient potteries was obtained with magnetite. The flux for this was probably made from silica and alkali salts.—D. **Gauthier**: Syntheses of the secondary α-ketonic alcohols. The only ketones of this type described up to the present have the composition R.CH(OH).CO.R. In the present paper a general method of preparing ketones of the type R_1.CH(OH).CO.R_2 is given. An aldehyde R_1.CO.H is treated with hydrocyanic acid, giving R_1.CH(OH).CN. In presence of two molecules of an organo-magnesium compound R_2.MgX, the alcohol ketone R_1.CH(OH).CO.R_2 is obtained.—Amé **Pictet** and Alphonse **Gams**: The synthesis of oxyberberine.—G. **Darzens** and J. **Sejourné**:

The condensation of ββ-dimethylglycidic ether with brom-acetic ether.—A. **de Schulten**: The crystallographic examination of some silicides, borides, and carbides obtained by Henri Moissan and his pupils. Data are given for the silicides of iron, cobalt, manganese and chromium, for aluminium and beryllium carbides and for calcium, barium and strontium borides.—L. **Blaringhem**: The production of a new form of maize by a traumatism.—Léon **Pigeon**: A new form of stereoscope. This instrument has been designed specially for the physiological study of vision, for the study and treatment of astigmatism, and for ophthalmological clinical work.—René **Cruchet** and M. **Moulinier**: Pathological conditions induced by aviation. A description of the changes in the arterial pressure and nervous system caused by aviation. The most serious cause of trouble appears to be due to a too rapid descent from a high altitude.—Henri **Piéron**: The regressive evolution of mnemonic traces.—R. **Robinson**: The relations between the suprarenal glands with the state of gravidity, and on the use of adrenaline in the vomiting of pregnancy. Two cases of vomiting due to pregnancy, resistant to all ordinary methods of treatment, were cured by treatment with adrenaline.—E. **Bataillon**: Experimental parthenogenesis in *Bufo vulgaris*.—Armand **Dehorne**: The number of the chromosomes in the parthogenetic larvæ of the frog.—A. **Railliet**, G. **Moussu**, and A. **Henry**: Researches on the treatment of distomatosis of the sheep. Of all the medical agents tried, the only one which gave clear positive results was the ethereal extract of male fern. Four doses of 5 grams appear to be the minimum for success.—MM. **Bordas** and **Touplain**: The estimation of phosphorus in milk. A reply to some criticisms of MM. Fleurent and L. Levi.—Alexandre **Lebedeff**: The extraction of zymose.—F. L. Pereira **de Sousa**: The tidal wave of the great earthquake of 1755 in Portugal.

DIARY OF SOCIETIES.

THURSDAY, MAY 11.

ROYAL SOCIETY, at 4.30.—On a Method of making Visible the Paths of Ionising Particles through a Gas: C. T. R. Wilson, F.R.S.—The Vertical Temperature Distribution in the Atmosphere over England, and some remarks on the General and Local Circulation: W. H. Dines, F.R.S.—On some Mineral Constituents of a Dusty Atmosphere: Prof. W. N. Hartley, F.R.S.—The Path of an Electron in Combined Radial Magnetic and Electric Fields: Dr. H. S. Allen.—On the Absolute Measurement of Light—a Proposal for an Ultimate Light Standard: Dr. R. A. Houston.—On Harmonic Expansions: Prof. A. C. Dixon. F.R.S.

ROYAL INSTITUTION, at 3.—The Optical Properties of Metallic Vapours: Prof. R. W. Wood.

CONTENTS.

THURSDAY, MAY 18, 1911.

THE NORTH POLE.

The North Pole. By Robert E. Peary. With an introduction by Theodore Roosevelt. Pp. xii+326. (London: Hodder and Stoughton, 1910.) Price 25*s*. net.

PEARY'S narrative of the journey by which he reached the North Pole and satisfied his life's ambition cannot fail to command the respect of all who appreciate indomitable perseverance, high courage, and unfaltering devotion to an ideal. Peary cheerfully accepted months of drudgery, for although he describes life on the march in the Arctic as a dog's life, he regards the work as a man's work; and although he met with repeated disappointment—for beating the northern record without reaching the pole he despises as an empty bauble—his devotion was at length rewarded by well-earned success. Peary's last journey will probably always be his most famous, for it accomplished one of the greatest geographical quests; but its results are probably of less real geographical value than his exploration of northern Greenland, one of the most important of Arctic achievements.

Peary's book on the whole is disappointing. Its form at once arouses the prejudice of those who do not buy books by bulk. It is unnecessarily large, its size is increased by some illustrations which are neither instructive nor ornamental, and by the use of vast margins to the pages. The book is issued regardless of the congested conditions of most people's bookshelves, and is apparently intended for those who can find space for works with a large proportion of blank paper. The book has obviously been prepared in haste; the illustrations are in no particular order, and their titles cannot have been corrected by the author. Thus the view of the stone cairn, entitled "Camp Morris K. Jessup," that is, the camp at the North Pole, should be "Cape Morris K. Jessup," a mistake which might give rise to a serious misunderstanding. There is a map, inconveniently large, from which Crocker Land, one of Peary's most suggestive discoveries, has been omitted.

The book has no particular literary charm, although it is occasionally enlivened by touches of American humour, such as the statement that the atmosphere in Eskimo huts can be handled with a shovel.

The most interesting part of the book is the description of the Eskimo whose Mongolian affinities Admiral Peary clearly recognises. The account shows the author's tendency to judge everything by Arctic standards. Thus because the fair-skinned Eskimo were not as much impressed by white men as were some dark races, Peary dismisses with scorn the idea that any aborigines regarded the first Europeans they saw as superhuman. "Much nonsense," he says (p. 53), "has been told by travellers in remote lands about the aborigines regarding as gods the white men who come to them, but I have never placed much credence in these stories."

The book tells in detail the story of the expedition and its equipment; but in spite of the space available there are many omissions of the very things one would most like to know. Thus Peary claims that the success of his dash to the pole was only possible owing to the new sledges and portable stove that he designed for the expedition. He does not give future travellers the benefit of any descriptions of these instruments and their novel features. There is also little in this book to answer the criticism of those who have questioned Peary's actual attainment of the pole. There is an appendix by Mr. Henry Gannett, Admiral Chester, and Mr. O. H. Tittman, who state that they have examined Peary's journal and records, and they are unanimously of the opinion that he reached the pole. Some adequate statement of the evidence that was laid before these distinguished authorities might have been given as one of the appendices, of which there are three. There is no reason to distrust the fact that Peary reached the pole, or sufficiently near it for any practical purpose. The great increase in his pace after he parted from Captain Bartlett is not explained in the text, but the photographs of the area round the pole show wide stretches of smooth ice, hence exceptionally easy ice conditions may account for the speed of the final marches.

It is not easy to follow the story of the last few days of the approach to the pole, especially as the continuous daylight renders his references to morning and evening less helpful than they would be in following an ordinary itinerary. A tabular statement of his marches would have been very useful. The numerous references to the observations taken and the facsimiles of some of the calculations are not convincing, especially as a curious statement on p. 241 suggests that Peary has only a rule of thumb acquaintance with astronomical methods. He remarks that he had to strain every nerve to arrive at the pole by noon, so that he could at once take an observation for latitude; but at the pole the sun would be moving round at nearly a constant altitude, so that any time would have served for the observations, and time would not enter into the computation.

The author gives an interesting description of the arduous voyage up and down Kennedy Channel. He tells us that only four ships have made this dangerous passage, and of these one was lost and two were badly damaged. Peary's experiences show that Sir George Nares's successful navigation of this channel in the *Alert* is a feat which has not received the credit it deserves.

The most interesting geographical contribution in the book is the discussion by Mr. R. A. Harris, of the United States Coast Survey, of the bathymetric and tidal observations. The soundings taken show that a continental shelf covered by 100 fathoms of water extends for forty-six miles north of Grant Land. From the edge of this shelf, the sea deepens rapidly to 825 fathoms, but it then becomes shallower again to the north, and the depth lessens to 310

fathoms; the sea deepens again, and Peary's soundings found no bottom at 1500 fathoms. The existence of this shallow ridge has an important bearing on the possible existence of land further to the west. This question is discussed by Mr. Harris, and he concludes from the tidal evidence, and the fact that the flood at Point Barrow comes from the west and not from the north, that there must be a wide area of land or of island strewn sea to the west of the Arctic Archipelago. He estimates that there is an area of nearly half a million square miles either of land, of islands, or of shoals still undiscovered in the Arctic Ocean to the north of the western part of North America and of eastern Asia. Mr. Harris suggests that this land must extend from north of Bennett Land, which is to the north of Siberia, eastward to Crocker Land, and with Peary's attainment of the pole the settlement of this problem is the most interesting geographical question left in the Arctic Ocean.

ENERGY AND THE ORGANISM.

Vicious Circles in Disease. By Dr. J. B. Hurry. Pp. xiv+186. (London: J. and A. Churchill, 1911.) Price 6s. net.

A FEW days before this volume was placed in the hands of the reviewer he had been watching for a few minutes the race of a small brook into a larger but more sluggish stream. Curiously near the inrush a wisp of straws lay almost at rest, circling slowly round and round, but not swept with other wisps and leaves into the main current. This arrest was due to a still but deep whirlpool formed by the different velocities of the waters at the angle of meeting. Light objects which skirted this eddy swiftly vanished on their way to the sea; those caught in it were imprisoned. However, by placing a walking stick tangentially to the eddy, now one straw, now another, would dart aside, and, catching a streak of the main current, would speed off into liberty.

This humble little parable may serve to illustrate Dr. Hurry's interesting volume on vicious circles of disease. The author's message may be summed up thus: In health the confluent or congruent streams of energy should work in reciprocal harmony for the several ends of the organism as a whole; but in disorder this agent or that, alien or home-grown, may strike tangentially upon one or more of such streams and form a vortex, twisting the lines of function and setting up, in one or more situations, a focus of wasting energy, and, it may be, a trap for alien or degraded products which should be run out of the system. Now at some point in this circle the gyrating lines may be cut, the eddy may be diverted, and the lines of energy released to their normal directions. The hound which had turned to hunting its own tail may be put again on the track.

Among the absurd axioms which we are apt to repeat without thought is that which unconditionally impugns the practical impulse to "treat symptoms"; but in the majority of cases—in all for which we have no specific antidote—no other course is open to the practitioner. Moreover, even where we have such a specific, to refrain from treating symptoms, if the physician's, is not the patient's point of view. He asks for cure; but also for relief. Now these observations and maxims of Dr. Hurry emphasise a further truth—that in so doing we may be cutting across—at any point, it matters not where—a "vicious circle." To disperse a vortex, expending energy in mere friction, may serve even to disperse the malady; at least it may moderate its intensity, or dispel vexatious symptoms. But often the whole trouble consists in such a vortex, and in a single one; in these cases, therefore, of which the author gives many an instructive instance, to treat a symptom is to cure a disease; for the conception of disease as an "entity" ought to be banished even from the language of the modern physician. Sometimes it is the knife which must take the place of the walking stick of the parable; but happily milder means often suffice to divert the currents into the normal channels, but not, as Dr. Hurry inadvertently says (p. 167), to "reverse" the circular movement. This cannot happen—or, more accurately, never does. Evolution never returns by the way it came.

There is one more demur. Dr. Hurry seems scarcely to realise, or fully to impress upon us, the factor of "organic memory" in these phases of function, the bent of biological matter to repeat what it has done before; a faculty on which development and purpose depend. In vicious circles every gyration deepens the groove, an abnormal habit is formed, so that arrest of such a local waste of energy and such a distress becomes more and more difficult; herein enters the problem of "faith healing," of the stronger tangential force which is to dissipate the vortex and redistribute the currents of energy. The longer the "habit"—the fixture of organic memory—the harder the impulse needed to "break the circle," for the habit has become independent of the original cause, which indeed had often vanished.

Dr. Hurry does not pretend for a moment to have discovered this notion of vicious circles, but he has made it his own; it is one often remarked upon by medical practitioners, but no one has presented the subject systematically to us before in a printed book. But both in lectures and practice I remember that the Teales, of Leeds—especially Mr. Pridgin Teale—taught the principle emphatically, and, if they did not publish the experience, put it variously into practice. And so it has been, no doubt, with many another physician; but of this the author is well aware, while he has himself the merit of perceiving the need of a systematic study of the problem, of adapting the principle with much ingenuity to explain many morbid conditions, and of illustrating the practice by interesting examples. Out of his careful clinical studies and large experience Dr. Hurry is justified in pointing to the great array of evidence which he has brought forward in his chapters on the systems of the body, and formulated in diagram, and in declaring that this aspect of medicine "is one which no practitioner of the *ars medendi* can afford to neglect."

C. ALLBUTT.

ALCHEMY, ANCIENT AND MODERN.

Alchemy: Ancient and Modern: Being a Brief Account of the Alchemistic Doctrines, and their Relations, to Mysticism on the One Hand, and to Recent Discoveries in Physical Science on the Other Hand, together with some particulars regarding the Lives and Teachings of the most noted Alchemists. By H. Stanley Redgrove. Pp. xiv+141. (London: W. Rider and Son, Ltd., 1911.) Price 4*s*. 6*d*. net.

THE author of this book thinks he perceives in the trend of modern chemical doctrine an approximation to the fundamental dogmas of philosophical alchemy, as these were understood and taught by its greatest exponents. The application of the principles of evolution to the genesis of the chemical elements has, in his opinion, brought us back to the "basic idea" permeating all alchemistic theory, and that, in his judgment, the time is gone when it may be regarded as legitimate to point to alchemy as an instance of the aberrations of the human mind. How far the general proposition is, or can be, substantiated by the facts of experiment at present known to us, may be seriously questioned. It is practically certain that no proof of transmutation has ever been given. Allegations of such an occurrence have been made, of course, times without number. But whenever any instance of the kind has been properly scrutinised, the allegation has been wholly disproved, and the evidence that it has been made in bad faith and as the result of conscious fraud, and not merely of honest self-deception, is, in a large number of instances, complete and irrefutable.

Does the evidence to be obtained from modern experimental inquiry place the "basic idea" on any surer foundation? Mr. Redgrove evidently thinks it does. Otherwise the *raison d'être* of his book is gone. He is, he tells us, not only a student of chemistry, but also of "what may be generalised under the terms Mysticism and Transcendentalism"; and he hopes that this unusual combination of studies has enabled him to take what he calls a broad-minded view of the theories of the alchemists, and to adopt a sympathetic attitude towards them. No one can possibly object to Mr. Redgrove taking a broad-minded view of anything—certainly not of chemical theory, whether ancient or modern. But theories in chemistry stand or fall by facts. The ancient alchemists certainly never proved their theories. Have the modern alchemists done any better?

That there is such a thing as the philosophy of alchemy is undoubted. Some of the earlier followers of the art were men whose names are not merely hallowed by a hoary antiquity, but who are known from their writings and by the testimony of their contemporaries to be earnest, thoughtful philosophers, actuated by the true spirit of science. It is difficult to believe that such men were not influenced by some guiding principle, and that they followed their calling simply as empirics. That many of them were churchmen, and some of them mystics, has lent colour to the supposition that they regarded alchemy as a form of transcendentalism, and the general character of certain of their writings may be pointed to in proof of such a view. But although at various periods in the history of alchemy there were men—John Dee was such a man—whose conduct and mode of study were largely influenced by their predilection towards occultism, it is quite certain that by far the greater number of adepts were swayed by the most mundane and even the most sordid of considerations. However desirous we may be to share Mr. Redgrove's sympathy and broad-mindedness, we fail to perceive that he has done anything towards the elucidation of the philosophy of alchemy. He has advanced no view that has not already been presented and examined, and he has given no facts that are not to be found in other works, such as those of Kopp, Hoefer, Figuier, Gerding, or the more recent publications of Mr. Waite. Davy once said that analogy was the fruitful parent of error. The author has been actuated by an analogy which is fundamentally unsound and treacherous.

There is really no evidence that modern science is permeated by the spirit of alchemy, and, therefore, strictly speaking, there is no meaning in the phrase "modern alchemy." The fact is, Mr. Redgrove has been led away by an inconstant and wandering affection. He will learn in time, if he does not already know it, that he cannot serve two mistresses, and that he had better be off with the old love before he is on with the new. At the moment his true love for chemistry has been somewhat obscured by an illicit, but we trust transient, affection for that Delilah named Mysticism, and the present book is apparently the product of his mixed emotions. He had better return to chemistry, and give her his undivided allegiance. As he knows her more thoroughly he will learn to appreciate her whole-heartedly. There is not much romantic fascination about her; she has nothing of the glamour of mysticism; indeed, she tends to be rather matter-of-fact, but then that is one of her strongest points.

There is a certain type of mind from which the facts slip off like the proverbial water from the duck's back, but which nevertheless prides itself on its receptivity for "broad views." The views are frequently made so very broad that they have actually no depth. It is only to this type of mind that Mr. Redgrove's book can appeal.

THEORIES OF THE AETHER.

A History of the Theories of Aether and Electricity from the Age of Descartes to the Close of the Nineteenth Century. By Dr. E. T. Whittaker, F.R.S. Pp. xiv+475. (London: Longmans, Green and Co.; Dublin: Hodges, Figgis and Co., Ltd., 1910.) Price 12*s*. 6*d*. net.

WHEN we turn to an historical survey of electrical theory we are usually entertained by reprints showing scenes like the Abbé Nollet demonstrating the properties of an electrified boy, but the present work contains more satisfactory evidences of first-hand knowledge of the authorities. It traces carefully the growth, during three centuries, of optical and electrical science, more especially in rela-

tion to the theory of the æther. As regards mathematical calculations, space is saved by expressing results in vector notation, as well as by numerous references to the original memoirs; the treatment of the more important advances, without being exhaustive, is sufficiently adequate to define them clearly in their historical setting, that being the proper function of a work of this type.

Two-thirds of the book are devoted to the period ranging from Descartes to Maxwell. For most students this will probably be the more valuable portion, epitomising work which is not easily accessible.

Dr. Whittaker makes an interesting addition to the history of the law of electrostatic attraction between two charged particles. The law of inverse square of the distance is commonly ascribed to Coulomb, on account of his direct verification by means of the torsion balance (1785). When the researches of the Hon. Henry Cavendish were edited by Maxwell in 1879, it was seen that the same law had been established by a different method as early as 1773; on referring to early literature, such as Young's "Lectures," it appeared that the unpublished work of Cavendish was quite unknown to his contemporaries. Dr. Whittaker directs attention to a still earlier statement in Priestley's "History of Electricity," published in 1767. It appears that Priestley, following Franklin, had made experiments which showed that, when a hollow metallic vessel is electrified, there is no charge on the inner surface, and no electric force in the air inside. Priestley then continues:

"May we not infer from this experiment that the attraction of electricity is subject to the same laws with that of gravitation, and is therefore according to the squares of the distances; since it is easily demonstrated that were the earth in the form of a shell, a body in the inside of it would not be attracted to one side more than another?"

The chapter on elastic solid theories covers an important period. Cauchy, who was first in the field, obtains full credit for his various theories; although one sees how his work failed to stimulate later writers, especially of the English school. Dr. Whittaker remarks that his point of view in the earlier theories appears to have been: Given the equations of vibration of an elastic solid, what boundary conditions must be used in order to obtain Fresnel's results? It was Green who first showed that with a properly localised energy function, the Lagrangian method gave not only the equations of motion, but also the correct boundary conditions.

Some attention is paid to the æther of Cauchy's third theory of reflection, better known as the contractile æther of Lord Kelvin. The form of energy function used by Lord Kelvin might have been noticed; after beginning with the ordinary form for an elastic solid, he transformed it, by integrating by parts, into a form similar to that of MacCullagh's theory. One would consider this form as properly localised, not for the contractile æther, but for a medium specified to be rotationally elastic.

In the later portion of the book mechanical theories are treated further under the more modest description of models of the æther; there are also chapters on the followers of Maxwell, on conduction in solutions and gases, and on more recent theories of æther and electrons. These give a general account of various lines of advance since the time of Maxwell; in particular one notices the problem of relative motion of the earth and the æther, leading to a consideration of the nature of systems of measurement of space and time. The period of the book closes with the æther still endowed with a certain degree of substantiality, however different it may be from ordinary matter. In view of more recent developments based on the theory of relativity, Dr. Whittaker's treatise appears at an opportune time; it forms an important and valuable aid to a comparative study of theories of the æther.

T. H. H.

DISEASES OF ECONOMIC PLANTS.

Diseases of Economic Plants. By Prof. F. L. Stevens and J. G. Hall. Pp. x+513. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 8*s.* 6*d.* net.

THIS book is primarily intended for those who wish to recognise—without having recourse to the microscope—and then to combat fungous diseases of cultivated plants. Descriptions are given of the prominent characteristics of the most destructive diseases of fruit and vegetables cultivated in the United States, as well as information regarding the latest methods of prevention or cure. All the best bulletins of the numerous State agricultural experimental stations and of the U.S. Department of Agriculture have been examined for facts; the authors have had the help also of various specialists in reading over the proofs of certain parts, *e.g.* Dr. Erwin F. Smith has thus assisted with the bacterial diseases, Dr. L. R. Jones with potato diseases, and so forth. Short, clear, scientific descriptions are given of the various life-stages of the species of fungi causing plant diseases; these are accompanied by practical advice as to the methods to be employed against each stage by the grower. In many cases, *e.g.* in that of the onion "smut" and of the "common scab" of the potato, and of the various diseases of the apple, the account given is a model of what should be provided by the man of science for the practical man. Clear directions are given for the making and application of fungicides, and also useful information on the subject of spraying machinery. It would have been well, however, to have supplied fuller information on the subject of "Bordeaux injury," and how it may be avoided. Practical details are given of the disinfection of seeds by the use of formaldehyde gas, and the various methods of soil disinfection are discussed. It is pointed out that the presence in land of such ineradicable soil diseases as the melon, cowpea, cotton, or tobacco "wilt," onion "smut," cabbage "black rot," &c., may result in a depreciation of 50 per cent. or more in the market value of the land. In dealing with many of the diseases of cereals, pea, bean, lettuce, celery, potato, carnation, violet, asparagus, grape, strawberry, and other fruits the authors are not content with merely

stating that "resistant" varieties or "strains" should be grown but in all cases mention the names of such "resistant" varieties obtainable on the market. Such practical information is likely to be of great value to the market grower or gardener; it must be admitted that such assistance as this is not yet able to be given in this country, except in a few cases, by the man of science to the grower.

Throughout the book we find instances given of fungous diseases of different crops which have become epidemic in various districts in the States and caused serious money losses; on the other hand, we have detailed evidence given showing that such losses may often be avoided by careful and thorough spraying with the right fungicide at the right time. The annual loss caused by potato "blight" in the United States is estimated at 36,000,000 dollars; that caused by wheat "rust," 67,000,000 dollars. Turning to horticultural crops, we are told that the violet "leaf-spot" caused, in 1900, a loss of 200,000 dollars; the celery "leaf-spot"—which for the past three seasons has been causing havoc in several counties in this country—is stated to have caused a loss, in California, in 1908, of 1950 car-loads, and a money loss of 550,000 dollars. An interesting account is given of the gradual invasion of the States since 1896 by the asparagus "rust"; it is now known in every State where asparagus is grown—

"In some States the invasion of this disease has almost, if not quite, prohibited commercial asparagus growing. . . . The Palmetto varieties are quite resistant, and offer a solution of the rust problem in some localities."

Of the American gooseberry mildew (which we may remember has, since its introduction into Europe, about 1900, now spread over the whole of Ireland and England) it is said:—

"This disease has quite prohibited the cultivation of the finer sorts of English gooseberries in America, and is a grave menace to the culture of gooseberries in Europe."

One or two points of purely scientific interest may be noted. The statement is made that the pea mildew (*Erysiphe polygoni*) hibernates in seed derived from affected pods, and that the celery "leaf-spot" (*Septoria petroselini*, var. *Apii*) is probably carried by the seed of celery. The mistake is made of identifying the mildew on cucumber, cantaloupes, and musk-melons with *Erysiphe polygoni*, although Reed's interesting work on the specialisation of parasitism shown by this mildew—which this mycologist correctly referred to *E. Cichoracearum*—was recently published in the States. In place of *Podosphaera* the misprint *Podosphaeria* (with the "popular" (!) name "podosphæriose") appears three times; also the erroneous name of *Sphaerotheca mali* is continued for the apple mildew, and the mistake made of supposing that *Podosphaera leucotricha*—of which *S. mali* is a synonym—is a distinct species.

The book is very well illustrated, and the writing remarkably clear and to the point. There is one touch of pedantry—quite out of place in such a practical book as this—against which a strong protest must be raised—the attempt to create "popular" names derived from the generic name of the fungus causing the disease. Thus we have "Sphæropsose" proposed for "black rot," caused by *Sphaeropsis*, and such verbal monstrosities as "pseudomonose," "lasiodiplose," "merуliose," &c.

A chapter on the legislative regulations—Federal and inter-State—in force in America might have been added to make the admirable thoroughness of this book quite complete. As it is, this book should be in the hands of all the officials—both the Board of Agriculture's inspectors and the inspectors of the various county councils—who are now engaged in England in the work of combating fungous diseases under the provisions of the "Destructive Insects and Pests Act." The importance of the need to create a more enlightened public opinion on matters connected with plant protection and plant sanitation is rightly insisted upon in this book; as its authors say:—"To create a much-needed, enlightened, aggressive public opinion is part of the duty of plant pathology."

(2) *The Student's Arithmetic.* By W. M. Baker and A. A. Bourne. Pp. viii+328+1. (London: G. Bell and Sons, Ltd., 1910.) Price 2*s*. 6*d*.

(3) *First-Year Mathematics for Secondary Schools.* By Prof. G. W. Myers and others. Third edition. Pp. xii+365. (Chicago, U.S.A.: University of Chicago Press; London: Cambridge University Press, 1909.) Price 4*s*. net.

(4) *Second-Year Mathematics for Secondary Schools.* By Prof. G. W. Myers and others. Pp. xiv+282. (Chicago, U.S.A.: University of Chicago Press; London: Cambridge University Press, 1910.) Price 6*s*. net.

(5) *Geometric Exercises for Algebraic Solution. Second-Year Mathematics for Secondary Schools.* By Prof. G. W. Myers and others. Second impression. Pp. ix+71. (Chicago, U.S.A.: University of Chicago Press; London: Cambridge University Press, 1909.) Price 3*s*. 6*d*. net.

(1) THE introductory course provided by this text-book includes the solution of triangles, omitting the ambiguous case, applications to the geometry of the triangle and quadrilateral, and easy problems in surveying. Complicated identities are excluded on the ground that they belong to the programme of the specialist rather than the amateur for whose use this is primarily intended. The general character of the book will probably be considered unduly conservative. It fails to take cognisance of the recent movement affecting the teaching of trigonometry. There is scarcely as much numerical work as many teachers will require, and the quality of the problems, which profess to be practical, is distinctly poor. The best feature of the book is the material provided for oral work, which will be found invaluable for class purposes.

(2) This is an abbreviated edition of the "Public School Arithmetic," by the same authors. The number of examples worked out in detail has been materially diminished on the ground that the average boy is apt to rely too much on this form of assistance and so avoids the necessity of thinking for himself. This is, of course, a matter of opinion. It is not at all an easy thing to train students to read for themselves; in general they are far too prone to rely on oral help. In more advanced work, it is unquestionable that there is a real educational value in forcing a boy to find out for himself the meaning of what the text-book is explaining, provided only that the book itself is a good one. Of course, progress is made more slowly in these circumstances, but the substance of what is read is more likely to be digested owing to the increase of mental effort. It is, however, hard to decide at what stage this recourse to books should be encouraged. The present volume gives a very thorough account of all branches of the subject. Indeed, in our opinion it contains far more than it is desirable for the average boy to know. The time required for mastering its contents is so considerable that it will leave small opportunity for proceeding to more fruitful work. But so long as an exhaustive study of the subject is required by examining bodies, it will be necessary for writers to meet this demand. In this the present volume is eminently successful.

(3) and (4) In the opinion of the authors of this treatise, which is issued in two volumes, the subjects of algebra and geometry should be fused together as far as possible. It is suggested that students are more likely to realise the relations which subsist between these two portions of elementary mathematics, if a single text-book is placed in their hands. An examination of the contents of the separate volumes shows that algebra predominates in the first and geometry in the second; but in each case it is true to say that the correlation of the two subjects is kept consistently in view. The first course includes the elements of algebra up to simultaneous linear equations, factors, and fractions, and the fundamental ideas of geometry, viz., congruence, parallelism, and similarity, with numerical illustrations and straightforward constructions. The principle of moments is used to provide some interesting algebraic problems. The advanced course contains a more systematic account of formal geometry, the properties of the circle, theorems on areas and similar figures, the investigation of regular polygons, and more difficult constructions. With this is combined the general solution of the quadratic, the algebraic theory of proportion, graphical algebra, and simple numerical trigonometry restricted mainly to right-angled triangles. The manipulation which is expected from the student is of a simple character. This is probably the best plan for students of the age for which this book is designed. But we doubt whether it is equally desirable to exclude at the same time anything which can be properly called a rider. Numerical work in geometry provides the most certain means of elucidating new ideas, but unless this is combined with a certain amount of theoretical work, the intrinsic value of the subject is sacrificed. The ability to solve a simple rider is the best index of the intellectual growth of the student.

(5) The title of this book is an adequate description of its contents. It consists of about eight hundred examples, illustrating the theorems of elementary plane and solid geometry, and it yields a collection of questions which many will find a useful supplement to formal treatises.

OUR BOOK SHELF.

Ornitologia Argentina. Catálogo sistemático y descriptivo de las Aves de la República Argentina. By Dr. R. Dabbene. Tome Primers. Pp. xiv+513. (Buenos Aires: Museo Nacional, 1910.)

THE object of the present work, of which the volume before us is only the first, is to provide, as we learn from the preface, a systematic list of all the genera and species of birds inhabiting Argentina, mainly from the point of view of their geographical distribution, for the use, chiefly, of students of ornithology in the Republic. Most of the species common to the neighbouring countries of Brazil, Bolivia, Paraguay, and of the frontiers of Chili and Uruguay are included, since it is highly probable that the birds of these regions will be discovered in the Argentine when it is more fully explored. Included also are all the species inhabiting the archipelagoes and islands lying off the shores, as well as the lands extending southward to the Antarctic circle.

The work is to contain three parts. The first deals with those anatomical characters of birds which are of classificatory value. The second discusses the geographical distribution of the birds of the Republic, with a list in systematic order of all its recent and fossil species, and their assignation to the different zones—shown on a coloured map—into which the author divides the region. The final section, to be dealt with in future volumes, will contain brief diagnoses of the orders and families, &c., of birds represented in the Argentine, with keys for differentiating the species, which number 409, referable to 71 families. An extensive bibliography is appended to each section.

Although Dr. Dabbene is largely indebted, with due acknowledgment, for his morphological facts to European investigators, and among English workers especially to Huxley, Garrod, Forbes, Beddard, Chalmers Mitchell, Garrod, and Newton—from whose works most of his figures are derived, the volume will be of very great value to students so disadvantageously remote from the great European libraries and books of reference, as are those domiciled in Argentina. The section devoted to geographical distribution brings concisely together the data under this head, and will be appreciated by those elsewhere interested in South American ornithology. The volume is provided with very full indices.

Die Samenpflanzen (Blütenpflanzen, Phanerogamen). By Prof. K. Wilhelm. Pp. xvi+151. (Wien and Leipzig: F. Deuticke, 1910.)

THERE can be no disagreement with the author's opinion that the only satisfactory method of acquiring a knowledge of plant classification is to practise the determination of unknown species with the aid of a flora or other systematic compilation. It has been Dr. Wilhelm's object to supply a compilation suitable for the use of foresters, agricultural, pharmaceutical, and other technical students. The chief essentials for such a work appear to be a differentiation,

if possible analytically disposed into orders—better known as "cohorts"—a good description of the families, and an indication of important characters for leading genera. This requires a work of some magnitude, but not more extensive than Warming's "Systematic Botany," which follows these lines. Wilhelm's "Samenpflanzen" defines orders and families, and in the case of large families supplies discriminating characters for subfamilies, but only in occasional instances provides the necessary information for identifying genera.

The arrangement adopted is a modified Eichler-Engler system, prepared by Prof. R. Wettstein for his "Handbuch der systematischen Botanik," but the diagnostic characters have been redrafted by Dr. Wilhelm. A very valuable feature in the former book is the series of notes pointing out the probable relationships and affinities between various families, thus furnishing an important key to the system; a similar phylogenetic guide would be useful for the book under notice. The plants enumerated include European species, those yielding economic products, and timber trees; by the adoption of different printing types it is intended to give an idea of the comparative importance of the various genera. The lists are, so far as observed, both full and accurate.

The Past at Our Doors, or the Old in the New Around Us. By W. W. Skeat. Pp. xi+198. (London: Macmillan and Co., Ltd., 1911.) Price 1*s.* 6*d.*

IN this interesting little book Mr. Skeat shows how the past is not only at our doors, but upon our lips. Confining himself in the main to the subjects of food, dress, and the home, he brings together a multitude of facts bearing upon the history of the common objects and events of our domestic environment. The etymological bias is marked, but excusable—perhaps even inherited—and Mr. Skeat does not fail to emphasise the influence of our ancestors upon our deeds, as well as upon our words.

In the "Story of Our Food" the range is from meal times and their names, through the apparatus of the table, to hunting, ploughing, and the preparation of food, with other matters taken by the way. The section on "Dress" follows the general lines of recent works on the subject, and is more fully illustrated than the rest of the volume. The "Story of Our Homes" is chiefly an account of the evolution of the modern dwelling-house, including such furniture as cupboards, dressers, wall-hangings, carpets, and beds.

In view of the great variety of subjects discussed in a small space, some degree of discontinuity was unavoidable, and the book has the character of a work of reference on a small scale. If it is pemmican, it is good pemmican, and full value for the money.

H. S. H.

Serum and Vaccine Therapy. Bacterial Therapeutics and Prophylaxis Bacterial Diagnostic Agents. By Prof. R. T. Hewlett. Second edition. Pp. x+406. (London: J. and A. Churchill, 1910.) Price 7*s.* 6*d.* net.

THE second edition of Prof. Hewlett's book on serum-therapy, which has just appeared, does not claim to give more than an outline of the mode of preparation and employment of the therapeutic sera and vaccines. As such it ought to prove of service to the student or busy practitioner, who may not have the opportunity or the time to consult the larger works on this subject. It is doubtful, however, if the author has been entirely successful in his effort to condense the subject, for the requirements of the interested medical reader. The authorities quoted, though few, are not always the most authoritative, and their opinions are too frequently referred to without criticism or comment. A good account is given of the preparation of the antitoxins for diphtheria and tetanus and antivenin. Referring to the employment of antitoxin as a prophylactic against diphtheria, the author is apparently impressed with the objections raised against it on the ground that an anaphylactic state may be induced, and he thinks that a diphtheria-endotoxin, which he is at present elaborating, may prove an efficient substitute for antitoxic serum in prophylaxis. The appearance of this preparation will be awaited with interest by the medical profession. The intracerebral injection of tetanus antitoxin is recommended as the method which gives most hope of success in cases which have lasted any length of time, but it does not seem that trustworthy data on this question are available.

More space might have been devoted to the use of tetanus antitoxin as a prophylactic and to the anti-meningococcal and antidysentery sera, both of which have proved of the highest value in practice, and in point of efficiency should follow closely after diphtheria antitoxin.

Other sera, such as antipneumococcic and antityphoid, have more space devoted to them than their importance at present warrants.

Vaccine-therapy receives adequate treatment at the author's hands, but it is somewhat curious that the account should be prefaced by a dissertation on opsonins. These substances should surely take their place in the general scheme of antibodies called forth in response to immunisation.

The closing chapters of the book deal with the preparation of calf lymph, typhoid vaccine, mallein, tuberculin, and sour milk.

We observe at the close of the book certain trade advertisements, the majority of which deal with soured milk or cheese. These appear somewhat out of place in a scientific treatise.

Handbook of American Indians north of Mexico. Edited by F. W. Hodge. In two parts; part ii., N–Z. Pp. iv+1221. (Smithsonian Institution, Bureau of American Ethnology, Bulletin 30.) (Washington: Government Printing Office, 1910.)

THE second and concluding volume of the "Handbook of American Indians north of Mexico" has followed three years after the publication of the first volume. It consists of more than a thousand pages of closely printed matter in double columns; there is in addition a synonymy of 158 pages and an extensive bibliography; unfortunately, the latter is not quite complete. For example, Mr. C. Hill-Tout's papers on the Salish in the *Journal* of the Royal Anthropological Institute and Reports of the British Association, and his book on "British North America—I., the Far West" (1907), are totally ignored, both here and in the article "Salish." It is impossible to review a book of this kind as it is composed of an enormous number of notes and short articles written by experts, of whom fifty-four were employed on this volume alone. The information is given succinctly, and in most cases an adequate bibliography is added at the end of each article. There is as large a number of illustrations as space permitted. All those interested in North American ethnology and archæology will appreciate the value of authoritative statements on disputed points, and the references for further information thereon. It is also a great convenience to be able to discover the synonymy of a tribe and to be informed as to what may be regarded as its official designation. As a book of reference it is simply invaluable, and it should find a place in every public library; every ethnologist will procure a copy as a matter of course.

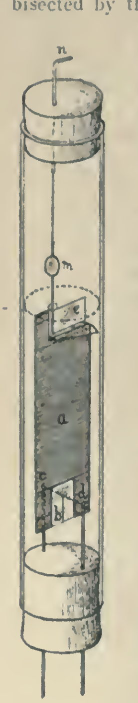
LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Thomson and Peltier Effects.

A MODIFIED Joule radiometer has been applied successfully to show the existence of the Thomson effect in copper and the Peltier effect at the junction of two dissimilar metals.

The lower part of a vertical glass tube 3 cm. in diameter was divided into two compartments by a cardboard diaphragm *a*, 12 cm. long. A rectangular strip was cut away from the upper part of the partition, and a mica plate, *b*, was substituted for a similar strip from the lower part. A thin copper wire *cd*, No. 36, was soldered to two thick copper leads, No. 16, fixed into a cork. The wire *cd* was passed through a slit in the mica plate *b*, and the cork was pushed to within 1 cm. of the lower edge of the partition. The wire *cd* was arranged so that it was nearly bisected by the mica plate. A mica vane *e* attached to an aluminium wire was suspended by a quartz fibre within the aperture in the upper part of the partition. A horizontal disc of cardboard, shown dotted in the figure, was fixed to the upper cork by a pair of rods, and fitted inside the tube just above the vane. A horizontal sector-shaped plate of mica was fastened to the partition just below the vane to complete a channel for the current of air from the warm to the cool side of the partition. The clearance between the edges of the vane and the opening was about 1·5 mm., and the angular movement of vane was restricted by stops to about 30°. The motion of the vane was observed by reflecting a beam of light from the mirror *m* on to a scale at a distance of 80 cm.



The partitioned tube, together with the suspended vane, constitutes a Joule radiometer in which unequal heating of the columns of air in the two compartments will cause a deflection of the vane. The radiant heat from a candle flame at a distance of 2·5 metres falling on one side of the partition produced a deflection of 5 cm. of the spot of light on the scale. Owing to its high sensibility, it was found necessary to shield the columns of air from draughts and radiant heat from external sources.

A current of 6 amperes was passed through the thin copper wire *cd*, and a temperature gradient was thus established from the centre towards each end of the wire. The vane was deflected owing to the Thomson effects and the inequality of the Joule effects in the two halves of the wire. The position of the vane was fairly steady after an interval of five minutes, and the spot of light was brought to the centre of the scale by turning the bent wire *n* attached to the fibre. The current was rapidly reversed, and the spot of light moved quickly through 8 cm. on the scale. The wire *cd* was adjusted to slightly different positions in order to vary the inequality of the Joule effects, and practically the same result was found in every case. It was concluded from the direction of motion of the vane that in copper heat was absorbed when the current flowed up the temperature gradient.

To show the Peltier effect, an iron wire 4 cm. long and 1 mm. diameter was soldered to another pair of copper leads and bent just under the partition. The passage of a current of 1 ampere through the junctions was sufficient to move the spot of light off the scale. There is no need to reverse the current in this case, and it can be shown quite easily that heat is absorbed when the current flows from copper to iron.

F. W. JORDAN.

South-Western Polytechnic, Chelsea, S.W., May 8.

Compulsory Latin Diagnoses for Fossil Plants.

THE question whether descriptions of new species, genera, &c., of *fossil* plants should be accompanied in future by a diagnosis or diagnoses in *Latin* has been recently discussed among those who are working on fossil botany. It is not proposed here to enter into the arguments which have been advanced either for or against this proposition. It appears, however, that, so far as palæobotany is concerned, the arguments against the use of diagnoses in Latin are held far to outweigh those in favour of such diagnoses. In order to test current opinion on this point, a memorandum has been recently circulated by the writer among those who are engaged in the study of fossil plants in this country and in the United States, and by Prof. Nathorst in Sweden and Denmark. The object of the memorandum was to ascertain the present intentions of those working at fossil plants as regards this much disputed question. The result of this exchange of opinion has been very remarkable. Every palæobotanist in this country, in the United States, and in Scandinavia to whom a copy of the memorandum has been sent has expressed his intention of avoiding the general use of diagnoses in Latin, and, further, of recognising as valid diagnoses instituted in the future which are not published in Latin.

The memorandum in question contained two statements of intention, which were as follows:—

(1) "I do *not* propose to include a diagnosis in Latin in the description of any new species, genus or family that I may institute in the future, unless there appear to me, in particular cases, to be special reasons for so doing."

(2) "I will *not* refuse to accept new species, genera or families of fossil plants instituted by other workers in the future, solely on the ground that their description is not accompanied by a diagnosis in Latin."

The following is a list of those who have subscribed to both these statements. In the case of those names indicated by a *, some slight modification of the wording of one or other statement was made. These reservations follow the list of signatures:—

Mr. C. T. Bartholin, Copenhagen, Denmark.
Dr. M. J. Benson, Royal Holloway College, Englefield Green, Surrey.
Prof. E. W. Berry, Johns Hopkins University, Baltimore, U.S.A.
Prof. T. D. A. Cockerell, University of Colorado, Boulder, U.S.A.
Mr. W. T. Gordon, The University, Edinburgh.
Dr. Th. G. Halle, Stockholm, Sweden.
Dr. N. Hartz, Copenhagen, Denmark.
Dr. G. Hickling, The University, Manchester.
Mr. H. S. Holden, University College, Nottingham.
Mr. A. Hollick, New York Botanic Garden, New York, U.S.A.
Prof. E. C. Jeffrey, Harvard University, Cambridge, U.S.A.
Dr. R. Kidston, F.R.S., Stirling.
Dr. F. H. Knowlton, U.S. Geological Survey, Washington, U.S.A.
Mr. F. J. Lewis, The University, Liverpool.
Mr. A. J. Maslen, London.
Dr. H. Möller, Falun, Sweden.
Prof. A. G. Nathorst, Stockholm, Sweden.
Prof. F. W. Oliver, F.R.S., University College, London.
* Mr. Clement Reid, F.R.S., The Geological Survey, London.
* Mrs. Clement Reid, Milford-on-Sea, Hants.
Dr. D. H. Scott, F.R.S., Oakley, Hants.
Mrs. D. H. Scott, Oakley, Hants.
Dr. M. C. Stopes, The University, Manchester.
Mr. H. H. Thomas, The Botany School, Cambridge.
Mr. D. M. S. Watson, The University, Manchester.
Prof. F. E. Weiss, The University, Manchester.
Dr. D. White, U.S. Geological Survey, Washington, U.S.A.
Dr. G. R. Wieland, Yale Museum, New Haven, U.S.A.

Mr. and Mrs. Clement Reid have signed both statements with the addition of the words "if it is accompanied by a recognisable figure" at the close of the second statement after the words "diagnosis in Latin." They add

"we consider that the international character of the diagnosis will better be maintained if the Vienna rule be altered so as to read 'either a diagnosis in Latin *or a recognisable figure*.' This alternative would do away with the difficulty as to language, and would allow botanists to use their own language, provided they give a characteristic figure."

Prof. Seward has signed the second statement, and has added the following remarks:—"In view of the nature of much of the material available for investigation, I consider that it is undesirable to insist on a Latin diagnosis for all species described by palæobotanists. In cases where a formal diagnosis is possible, such diagnosis and a figure of the specimen ought to be given, but for the present at least I am not disposed to bind myself to the publication of a diagnosis in Latin. It is, I believe, in the interests of the subject to avoid pledging oneself to any fixed rule as regards either a diagnosis or the language in which the diagnosis is to be written.—A. C. Seward."

Prof. Zeiller, of Paris, to whom a copy of the memorandum was forwarded, has signed the second statement mentioned above, and has kindly expressed his reasons for being unable to subscribe to the first. These are as follows:—

"M'étant, au Congrès de Bruxelles, rallié, dans un esprit de conciliation, à la disposition générale qui fait de la diagnose latine une obligation, je n'en persiste pas moins à penser que cette obligation ne devrait pas être étendue à la paléobotanique, l'application s'en heurtant souvent, avec l'état fragmentaire et incomplet des fossiles végétaux, à des difficultés presque insurmontables, notamment lorsqu'il s'agit d'échantillons à structure conservée ne montrant que des caractères anatomiques internes.

"J'émets le vœu que tous les paléobotanistes s'unissent pour demander au prochain Congrès de leur laisser à cet égard la liberté dont ils avaient joui jusqu'ici, et à l'encontre de laquelle on n'a relevé aucun inconvénient.—R. Zeiller."

In conclusion, while, as we have seen, the British, American, and Scandinavian palæobotanists have agreed to avoid the *general* use of Latin diagnoses for the present, it should be pointed out that the object of the memorandum mentioned above has been solely to ascertain the opinions and *present* intentions of workers on fossil plants in this respect. It is, of course, understood that those who have subscribed to the two statements quoted above are not in any way bound as to the future, and they are at perfect liberty if, in altered circumstances in the future, they should wish to depart from their present opinions and intentions to do so. The view is widely held that perfect liberty in regard to matters of nomenclature, as in other directions, is essential to the progress of our knowledge of fossil plants.

E. A. Newell Arber.

The Sedgwick Museum, Cambridge.

Spitting Cobras.

The following note may be of interest, the more so as the existence of cobras in Borneo is denied in a recent work on Borneo ("Seventeen Years among the Sea Dyaks"). In your "Notes" in Nature of May 4 (p. 320) you refer to the "spitting cobras" of East Africa. The cobra of East Borneo also has the power of projecting its poison to a distance of at least 1 metre. In January of last year I was walking along a narrow jungle track about twenty miles from the coast, in lat. 1° 10′ S., when I saw a cobra erect preparing to strike at me. I struck it about 30 cm. from the head and broke its back (as I thought). It then projected two streams of liquid at me as I stood over it. A Bugis close beside me exclaimed, "dia menumpit!" (menumpit = to shoot with the blow-pipe). One stream struck the lapel of my coat, but I did not notice where the other struck. I placed the dead (?) cobra on a tree, intending on my return to carry it to my camp and bottle it, but when I returned it was gone.

About two hours after the incident I felt an irritation on my skin, which lasted for some hours, and then gradually disappeared. There was a newly healed leech wound at the place, but I could hardly believe that the cobra venom could have penetrated thick puttees, trousers, and socks all wet through. But I sent for the Bugis who had accompanied me, and without telling him anything, asked him to point out where the cobra poison had struck me. He immediately placed one finger on the lapel of my coat and another on my shin exactly where the irritation was.

He added that about ten miles away his brother had lost the use of his arm for three months because of a cobra which had projected its poison at him.

The cobra was black with a bluish sheen, but the throat was yellow. Estimated length, 1600 mm.

Boscombe, May 8. T. R. H. Garrett.

The Reform of the Calendar.

The article in this week's Nature on "Daylight and Darkness" leaves little to be said with regard to the so-called Daylight Saving Bill. Its adoption would indeed render us "the laughing-stock of the enlightened people of the world." No object, however good in itself, can be attained by a deceitful and underhand process, which must lead to many inconsistencies and misunderstandings. There is no reason why 12 o'clock should be the exact time of noon; in point of fact, it seldom is, as clocks must be regulated to keep *mean* time. But there is a very good reason, and it is of great importance, that the interval between two consecutive hours by the clock should be always exactly one hour. To regulate it otherwise would be deceitful and confusing.

My purpose, however, in this letter is rather with reference to Mr. Philip's letter on the "Reform of the Calendar." He denies that the week has had an unbroken continuance, because the paschal full moon on A.D. 31 (which he thinks was the year of the Crucifixion) fell on March 27, which was a Tuesday. Now the Jewish Passover had nothing to do with the day of the week, and might fall on any day, being regulated by the moon. That it fell in A.D. 31 on a Tuesday proves that that could not have been the year of the Crucifixion, which was probably A.D. 30, or possibly (as Prof. Sanday now thinks) A.D. 29. The seventh day of the week (the Jewish Sabbath) was the day after the Crucifixion, and the day after that, the first day of the week, the day of the Resurrection. Christians observed that day as their sacred day every week, and the Church decided (after the early Quartodeciman controversy, settled by the Council of Nicæa) to keep the Christian Passover (which we call Easter) always on that day of the week. There has, then, never been any break in the continuity of the week.

Blackheath, May 13. W. T. Lynn.

The Rusting of Iron.

In view of the correspondence which has taken place recently in Nature on this subject, I should like to refer to the results of some further investigations which I have made in conjunction with Mr. J. R. Hill in continuation of those published in the Journal of the Chemical Society in 1905. In that paper, and in other previous publications, experimental evidence was brought forward to show that the rusting of iron can take place in the absence of carbon dioxide, contrary to the generally accepted view. Several chemists have addressed themselves to the task of defending the old opinion that carbon dioxide is necessary. Their arguments were summarised recently in an article in Nature initialled "T. M. L." No exception can be taken to this article if its limitations are clearly recognised. It omits all reference to the large body of experimental work which has been published by Whitney, Tilden and others, in addition to myself, to show that the old view must be abandoned. The most recent work of Lambert and Thomson confirms this conclusion, whilst making an important addition to our knowledge of the conditions of reaction between iron, oxygen, and water when brought together in the most highly purified forms.

My object in writing this note is to state that I have now ascertained the cause of the inhibiting effect which certain substances, including alkalis and potassium bichromate, exert in preventing the rusting of iron, and it therefore becomes possible to explain a number of facts, including certain results which have been held to prove that carbon dioxide is a necessary factor in rusting.

It is now clear that all those agents which inhibit the rusting of iron (see Journ. Chem. Soc., 1905) also render the iron "passive" to a greater or less extent, and that this passivity of iron persists after the metal has been removed from the effective solution. Iron which has been immersed in alkalis or in a solution of potassium bichromate is found still to be passive after careful washing with water, that is, after removal of all trace of the solution which produced the effect. The iron is no longer attacked by nitric acid of a certain strength or by the appropriate solution of copper sulphate, nor does it "rust" in presence of oxygen and water. Contact with certain substances, especially dilute acids, including carbonic acid, at once destroys the passivity, and the iron becomes active again in all respects. A full account of this work and of its bearings will shortly be given.

The fact alluded to in recent correspondence, that an iron cylinder which has been immersed in potash solution and afterwards washed with water will not rust in air until carbon dioxide is admitted, does not prove that carbon dioxide is necessary for rusting. The observed facts are due, first, to the passivity of the iron induced by the alkali, and, secondly, to the destruction of this passivity by the carbon dioxide. The same piece of iron will rust freely in air deprived of carbon dioxide, provided that it has not been in contact with alkali of such a strength as will induce passivity.

May 9. WYNDHAM R. DUNSTAN.

SCIENCE AND THE IMPERIAL CONFERENCE.

SUCH words as Empire and Imperial, like many others, suffer some disadvantage from their historical antecedents. Looked at in the past they recall something Roman, something Napoleonic; the rule of dependent peoples, conquered by the sword, and governed, not wholly inefficiently, but without much say in the matter, by military power. Looked at in the present and with a scientific eye, the British Empire reveals itself as something fundamentally different. It is simply the last term of social aggregation. Free peoples, starting from the family, aggregate themselves into larger and larger groups, and the common freedom is maintained by the naval supremacy of the mother-country. The Crown consecrates the unity of the whole.

Every stage of aggregation in such a system has its common interests which require concerted action. The recognition of this inevitably leads to some sort of what Herbert Spencer would have called physiological integration in which the whole is greater, or at any rate more efficient, than the sum of its parts. The Imperial Conference, which is about to meet, has come into existence just as naturally as a municipality or a county council. The essential principle is the same: the scope of its deliberation will only extend to larger problems.

Such problems will be matters of high policy, and though it may be hoped that they will be dealt with in a scientific spirit, it is improbable that the direct interests of knowledge will for the moment find a place amongst them. But the principle of Imperial Conference, which happily there is every reason to regard as permanently established, has already received a development in a more detailed direction. The Imperial Education Conference, which held its last public sitting on April 28, has now received Government recognition, though its first meeting in 1907 was the result of unofficial initiative. It is not improbable that its example may be followed on behalf of other interests of no less importance.

Knowledge in a logical order would come before education. But the machinery of an Imperial Conference would probably not be very helpful to the progress of science in the abstract, as that cannot be earmarked to any nationality. The scientific study of the Empire itself is a field in which that machinery could find employment with results of the most profound scientific interest and the greatest practical utility.

Looking at the magnitude of the Empire, nothing is more remarkable than the feeble interest it excites in the mind of the average citizen. His horizon is rarely more than parochial, and the only imperial problem on which he probably has a distinct conviction is the necessity of maintaining our naval supremacy. It is something that in a vague way he should wish it to be maintained. But what the Empire is, or what are its future possibilities, he neither knows nor cares. In this he is hardly to be blamed. He was taught in his youth, as we may learn from the "Reminiscences of Goldwin Smith," that Colonies were a source of weakness, and we may learn from the same authority that half a century ago even the Colonial Office was animated with the idea of getting rid of them decently. If, since that day, opinion has changed to acquiescence in the existence of Empire, it is due to the influence and advantages of a peaceful commerce. Perhaps in generations to come it may excite a livelier enthusiasm.

A common attack, such as a conference might stimulate, on scientific problems, might do something to bring this about. There is no suggestion that science should be centred in the home-country. The dominions have their own scientific activity, and the ranks of the Royal Society are open to their workers. The problems that demand cooperation are not local but far extending, even cosmical.

Our Admiralty has charted the shores frequented by our shipping, and the world's navigation has the benefit. The international recognition of the meridian of Greenwich is our reward. But though the *Challenger* expedition made a noble beginning, a thorough exploration of ocean depths still remains to be accomplished, and is a task which naturally falls to a maritime race. But the land cries out to be accurately mapped. Both Africa and Australia have suffered from using imperfectly determined meridians of longitude as boundaries. The accurate determination of the position of salient points throughout the Empire would alone be a sufficient subject for a conference. Were this accomplished local surveys would start from a sound basis in filling up the details. As it is, even the survey of the United Kingdom is not absolutely coordinated with that of the continent. Such an enterprise as that of Sir David Gill in measuring an arc of the meridian from the Cape to the northern hemisphere would not be left to private initiative.

If the topography of vast territories is still imperfectly known, their geology is practically untouched. Africa differs from neighbouring continents in being all but an island. It seems to be the part of the earth's surface which has been least disturbed by volcanic action. It has preserved a structure of great antiquity. Thoroughly understood, it would throw light on an early chapter of the history of the earth.

In the southern hemisphere British maritime activity is dominant. A knowledge of the meteorology of its oceans is a necessary condition of their secure navigation. Sir Charles Bruce, in his "Broad Stone of Empire," has given a striking account of what has been accomplished towards it by the Mauritius Meteorological Observatory. Such a measure of undoubted success should stimulate further endeavour and the provision of other stations. It ought to be possible to predict the disastrous droughts of India

and Australia. This will never be accomplished until we thoroughly understand the influence of the Antarctic Continent. Its investigation would alone be a fit subject for an imperial conference. It is a problem which should no longer be nibbled at, but made the object of systematic attack.

If we turn from the physical to the biological field the need of cooperative endeavour is no less insistent. The problems of geographical distribution are hampered for want of material from large, uninvestigated areas. In anthropology our knowledge is still fragmentary, even of the subject races of the Empire. Commerce affords a wide area for the distribution of their local diseases. Cases of sleeping sickness are to be seen in our hospitals, and beri-beri has sometimes produced a panic in our ports. Yet the campaign against tropical disease has only begun.

If it is objected that such schemes are visionary, it may be replied that half a century ago they were actually within the field of practical politics, and that, too, at a time when anything like Imperialism was certainly not in fashion. In 1859 the Duke of Newcastle, the Secretary of State for the Colonies, wrote officially that "her Majesty's Government have under their consideration a project for collecting the materials of a National Work on the Astronomical features, the terrestrial physics, the botany, zoology, and geology of the Colonial Possessions of the British Empire." All this remained a project except as regards botany, which was imposed on Kew. The task, with various fortunes, sometimes of neglect and discouragement, has occupied it steadily ever since. With the completion, now in sight, of the two great Floras of Africa, under the editorship of Sir W. Thiselton-Dyer, the vast undertaking will have been practically accomplished. It is to be noted that except in the case of tropical Africa, the expense has been borne by the Dominions and Colonies concerned. And to the Flora of South Africa a spontaneous and not the least liberal contributor has been the Transvaal Government.

The inference that may be drawn from such facts is that while the Imperial Government could probably be induced to aid well-considered scientific work in the Crown Colonies and Protectorates, funds would be forthcoming for the share of that of the Dominions. Cooperation would give them a voice in the scope and character of any scheme, and a guarantee of its efficient and economical execution.

Such a sketch of what imperial cooperation might do for knowledge of the globe on which we live has at any rate the charm of a pleasant dream. Will it ever be realised? Not as long, certainly, as a Prime Minister can describe our Government as "the organised power of Philistines." The Philistine has the Government he deserves, and Philistine he will remain until the schoolmaster is touched with idealism and the aim of life ceases to be purely materialistic. Men may learn that though the pursuit of wealth may be exciting its attainment is dull in its results and usually mischievous in its effects. Ambition may prompt the rich to leave a worthier monument behind them than the mere record of their death duties. The value of wealth consists not in its possession but in its power, whether for good or evil. Perhaps the sporting instinct will come to the rescue of knowledge. Wealth may effect the performance of what a man may not be able to achieve himself, and yet feel some pleasure in seeing done. Money has been found to explore the ornithology of New Guinea, and men have been ready to risk their lives in the enterprise. Such sporadic efforts will never be wanting; what is needed is the coordination which will unite them in a considered campaign.

NATURAL HISTORY OF THE BIBLE.

THE celebration of the tercentenary of the English authorised version of the Bible is an event of national importance, when everything connected with Holy Writ commands, if possible, more than ordinary interest, not only from Biblical scholars, but also from a large section of the general public. Among the numerous sections of the subject, that which most commends itself to students of natural science is, of course, the natural history of the Bible in the wider sense of that term—that is to say, inclusive of zoology, botany, and mineralogy; and the present celebration affords a fit opportunity of reviewing and revising our knowledge of Bible animals, plants, and minerals, and also of considering whether any emendations of the names by which some of them are referred to in the authorised version ought not to be amended. This has been recognised by the authorities of the British Museum, who are now arranging in the hall of the Natural History Branch at South Kensington an exhibition of Bible animals, plants, and minerals, which will be opened in due course, and will doubtless attract a large amount of attention and interest on the part of the public.

Although comparatively little interest and importance attaches to the list of species regarded by the ancient Jews as unclean, the correct identification of the animals and plants referred to in other parts of the Bible is in many cases essential to a proper appreciation of the context, more especially when they are introduced to illustrate a simile, or to accentuate some striking or picturesque feature in local conditions. At the time when the authorised version was written natural history had scarcely attained the position of a science, even the birth of Linnæus not having taken place until nearly a century after the translators had finished their labours. But this lack of knowledge of natural history common to all educated persons of that day was by no means the only difficulty with which the translators had to contend. For, in the first place, the animals and plants of Syria and Palestine were probably even less known than those of several other parts of the world; while, secondly, the dispersal of the Jews had led to the proper meaning of many of the old Hebrew names of animals and plants being more or less completely forgotten.

Consequently the translators were plunged into a very sea of difficulties, from which, considering all things, it is little short of a marvel that, despite many egregious blunders, they emerged as creditably as they did. In regard to names of which the true signification was not apparent the translators followed two distinct courses. In some cases, as, for instance, with *shâphân* ("the hider"), they made a "shot" at the meaning of the name, rendering the one quoted by coney, the then current designation of the rodent we now term (except in legal phraseology) rabbit. On the other hand, some Hebrew names, like *shittim* and *almug*, among the designations of timber and trees, were transferred directly to the English version without any attempt at translation or identification. And there is little doubt that this latter was the preferable course. Indeed, in the case of almug trees it is almost the only legitimate one, as the species is not yet identified with absolute certainty, although it may be the red sandal-wood of India. Shittim-wood might, of course, be now translated as acacia, but even this would be unsatisfactory, as the tree popularly known in this country by the latter name is really a Robinia.

In a few instances, as in the case of "pygarg" for *dishon*, the translators used terms of which they could not possibly have known the proper meaning;

the African antelope termed *πύγαργος* by Herodotus being still unidentified, and therefore having no claim to be regarded as the equivalent of the Hebrew *dishon*.

The real misfortune is, however, when well-known English names of plants and animals are given as the equivalents of Hebrew words of totally different signification. Examples of this are apple for apricot, chestnut for plane, sycomore or sycamore (etymologically justifiable) for a fig of the banyan group, ferret for an animal which may have been a gecko, the aforesaid coney for the Syrian hyrax, and, above all, badger (in the shape of badgers' skins) for the Red Sea dugong. The last is indeed a particularly bad case, as it should have been obvious that badgers' skins, even in a comparatively dry climate, do not form suitable material for a church-roof. The case of "coney" has been complicated by the word having fallen practically into disuse, in the original sense, in consequence of which many persons, and especially Americans, appear to regard it as the proper English name of the hyrax.

In nearly all the cases where the real meaning of the original cannot be ascertained, or where, as in the instance of sycomore, we have no vernacular name for the species referred to, it appears to me that it would be much better if the Hebrew word were retained, with a brief marginal explanation.

In modern times much light has been thrown on Bible natural history by identifying the old Hebrew names of animals and plants with their apparent equivalents in Arabic and Coptic, and likewise by the study of the animals represented in the Assyrian and other ancient sculptures, as well as in the Egyptian frescoes. The mummified animals of Egypt have also contributed their quota of information. There is, however, little doubt that if further attention were devoted to the correct identification of the animals in the magnificent series of Assyrian and Babylonian sculptures in the British Museum still more information might be obtained.

In our own country the great pioneer in this line of research was the late Canon Tristram, whose "Natural History of the Bible" and "Fauna and Flora of Palestine" still remain standard authorities. To Tristram we owe the identification of the Hebrew *reem*, mistranslated unicorn in the authorised version, with the extinct wild ox, or aurochs, the name apparently still surviving in the Arabic *rim*, now applied in North Africa to certain large gazelles. And in his works will be found mention of the identity of the Hebrew *nesher* (translated eagle) with the Arabic name, *nisr*, of the griffon vulture; of the Hebrew *cabh* (rendered tortoise) with *dab*, the Arabic term for the lizards of the genus Uromastix, and many other analogous instances. Unfortunately, Tristram was led to believe that several kinds of large North African antelopes, such as the bubal hartebeest, the addax, and the white or sabre-horned oryx, were natives of Palestine and the adjacent regions, whereas it is now ascertained that none of these ranges to the east of the Lower Nile, although the white oryx was brought down from the interior by the ancient Egyptians. Consequently his identifications of Bible ruminants are to a great extent erroneous, but an attempt has been made to correct them in the new edition of "Murray's Dictionary of the Bible." Important information, especially in regard to insects, will also be found in the "Oxford Bible." On the Continent, Dr. Duerst, in various publications, has contributed largely to our knowledge of the cattle—wild and tame—of Biblical times, while Dr. Lortet and his associates, whose studies of their mummified remains are published in the Archives of the Lyons Museum, have done the same for the sheep, goats, dogs, &c.

To attempt anything like a complete survey of Biblical natural history in the space at my disposal is obviously impossible, and references can only be made to a few points of general interest. Whatever may have been the origin of the story of Jonah, it is curious to note that in the Ethiopic Bible the whale is referred to as *anber*, the Arabic equivalent of ambergris, and was thus evidently regarded as the sperm-whale, by which alone that perfume is produced. Here my readers may be reminded that ambergris was the original amber, the latter word having been subsequently transferred to the substance now known by that name. Although leviathan in one passage seems undoubtedly to indicate a whale, it generally refers to the Egyptian crocodile, the range of which, until recently at any rate, extended to Syria, and formerly, as attested by the story of St. George and the dragon, included Asia Minor.

The above usage of one and the same Hebrew word in two senses is not unparalleled in the Bible, and must have been another sore difficulty in the path of the translators. *Tinshemeth*, for instance, which is translated in one passage as mole and in others as swan, is considered to indicate the chamæleon in Leviticus xi. 30, while in another part of the same book it is believed to stand for some kind of aquatic bird, which may perhaps have been the purple water-hen. Before leaving *tinshemeth*, it may be added that not only were the translators wrong when they rendered it mole, but that they were also in error when they identified another Hebrew word, *hephor-perôth*, with that animal; for, as a matter of fact, there are no moles in Palestine and Syria, and the burrowing animal indicated would seem to be one of the rodent mole-rats of the genus Spalax.

In the rendering of the names of birds, the translators were in several instances either exactly or approximately correct, pelican, crane, stork, quail, and partridge being exact translations, while glede (an old name of the kite) and hawk are near enough approximations for the smaller birds of prey, as is also swallow for swift. It is curious, however, that in two passages where swallow and crane are mentioned together, the latter name is employed as the translation of the Hebrew word meaning swallow (or rather swift), and *vice versâ*. Sparrow, the translation of *tzippor*="the chirper," is doubtless used in a general sense, although, as Tristram pointed out the solitary sparrow on the housetop is in all probability the blue rock-thrush. Possibly such names as "gier-eagle" (from the German *gier*, a vulture, and familiar in the form of lammergier) and "ossifrage" may have been in use in this country in the seventeenth century, but nowadays neither conveys any definite meaning to the reader, the former really indicating the Egyptian scavenger-vulture, or "Pharaoh's hen," and the latter the lammergier. Lapwing is distinctly an unfortunate translation, the bird indicated being probably the hoopoe.

In regard to invertebrates, it may be noted that the rendering of *sās* in Isaiah as worm is not far out, as the word indicates the larva of a clothes-moth, and it has been suggested to me that the "booth that the keeper maketh" (Job xxvii. 18) refers to the rough larval case of a psychid moth. "Cankerworm" is now generally admitted to refer to one of the immature stages of the locust, and in the Oxford Bible it is suggested that "palmer-worm" may include not only caterpillars, but likewise a second immature phase of the locust, which would accord well with the context. Locust, grasshopper, ant hornet, bee, fly, flea, and scorpion are correct, or

nearly correct, renderings of the Hebrew names for which they stand; and the same is doubtless the case with coral, which is found in the Red Sea and the Persian Gulf. Pearls in the Old Testament is, however, the rendering of the Hebrew *gābhîsh*, signifying ice and thus rock-crystal, whereas in the New Testament *μαργαρῖται* is rightly translated pearls. Manna, it is perhaps needless to add, was certainly not the product of a Coccus, as the natives of Palestine now tell travellers, but apparently a mountain lichen, of which quantities were at times blown down to the plains.

A few allusions to botany have been already made, and it may be added that in the case of cultivated plants many of the translations are more or less nearly true to nature. A "garden of cucumbers," for instance, conveys an excellent idea of the abundance of melons, gourds, cucumbers, &c., characteristic of so many Eastern countries; but a local touch of colour is unfortunately lost in the reference to "white, green, and blue hangings," in which the word rendered "green" should have been translated "cotton," so that the passage should run "where were hangings of white and violet-coloured cotton." Lack of space prevents me, I regret to say, saying more on this part of my theme, and the same limitation prevents a discussion on minerals. This, however, is not a matter for regret, as Dr. Fletcher informs me that the whole subject is in great confusion, and it will therefore be advisable to await his contribution to the forthcoming exhibit at the Natural History Museum. It may be mentioned, however, that in many cases at any rate the precious stones referred to in the Bible are rightly identified only so far as the matter of colour is concerned, sapphire being apparently lapis lazuli, ruby an unknown red stone, chrysolite probably a topax, and chrysoprasus a green chalcedony akin to the "prase" from which Egyptian scarabs were cut.

I should have liked to say something with regard to the animals of the New Testament, but can only refer to Prof. Ridgeway's identification of the "pale horse" (*ἵππος χλωρός*) of Revelation with the dun breed, or the one of the colour of dry grass. Naturally one would have expected to find the black horse associated with Death; but, according to Prof. Ridgeway, the dun was regarded as the worst breed, and accordingly despised, a fact which, it may be suggested, perhaps affords another argument in favour of the antiquity of this type.

R. L.

MEDITERRANEAN CIVILISATION AND THE PHAESTOS RIDDLE.[1]

JUDGED by the declared aims of the author, who before his lamented death, was one of the brightest of Italian men of science, this is an eminently successful work. He is "convinced that it is worth while to excite the curiosity of those who are not archæologists," and he never forgets the average reader. He is equally convinced of the independence of Mediterranean civilisation, and he has undoubtedly made out a very strong case. The author's enthusiasm sometimes makes the reader unnecessarily suspicious, but added to the popularising and argumentative motives of the author is a sincere respect for facts, and the wants of the specialist are also provided for in numberless references and footnotes. The author was himself an experienced explorer, and he has some interesting theories of his own to put forth, such as that Cyprus is not "the land of copper" and that the word *bronze* is a form of Brindisi (p. 208). On Minoan matters he writes from first-hand knowledge. In Italy he did excellent work in completing a survey of the known dolmens of that country. The dolmens illustrated are remarkably similar to our British cromlechs. The book is

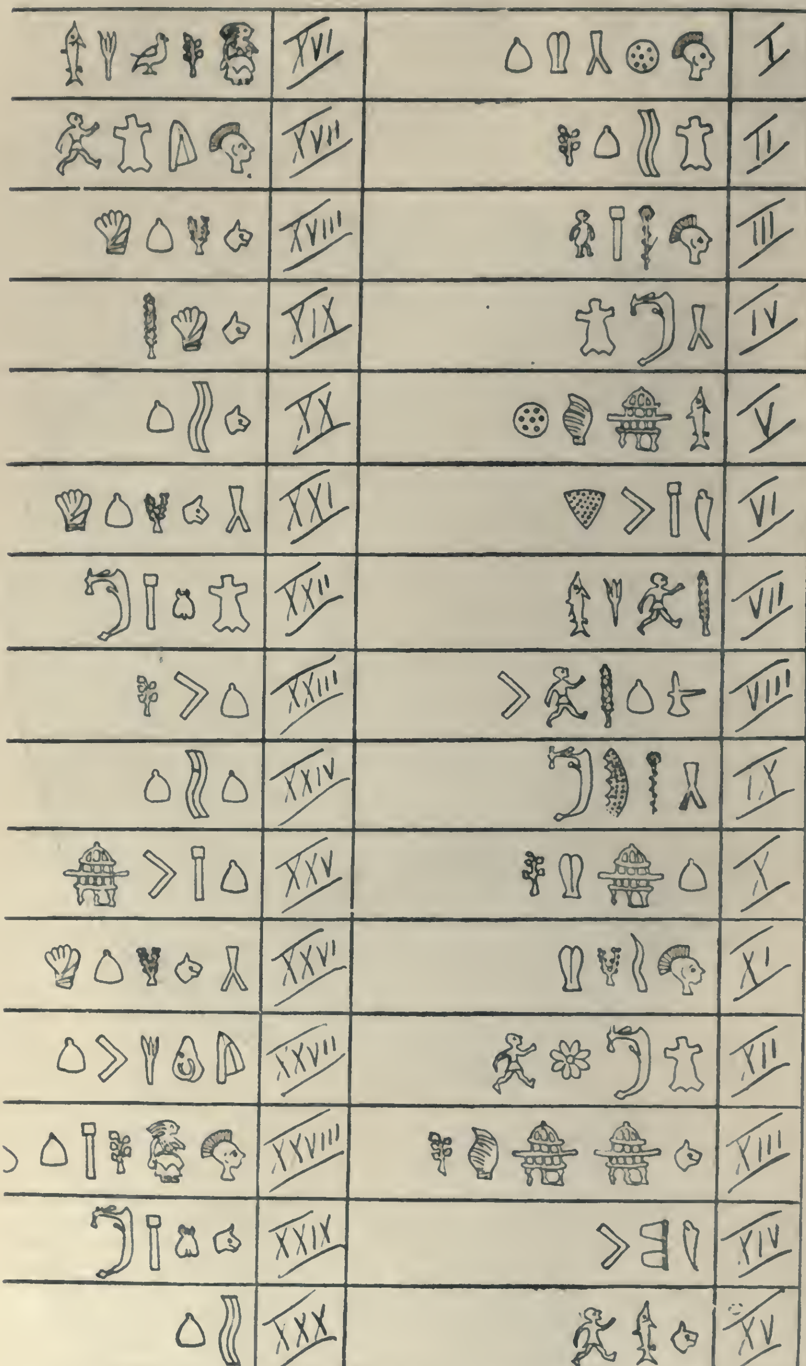
Face A.

FIG. 1.—Disk, with Hieroglyphic Inscription, from Phæstos. From "The Dawn of Mediterranean Civilisation."

[1] "The Dawn of Mediterranean Civilisation." By A. Mosso, translated by M. C. Harrison. Pp. xxiii+424. (London: T. Fisher Unwin, 1910.) Price 16s. net.

very usefully illustrated, and the translator's work is excellently done.

On one important point the author gives the average reader more than the latter might expect. He takes us into the laboratory, with the usual result of making us a little uncomfortable. I refer especially to a section entitled "Dr. Evans's Chronology" (pp. 98–102). We have lately been in the habit of accepting without hardly a question the opinions expressed by experienced explorers respecting periods and stages of culture based on the depth and stratification of deposits. The author's remarks on this point are so important and disconcerting that his conclusion as regards the deposits at Phæstos should be cited here in full.



Face B.

FIG. 2.—Transcription of the Inscription on the Phæstos Disk. From "The Dawn of Mediterranean Civilisation."

"Dr. Mackensie has already expressed a doubt that a stratum may be missing at the end of the neolithic period in the soil of Knossos. My own conclusion would be to fix the duration of the neolithic occupation of Phæstos at about 2500 years, while for a complete estimate of the whole period up to the Christian era—the depth of neolithic strata in a pit at Knossos being seen to exceed 8 metres—Dr. Evans being of opinion that at a moderate estimate a period of 14,000 years from the first neolithic stratum at Knossos must be reckoned, in my opinion it should be estimated at not more than 7000 years, or possibly less.

"With every respect for the great authority of Dr. Evans, I should give a provisional character to these critical remarks until the doubtful points I have alluded to are cleared up. The chronological computation of the rapidity with which the level of the soil rises on sites of human habitation in the neolithic age and during later periods is a complex problem which depends on coefficients which are not constant, but variable. I am convinced that in the case of Knossos the quota of 1 metre for every 1000 years, as fixed by Dr. Evans, is too small" (pp. 101–2).

It is passing strange that an explorer with such a deep conviction of the variability of archæological coefficients has never a word to say of the results of a search for constant coefficients in astronomical data. Surely one-half of the archæological world knows nothing of the other half: at any rate, one would rather risk such a reckless statement than to suggest that such a fair-minded critic of archæological methods should, for no conceivable reason suppress any evidence whatever. Any suppression of the kind would only intensify a retributive reaction.

Here in Britain astronomical archæology is now so much in evidence that every archæologist seems to have formed a definite opinion of its worth. The majority, perhaps, would prefer pointing out its worthlessness, but it happens that a majority in such a case might mean next to nothing, especially as I have not yet seen any demonstration of the worthlessness of the astronomical method involving sufficient technical knowledge to use the method itself. Round condemnatory statements

of that method have been made by some of the authorities whose own criteria are criticised by our author. Behold, now, the day of retribution!

The author gives a useful general account of the important find made by Dr. Pernier, of the Italian Archæological Mission, at Phæstos, Crete, in 1908. It was a clay disk inscribed on both sides with lines and pictographs. Judged by such standards as the author himself questions, the inscription is supposed to belong to the eighteenth century B.C. The authorities cited are very much divided as to what the inscription is and the affinities of the strange characters with known forms. Not one of those cited seems to have gone so far as Prof. Hempl, in *Harper's Magazine* for January, and Miss Stawell, in the *Burlington Magazine* for April, as to attempt a more or less complete interpretation.

In neither of the interpretations referred to is the possible calendric character of the document taken into consideration, and as I think it is a calendar, the opportunity for reproducing our author's illustrations of the document is my excuse for appending a brief outline of my findings.

In form the calendar is a rough copy of the use made of concentric circles. The pictographs on face A number 123, and not 122, as stated by our author; those on face B number 119. Each pictograph represents one degree of angular distance, and it is to be multiplied by three to make up the number of days in a year. Year A was $123 \times 3 = 369$ days, which on evidence given by Mommsen was once the length of a Roman year. Year B was $119 \times 3 = 357$ days. Assuming such a rotation as A B A, the sun would have travelled 365 pictographs or degrees in three years of the average length of 365 days. If the exact *locale* of the calendar were certainly known, its date might be made out by means of established formulæ. Its physical basis was a latitude where the apparent distance between the solstices was about 60° 50′. Of that figure I am fairly sure, and it would have roughly suited Crete in 1800 B.C. The latitude of Phæstos on an Admiralty chart is 35° 25′ N. It is much doubted, however, that the disk originally belonged to Phæstos, so that any calculation on the basis I have suggested would not materially help in fixing a date.

The calendar is quite complete, and a marvellous compendium of calendric contrivances. It is all based on the intersolstitial distance, expressed in integers, and divided by 3, 7, 17, and other numbers, an artificial system, it is true, but a very convenient one. The calendric significance of many of the pictographs stands clearly revealed when the numbers are noted. Some of them are very curious rebuses, a proof of considerable antiquity. For instance, the pagoda-like structure I felt sure stood for the number 20 in degrees and 60 in days, but for many a day I could not see either number in it. It is a four-storey building, the beams of each section numbering 5; hence $5 \times 4 = 20$, and $15 \times 4 = 60$. It indicates a legislative assembly, corresponding in significance and dates to the Tiocobrextio of the Coligny Calendar, and the entries under March 24 and May 24 in the Roman Calendar.

In all I have said so far there is hardly an element of speculation, and none of the ingenuity shown in such interpretations as those referred to. There is a precedent and an established formula to aid the inquiry at every step. A complete astronomical interpretation of the calendar will strike all students of our monuments, astronomically considered, as something quite familiar, while a sufficient scope will be left for authorities on ancient scripts to do all they can to determine the linguistic values of the pictographs, a subject I can hardly touch.

JOHN GRIFFITH.

MILITARY AVIATION AT HENDON.

THE demonstration of flying organised by the Parliamentary Aerial Committee, which took place on Friday last at Hendon, cannot be described as other than an unqualified success. If experts learnt no new lesson, if aviators acquired no new experience, the onlookers, including almost all those whose opinions would be sought and whose dicta may become law, must have had their eyes opened to the great possibilities as to the utility of the aeroplane in war.

A number of different types of machine, Farmans, Blériots, Cody, Roe, and Valkyrie were to be seen, and their respective merits compared. Besides exhibitions of rising quickly from the ground, descending near a given spot, turning and planing in the air, all of which were carried out in a superb manner, there were many tests having reference to warlike operations. A number of small dummy bombs were dropped from different machines on to ground marked out to represent the deck of a battleship. The idea was to test the possibility of attack by such means, but, although many good shots were made by dropping the missiles while travelling at a speed of perhaps 40 miles an hour, yet most of them were made from a height of only a few hundred feet, whereas to be of use in war they should be discharged from machines at least 2000 or 3000 feet above the ship. However, it is evident that if good shooting can be made in this way, it is only a matter of judgment and practice to be able to achieve good results at a much greater range. Another purpose to which such a method of attack is applicable is that of destroying dirigible balloons, and in such case the aeroplane might well be within a hundred feet of the target below it.

A more important experiment was that of discharging heavy weights, said to be 100 lb., from a flying biplane. It seemed probable that this might affect the balance of the machine, and cause it to pitch or jump, but careful observation showed that the aeroplane maintained a perfectly steady course, and was unaffected by the sudden loss of this load.

But the finest display, and perhaps the most practical experiment, so far as the immediate use of aeroplanes is concerned, was that of sending off a dispatch to a distance. Mr. Hamel went off on a Blériot monoplane to Aldershot, a distance of 32 miles "as the crow flies," though, as a matter of fact, the aviator went in a not perfectly straight line, in order to pick up familiar landmarks, and so make sure of his way.

Having handed in the dispatches at Aldershot, he returned with the reply, and it was a very impressive sight for those at Hendon to descry, high up in the sky, to the south-west, a small speck, estimated at 4,000 feet, which gradually approached and became recognisable as the monoplane, which, sweeping round a large circle, glided downwards and landed within a few feet of the starting-point. The message had been delivered and returned within two hours, the actual times being:—

Left Hendon	3.35
Arrived Aldershot	4.20
Left ,, ...	5.0
Arrived Hendon	5.35

Other events were the ascents of two staff officers on biplanes piloted by experienced aviators, who, without any previous experience, were to report on the position of certain troops which had been posted in the neighbourhood. This was most successfully accomplished. Short trips made by Mr. Balfour and by Mr. McKenna, First Lord of the Admiralty, tend

to bring home to the public the ease and safety of aeroplane travel.

One important item of the programme was not carried out. It was announced that if the circumstances were favourable the Army dirigible "Beta" would come up from Aldershot and take part in the proceedings. The weather proved perfect, it being almost a dead calm with bright sunshine. The "Beta" was ready and actually made one ascent, but for some reason which has not been given out she did not attempt the journey. Advocates of the aeroplane as being a more practical apparatus than the dirigible claim this as a triumph for their cause.

B. BADEN-POWELL.

SPORT AND TRAVEL IN CENTRAL ASIA.[1]

THIS book, as its writer says, is merely "a plain record of a year's wanderings in the lesser known parts of Central Asia for the purpose of sport and travel." Its author had eyes for little else than the quest of large game for the sake of their heads as trophies. Of the country through which he passed or of its people, he tells us little, and nothing at all of its other fauna or its flora, and of many of the topics of human and scientific interest which the general reader expects to find in travel-books of little-known regions. Even in regard to the large game themselves the bald narrative provides no new facts nor any intimate study of the animals or their haunts. The photographs of the heads, however, are of some interest, as the specimens hitherto figured are not numerous and the limits of several of the species are not yet clearly defined. The account of the camp outfit also may supply some useful hints to sportsmen who contemplate an excursion in those regions.

Ovis Karelini. From "Across the Roof of the World."

Starting from Kashmir, the author crossed the Pamirs by the usual route, shooting on the way an *Ovis poli*, the horns of which measured (doubtless along their inner curve, as usual) "under 50 inches"; but he saw a pair on a tomb at Kashgar which were 72 inches. Beyond Turkestan, in the Thian Shan, he shot two specimens of the great stag generally termed the "Asiatic Wapiti" (*Cervus canadensis songdricus*), locally known as "Boga" by the Mongols, with horns measuring respectively 48 and 49 inches, the latter pair carrying 14 points or tines. A specimen of the *Ovis karelini*, with horns "just over 40 inches," was shot there, also the Turkestan ibex, with a horn length of 55 inches—the record being 57½ inches—and several Siberian roedeer (*Capreolus pygargus*). It is rather surprising to read that the skins were merely rubbed with crude wood ashes as a preservative and nothing else. Continuing northwards through Dsungaria, Lieut. Etherton sighted, on the plain of Lake Ebi, what he believed were wild horses (*Equus prejevalski*). The Altai was crossed in mid-winter, too late to attempt following the *Ovis ammon*, for which that range is famous, so our traveller turned down the steppes of the Irtish and Obi valleys to the Trans-Siberian Railway near Tomsk, where civilisation was reached once more.

[1] "Across the Roof of the World."—A Record of Sport and Travel through Kashmir, Gilgit, Hunza, the Pamirs, Chinese Turkistan, Mongolia and Siberia. By Lieut. P. T. Etherton. Pp. xvi+437. (London: Constable and Co., Ltd., 1911). Price 16s. net.

NOTES.

IN consequence of the Whitsuntide holidays, the annual visitation of the Board of Visitors to the Royal Observatory, Greenwich, will take place on Friday, June 2, instead of on Saturday, June 3.

THE newly erected Cancer Research Institute at the Cancer Hospital is to be opened by H.R.H. the Duke of Connaught on Tuesday next, May 23, at 3 o'clock.

AN earthquake shock was felt at 8.50 a.m. on Tuesday last in the Ullswater Valley.

WE regret to learn from a Reuter telegram that Prof. Ernst Haeckel met with a serious accident on Tuesday. In endeavouring to reach a book from a high shelf he fell, breaking his hip bone.

WE regret to notice the death, at the age of eighty-two years, of Sir Nathan Bodington, Vice-Chancellor of the University of Leeds.

THE death is announced, at the age of sixty-five years, of Mr. Emerson M. Bainbridge, well known for his work in connection with coal-mining. In 1867 he was selected to report to the North of England Institute of Mining Engineers on the haulage of coal, and received for his services a valuable premium. Two years afterwards the Institution of Civil Engineers awarded him the Manby premium for a paper upon the probability of working coal at a depth of 4000 feet. Another paper, on the prevention of colliery explosions, was rewarded by the conferment of one of the Herman prizes. Mr. Bainbridge was a member of the Royal Commission on Coal Dust in Mines in 1891, and a juror of the Inventions Exhibition of 1883.

IT is announced in the *Revue scientifique* that a committee has been formed for the purpose of erecting a monument to the late M. Bernard Brunhes, who died last May at the age of forty-two years. M. Brunhes was for ten years director of the observatory at Puy-de-Dôme.

A MEETING of the Society of Tropical Medicine and Hygiene will be held at 11 Chandos Street, Cavendish Square, to-morrow—Friday—evening, when a discussion on the present position of the prophylaxis of malaria by quinine will be opened by Dr. W. Carnegie Brown, and a paper on the nature of Zambezi fever, by Dr. W. I. Bruce, of Chinde, and a note on cultural characteristics of a variety of the streptothrix of white mycetoma, by Dr. N. F. Surveyor, of Bombay, will be presented.

THE 129th Harveian Festival of the Royal College of Physicians of Edinburgh is to be held to-morrow, May 19, when Sir Alexander R. Simpson will deliver an oration on "Life and its Epiphanies."

THE Faraday Society has organised a general discussion on high temperatures, to be held on Tuesday, May 23, at the Institution of Electrical Engineers, Victoria Embankment, W.C. The following programme has been arranged:—Dr. Arthur L. Day will read a paper on recent advances in gas thermometry; Dr. J. A. Harker, F.R.S., will describe the high-temperature equipment at the National Physical Laboratory; Mr. H. C. Greenwood will read a note on boiling points of metals; and Mr. A. Blackie will speak on the behaviour of silica at high temperatures. Contribution to the discussion have been promised by Prof. Bodenstein on the maintenance of constant high temperatures, M. Féry on stellar pyrometry, and others. Dr. R. T. Glazebrook, F.R.S., director of the National Physical Laboratory, will preside. During the afternoon the society, by the invitation of the director, will visit the National Physical Laboratory to inspect the high-temperature equipment of the laboratory.

DR. HENRY HEAD, F.R.S., will deliver the Croonian lectures (upon "Sensory Changes from Lesions of the Brain") before the Royal College of Physicians of London on June 13, 15, 20, and 27.

AT the convention of the Incorporated Municipal Electrical Association, which is to take place at Brighton and at Portsmouth on June 27 to 30, the following papers are to be read and discussed:—electricity supply viewed from the municipal committee's standpoint, by Councillor H. Leese; modern wiring practice, by Mr. J. W. Beauchamp; internal-combustion engines in power stations, by Messrs. H. L. Howard and R. M. Carr. There will also be discussions on purchase of fuel and street and shop-front lighting, opened, respectively, by Mr. C. E. C. Shawfield and Mr. A. H. Seabrook.

THE annual general meeting of the Society of Chemical Industry is to be held in Sheffield on July 12. Dr. R. Messel has been nominated as president, and Sir William Crookes, F.R.S., Dr. G. G. Henderson, and Messrs. H. Hemingway and W. F. Reid have been nominated as vice-presidents.

THE ninety-fourth annual meeting of the Société Helvétique des Sciences Naturelles will be held this year at Soleure from July 30 to August 2. The first general meeting will take place on July 31, when the president for the year, Dr. A. Pfaehler, will give his opening address, and the following lectures will be delivered:—M. Georges Claude, on "La Liquéfaction de l'air, son état actuel et ses applications"; Prof. Ursprung, of Freiburg, on "Der heutige Stand des Saftsteigungsproblems"; Dr. H. Stauffacher, of Frauenfeld, on "Die Rolle des Nucleins bei der Fortpflanzung"; and Prof. Otto Schlaginhaufen, of Zurich, on "Reisen und Forschungen in Melanesien." The second general meeting will be on August 2, for which the following lectures have been arranged:—Prof. Abderhalden, of Berlin, on "Neuere Anschauungen über den Zellstoffwechsel"; Prof. P. Gruner, of Berne, on "Die neueren Vorstellungen über das Wesen der Elektrizität"; and Dr. Albert Brun, of Geneva, on "Les recherches modernes sur l'exhalaison volcanique." The annual meetings of the Swiss societies of botany, chemistry, geology, mathematics, physics and zoology will be held also at Soleure on August 1.

A COLLIERY and General Mining Exhibition, lasting a fortnight, was opened in Manchester on Friday last by Prof. Sir Thomas Holland, K.C.I.E., F.R.S., who in the course of his remarks said the exhibition contained methods for securing safety underground and rescue apparatus for saving life after accidents had occurred. The improved methods of machines on view had an important bearing on the economy of mining, and thus the exhibition would be of service in showing how our natural resources could be turned to full account. He reminded his hearers that large quantities of coal were destroyed in the process of mining it, and that every ounce of coal ore or mineral that was destroyed was destroyed once for all without possibility of replacement. He suggested that, if the colliery owners of Lancashire would get together in groups and employ young geologists to correlate the information that was available, a geological map of the district might be constructed the practical usefulness of which would repay its cost many times over.

THE first International Chemical Engineering and Industries Exhibition was opened on Saturday last at the Royal Agricultural Hall, Islington, by Lord Denbigh.

DR. E. J. RUSSELL, of the Lawes Agricultural Trust, having directed attention to the need and value of photographs illustrating the scenery associated with various geological formations, the Tunbridge Wells Natural History Society is offering for this purpose a series of prizes, of 2*l*. each, for the best set in the following subjects:—first, scenery of the chalk districts—hills, sections, valleys and combes; second, scenery of the Wealden sandstone formation—sections, &c.; third, scenery of the Tertiary beds; fourth, scenery connected with shingle, gravel or sand beds; fifth, river and marsh scenery. Messrs. W. Whitaker, F.R.S., and R. Child-Bayley, editor of *Photography and Focus*, have kindly promised to act as judges. Full details of the competition can be had on application (stamp should be enclosed) to Mr. Geo. Abbott, 2 Rusthall Park, Tunbridge Wells, and the prints should be sent to him on or before March 1, 1912.

ACCORDING to *The Athenaeum*, an expedition to south-east Arabia has been planned by the Danish Royal Geographical Society, the object being the mapping of parts of Oman and the studying of the ancient memorials and commercial prospects of the country.

THE Research Committee of the National Geographic Society of Washington has made an appropriation of 5000 dollars for continuing the glacier studies of the two previous years in Alaska. The work, beginning in June, will be done by Prof. R. S. Tarr, of Cornell University, and Prof. Lawrence Martin, of the University of Wisconsin, who have directed the National Geographic

Society's Alaskan Expeditions of 1909 and 1910 in the Yakutat Bay, Prince William Sound, and lower Copper River regions. The 1911 expedition will study briefly a number of regions of glaciers not previously investigated by the National Geographic Society, although partially mapped by the Alaska Division of the U.S. Geological Survey, the Boundary Commissions, &c. Work will be done on the present ice tongues and the results of glaciation in the mountains and plateaus of parts of the interior and some of the fiords of south-eastern Alaska, the former having lighter rainfall and smaller ice tongues than the Yakutat Bay and Prince William Sound regions.

To *Naturwissenschaftliche Wochenschrift* of April 30 Prof. Branca communicates a popular notice of the dinosaurian remains obtained from the Lower Cretaceous of the Tendaguru Mountains of German East Africa by the recent expedition from Berlin. The most noteworthy feature of these remains, so far as they have been examined, appears to be their gigantic dimensions, which largely exceed those of Diplodocus. The longest rib of the latter measures, for instance, 1·86 m., whereas some of the African ribs are no fewer than 2·50 m. in length. Again, the longest cervical vertebra of the former is 0·64 m., in contrast to which is one from Tendaguru—possibly not the biggest—measuring 2·10 m., while a humerus of the African dinosaur is $2\frac{1}{4}$ times as long as the corresponding bone of Diplodocus, measuring 2·10 m. (6 feet 10 inches) against 0·95 m. (3 feet 1 inch). It should, however, be borne in mind, although this is not mentioned by the author, that Diplodocus is not the largest known reptile, its femur measuring 1·542 m., or 5 feet $1\frac{3}{4}$ inches, against 6 feet 2 inches in that of Atlantosaurus. Still, as the femur is always a much longer bone than the humerus, the advantage is largely on the side of the African reptile. According to the author, the remains previously obtained from East Africa by Dr. Fraas were much larger than those of any other known dinosaur, but these are completely eclipsed by the new specimens. In addition to the dinosaurs, remains apparently referable to pterodactyles have been obtained. Remains have likewise been discovered in several other localities of German East Africa. Prof. Branca adds some remarks in regard to the pose and food of the sauropod dinosaurs, observing that if these reptiles subsisted on a vegetable diet, it is difficult to imagine how they obtained sufficient nutriment. The same difficulty, it may be mentioned, has occurred to another naturalist, Mr. J. Versluys, who has suggested in the *Zool. Jahrb., Abtheil. f. Systemát.*, vol. xxix., p. 425, 1910, that these reptiles fed on fishes. Prof. Branca is also exercised in his mind how the sauropods obtained sufficient calcareous matter for their enormous skeletons; but it may be pointed out that the supply of this substance would increase *pari passu* with the amount of food consumed. In this connection, it may be noted that *The Scientific American* of April 8 contains an illustrated account of the life-sized restorations of dinosaurs recently installed by Mr. Carl Hagenbeck in his Tiergarten at Stellingen, near Hamburg.

MR. L. L. WOODRUFF has contributed to the *Archiv für Protistenkunde* (vol. xxi., 1911) a remarkably interesting account of the results which he has obtained in breeding experiments with Paramœcium. Of late years there has been a tendency amongst biologists to accept the view that the multiplication of unicellular organisms by simple fission cannot go on indefinitely, but leads ultimately to exhaustion and even extinction of the family unless the failing vitality be renewed by conjugation. According to Mr. Woodruff, this only holds true when the organisms are exposed to a more or less constant environment. He finds that by subjecting the Infusoria to a varied environment (represented in this case by the culture medium), they can be made to keep on dividing indefinitely in a perfectly normal manner without conjugation or the use of artificial stimulation. The culture on which this conclusion is based has been kept under observation for nearly three and a half years, during which time over two thousand generations of Paramœcium have been produced, giving an average of about one division every fifteen hours.

IN the March issue of *The National Geographic Magazine* Messrs. Collins and Doyle, of the U.S. Department of Agriculture, describe a tour in southern Mexico undertaken with the object of investigating the causes of the immunity of the crop in that region from the destructive cotton-boll weevil. The results are not quite conclusive, but it appears that in some districts the practice of planting the cotton crop only in alternate years is a successful method of combating the weevil, and that in other places the boll is found to be naturally protected against its attacks by the abnormal growth of proliferating tissue, or in some cases that the aperture by which the weevil enters the boll was sealed up by the growth of the web of a small jumping spider (*Aysha minuta*).

AN interesting article on the plant knowledge that prevailed formerly among the Gosiute Indians is communicated by Mr. R. V. Chamberlin in the Proceedings of the Academy of Natural Sciences of Philadelphia (February). The tribe inhabited the desert region lying to the southwest of the Great Salt Lake in the State of Utah, but nevertheless made very extensive use of plant products for food and medicine. Green vegetables were prepared from the leaves of the composite *Balsamorhiza sagittata* and the umbellifer *Cymopterus montanus*. The tuberous roots of *Carum Gairdneri* were much esteemed, also the bulbs of *Calochortus Nuttalli*. Seeds were gathered from *Salicornia herbacea*, species of Atriplex and Chenopodium, *Sisymbrium canescens*, various composites, *Triglochin maritimum* and *Typha latifolia*; while the "nuts" of *Pinus monophylla*, formerly of necessitous importance, are still collected in quantity. Pharmaceutical remedies were prepared from the roots of *Ferula multifida*, *Valeriana edulis* and *Spiraea caespitosa*, and from the leaves of *Artemisia tridentata*.

THE annual report for 1910 issued by the director of Rothamsted Experimental Station reflects to a great extent the unfavourable conditions that prevailed during the summer. The yields of wheat, barley, and grass crops were all low, but mangolds were good, and a second crop of clover on one field was very large. A noticeable feature on the barley plots was the value of phosphate manuring, which becomes more marked in a wet and cold season. Striking evidence was obtained of the beneficial effects which result from preceding wheat with a leguminous crop. A report by the director and Dr. E. J. Russell on the soils in the south-east of England is being published by the Board of Agriculture, and a paper by Miss Brenchley dealing with the weeds prevalent in Rothamsted district is announced.

FROM the account of the gardens at Llanover, Monmouthshire, contributed by Mr. G. Went to *The Gardener's Chronicle* (May 6), it is evident that natural conditions and careful management have combined to produce a magnificent collection of trees. Mention is made of some fine specimens of *Sequoia gigantea* and a lofty tulip tree, all exceeding a height of 100 feet, and of specimens of *Alianthus glandulosa*, *Abies Smithiana*, and *Pinus excelsa*

almost as high. Fuchsias of the types of *globosa* and *Riccartonii* attain large proportions, and a plant of the *nobleanum* variety of *Rhododendron caucasicum* was estimated to cover an area 30 feet in diameter.

A double number of *The Indian Forester* (January and February) contains an article on forest railways for the extraction of timber, communicated by Mr. F. A. Leete, in which he describes an original type of monorail experimentally tried in Burma; a note on wood-pulp testing, by Mr. W. Raitt; and a report on the system of afforestation with field crops in Berar. Mr. Raitt states that four Indian conifers, *Picea Morinda*, *Abies Pindrow*, *Pinus excelsa*, and *Pinus longifolia*, yielded long-fibred, strong pulps of good colour and quality, while weaker but useful pulps were obtained from six hard-wood trees, including *Bombax malabaricum*, *Populus ciliata*, and *Ficus bengalensis*.

A thick volume, issued as vol. xiv., part i., of "Contributions from the United States Herbarium," is devoted to a compilation dealing with the lichens of Minnesota, in which Mr. Bruce Fink presents the data collected and conclusions formulated by several years' field work and study. Under the only American order of Ascolichenes, four suborders, Coniocarpineæ, Graphidineæ, Discocarpineæ, and Pyrenocarpineæ are delimited. The largest family, the Lecideæ, contains eight genera, of which Lecidea, Bacidia, and Buellia are the more important; Cladonia and Lecanora are also large genera. Artificial keys are provided for genera and species, and illustrations for one species of each important genus. Further, to add to its value as a practical handbook, the author has given an introductory account of lichen structures and modes of reproduction. Since the lichen flora of Minnesota is fairly representative of a large portion of the northern area of North America, the volume should be useful to British lichenologists for purposes of comparison.

The agricultural experiment station attached to the Purdue University, Indiana, has succeeded in coming into very close contact with the farmers by means of educational trains, field trials, and illustrated circulars dealing with various practical questions. The educational train is almost unknown in this country; it consists of a coach for the staff, two "audience coaches," and a "palace-horse" car, in which are kept the animals used for the demonstrations. The train stops at convenient centres, and is met by the local farmers; the staff then give lectures and demonstrations dealing with matters of local interest. Of the popular circulars recently to hand, we need only mention one on wheat, in which stress is laid on the fact that the average yield in Indiana is only 13·3 bushels per acre, whilst on the college farm it is 28 bushels per acre. The farmer is advised how he may make up the deficiency and improve his own crops.

With the union of the South African colonies, the issue of separate agricultural journals has become superfluous, and they are now all merged into a new *Agricultural Journal of the Union of South Africa*, issued monthly in English and Dutch by the Department of Agriculture. The first number contains articles on the cultivation of recently introduced crops, cotton, bananas, citrus fruits, and others, and records experiments on partial sterilisation of soil for tobacco seed beds. Dr. Theiler describes "stiff-sickness" in cattle, a disease very similar to laminitis in horses, which he traces to *Crotalaria burkeana*, a plant occurring in the pastures. Altogether the new journal reflects very great credit on all concerned in its production.

Three diseases of groundnut have been studied by Mr. F. W. South in the West Indies. A rust fungus, *Uredo arachidis*, is of very general distribution both on imported and on local varieties throughout all the islands. The amount of damage it is capable of causing appears to vary in different islands, as does the success of the control measures employed. A leaf-spot fungus, *Cercospora personata*, is more local and not as yet very serious. A root disease caused by a fungus not identified occurs in a number of the islands; its host plants are numerous and of a very general nature. No adequate method of control is known. Mr. South's observations are published in the West Indian Bulletin, vol. xi., No. 3.

We have received the first report of the Mine Rescue Station Commission of the State of Illinois, which contains some interesting information. Illinois has taken the lead in the United States, and has been the first State to provide a rescue service for its coal mines. Three stations have been built, namely, at Benton, Springfield, and La Salle. In general design and equipment they appear not to differ greatly from those already erected in Great Britain, containing a lecture room, a training chamber, store rooms, &c. Unlike most European rescue stations, they also contain dormitories, which are probably rendered necessary by the conditions of the case; the intention appears to be that men being trained in rescue work should give up their whole time to the training, and should live at the rescue station during their period of training; it seems to be considered that a fortnight should suffice for this purpose. A novel feature here is the provision of a travelling rescue station in the form of an old Pullman car, which has been re-fitted so as to carry rescue appliances, oxygen cylinders, and other requisites; one of these will be attached to each rescue station, where it will stand on a siding ready, so that a locomotive can be coupled up to it and it can at once be taken to the scene of any accident. This idea is well worthy of adoption in other places. Of course, each of the Illinois rescue stations has also its motor-car for road work. The Commission does not express its preference as yet for any one of the numerous forms of rescue appliances that have been designed during the last few years, and rather implies that it has not yet come across any thoroughly satisfactory pattern. Finally, and as perhaps the most important point of all, let it be noted that this is a State enterprise, and that the State pays all expenses, which already amount to some 15,000*l.*

The Journal of Genetics, the first number of the first volume of which appeared in November, 1910, is, as stated in that issue, "a periodical for the publication of records of original research in Heredity, Variation and allied subjects. The Journal," so the announcement continues, "will also, from time to time, contain articles summarising the existing state of knowledge in the various branches of Genetics, but reviews and abstracts of work published elsewhere will not, as a rule, be included." The number before us contains a detailed and copiously illustrated account, by Dr. R. N. Salaman, of his hybridisation experiments with the potato. The characters dealt with pertain to certain morphological features of the leaf and tuber, and also to the colour of the latter. The same laws of dominance do not hold with the wild *Solanum etuberosum* as with the domestic varieties of potatoes. In *S. etuberosum* it was shown that immunity to the attacks of *Phytophthora infestans* is inherited as a recessive character. There is a very interesting paper by F. Keeble and Miss C. Pellew, in which it is shown that the character tallness, treated by Mendel as a single

character, is capable of analysis into two characters, length and thickness of internode, which are inherited independently of one another. L. Doncaster and F. H. A. Marshall describe the results of experiments designed, amongst other reasons, to test the hypothesis put forward by Dr. Rumley Dawson in his Causation of Sex, that the right ovary gives rise exclusively to male-producing and the left ovary to female-producing ova. The results do not support Dr. Dawson's view. The journal is well printed and well illustrated, and is of a convenient size. We wish it success, which it will doubtless achieve.

In *Mitteilungen aus den deutschen Schutzgebieten*, Heft 1, K. Langbeck discusses the data obtained by means of self-registering raingauges on the Cameroon mountain. Situated near the equator, and swept by the south-west monsoon winds of the west coast of Africa, almost the heaviest rainfall in the world has been here recorded, Debundja receiving a mean annual rainfall of 10,140 mm., and Bibundi of 10,701 mm., so far as observations go at present. The article deals with the twelve months April, 1909, to March, 1910, and within this period the maximum rainfall occurs during the forenoon in the rainy season, and after midday in the dry months of the year. High values were recorded from 2 a.m. to 10 a.m. between June and October, and from noon to 4 p.m. and 6 to 7 p.m. between November and May. Utilising the data of previous years, a general excess of rainfall between 6 p.m. and 6 a.m. to the extent of about 60 per cent. is found, so that too great reliance must not be placed on a short period only. The investigation, however, is interesting, and as additional material is accumulated these apparent discrepancies will doubtless be explained. In the same number are published two maps of German South-west Africa, scale 1 : 200,000 and 1 : 400,000, which include the coast region from the Orange River up to lat. 26° S. A short description of the geography and the meteorology of the area is also given.

We have received from the observatory at Rio Janeiro a pamphlet entitled "Codigo Mnemo-Telegraphico," by Sr. N. Duarte, chief of the meteorological section, for the compilation and translation of weather telegrams, &c., by the use of words instead of figures, with the view of preventing mistakes in transmission. The principle bears resemblance to the *technica memoria* sometimes used in schools, with much advantage, for remembering dates, &c., by substituting letters for figures to form words. The present system is ingenious, and when the key is mastered the messages may be composed or deciphered without reference to the code. But it is not at all likely to compete successfully with the international telegraphic code now generally in use.

We have received from Major R. A. Marriott a pamphlet entitled "Why we may expect Warmer Winters," in which he seeks to revive a theory enunciated by his friend Major-General Drayson, whose scientific merits he wishes should be more fully recognised. We sympathise with his loyalty, but cannot accept his deductions. Major-General Drayson claimed to have discovered a "second rotation of the earth," and it is urged, as we think somewhat disingenuously, that there is evidence to show that General Drayson's reasoning was sound, and that errors have arisen in astronomical calculations from neglect of the principle. The practical effects of the neglect are urged as more important than the theoretical. Astronomers have assigned an erroneous value to the change of the obliquity of the earth's axis to the ecliptic. Instead of being limited to a quite small angle, the obliquity, it is urged, will change as much as 12°, naturally causing very great changes in the climate. Given the change, the result may be admitted, but inasmuch as the annual increment is only 40·9″, and the minimum is not reached until the year 2295, it is evident that from this cause there can be very little effect until after 2680 A.D., for whatever effect is produced in the first 385 years will be as slowly undone in the succeeding period of equal length. The author, of course, has greater scope when he applies his theory to geological changes, as in the case of the Ice age. But here his periods seem to be too short, as for the purposes of ordinary life they are too long. On this point, however, we cannot insist, for we do not know the date of the observed phenomena with sufficient precision to apply calculation. Within historic times, the facts are scarcely borne out. If we compute from General Drayson's data, the obliquity of the ecliptic at the earliest trustworthy observation, 230 B.C., we get the value 24° 19′ 20″, while the observed obliquity was only 23° 51′ 20″; the rate of change is made, therefore, more than twice as great as that of the observed. The price of the pamphlet is a modest penny, but unfortunately the name of the publisher is not given.

The difficulty of determining the true temperature of the radiating surface has been the greatest obstacle in practically all investigations of the radiating properties of metallic and other surfaces. A method of overcoming this difficulty is described by Mr. C. E. Mendenhall in vol. xxxiii., No. 2 (p. 91), of *The Astrophysical Journal*. In his experiments the author folded a piece of thin, flat, conducting ribbon of, say, platinum, parallel to its length, so that it formed a V-shaped cavity, and found that optical pyrometer observations of the temperature within the wedge-shaped aperture, particularly in one with reflecting walls, give the true temperature of the outside surface of which the radiation is to be studied. Various experiments with filaments of pure platinum verified the accuracy of the method.

The stability of the atom under changes of molecular kinetic energy has been investigated anew by Mr. Henry Clo, who tested the stability by the resistance of the atom to ionisation; previous investigators have failed to find any certain dependence of atomic stability on the temperature. A specially constructed cylinder containing hydrogen or air was surrounded by an electric furnace raised to various measured temperatures, and the contained gas submitted to the ionising influence of the γ rays of radium. The results, published in a paper appearing in No. 2, vol. xxxiii., of *The Astrophysical Journal*, indicate that the ionisation of air is independent of the temperature of the gas to within 0·2 per cent., up to 600° C., and that the same independence is exhibited by hydrogen up to about 430° C.; a variation of above 200 per cent. in the absolute temperature of a gas fails to affect the stability of the atom sufficient to change the ionisation more than about 0·1 per cent.

The Bulletin of the Imperial Society of Naturalists of Moscow for 1910 contains (pp. 70–212) a long mathematical investigation, by Prof. Ernst Leyst, of formulæ representing the action of one magnet on a second. After dealing with the ordinary simple conception of a magnet as composed of two point poles of opposite sign, Dr. Leyst considers the much more complicated case—applicable to thin-walled hollow cylindrical magnets—where each pole is regarded as a fine circular ring of positive or negative matter. In the most general case the mathematical operations are heavy, and the resulting formulæ long; the

coefficient of one single term occupies eight pages. More especial attention is paid to the two standard positions of Gauss and the two standard positions of Lamont. These have been treated with more or less completeness by several previous magneticians, amongst whom Lamont and Borgen are specially mentioned; but, according to Leyst, few if any of his predecessors who have given formulæ for all four cases have wholly escaped printers' errors. Expression is given to the belief that the differences between results obtained for the horizontal component of the earth's magnetic force with different magnetometers are due in large measure to insufficiency in the deflection formulæ employed. There seems, however, no reference to the theoretical or experimental work on this question carried out of late years in this country and in India.

The Electrician for April 14 contains an abstract of the last three of Sir J. J. Thomson's Royal Institution lectures on radiant energy and matter. They dealt with the distribution of energy in the spectrum of a black body, the relation between radiation and absorption of a body, the character of the absorption of gases, and the nature of radiation and of light waves. The same number of *The Electrician* contains a summary of the lecture on the deflection of the positive rays of the vacuum tube as a new means of chemical analysis. Since the ratio of the deflections of a particle in the electric and magnetic fields depends on the quotient of the electric charge carried by the mass of the particle, an examination of the deflections allows some deductions to be made as to the composition and charges of the particles. Oxygen, for instance, appears to exist in the tube in nine modifications, and these help us to understand why the same chemical substance is so often capable of giving entirely different spectra under different conditions.

The illuminating engineers of America appear to have commenced a crusade against the evil of "glare" in artificial illumination, and the subject is given a prominent place in several of the American scientific journals. *The Scientific American* for April 15 contains an article on light and shadows ministering to eye comfort, by Mr. E. C. Chittenden, of the Bureau of Standards. He considers that the present method of lighting large rooms by lamps concealed in recesses close to the ceiling gives too great uniformity of illumination to be pleasant to the eye, and prefers visible lamp fixtures provided with fittings of prism glass, which send the light in the direction required. According to the April number of *The Illuminating Engineer of New York*, an American Association for the Conservation of Vision has been formed, and the editor sums up a few of the questions at issue as follows:—(1) Is glare so injurious to the eyes as is generally believed? (2) Is indirect lighting good or bad? (3) Is the Cooper-Hewitt lamp injurious to the eyes?

A supplement to *The Electrician* of May 12 devotes nearly 200 pages to special articles on the present position of electric power in mining. Since the corresponding supplement was issued three years ago, new rules have been issued by the Home Office dealing with the use of electrical appliances in mines, and one of the articles is devoted to the elimination of risk from explosion and from shock in the use of electricity. Other articles deal with the supply of power, either from a public or from a private station to the colliery, the winding plant, the wiring of the mine, coal-cutting machinery, haulage plant, pumps, switches, and electric hand lamps. Each is written by a man well qualified to deal with his subject, *e.g.* Prof. W. M. Thornton, Mr. H. J. S. Heather, and Mr. W. B. Shaw.

Messrs. Negretti and Zambra have submitted to us a pair of folding prismatic binoculars, which we have carefully tested. The chief feature is the manner in which the binoculars may be folded for ease in carrying to fit into a case $3\frac{1}{2}$ inches wide and only *one inch thick*. This is achieved by mounting the prism in which the first two reflections occur separately from the prism producing the last pair of the four reflections of the usual prismatic system. This has not resulted in any sacrifice either in power, aperture, or—so far as we can see—in illumination. We have ascertained that the magnification and field of view as given by the makers, viz. 5·5 diameters and 8·3°, are approximately correct, and these compare very well with the ordinary prism-binocular. The focussing is smooth, the introcular distance can be adjusted, and for a small range the focus can be separately adjusted for each eye. The only criticism we have is of the spring catches which hold it in position for use, which do not appear quite strong enough. Incidentally, the glasses provide very interesting evidence of the power we possess of rotating our eyes in their sockets (by means of the oblique muscles). If the spring catches are released while looking through the glasses, and the bodies are slightly rotated, as in folding them, the images seen by the two eyes rotate in *opposite* directions. It will be found that for a few degrees either way the eyes are able to follow, and to fuse the images into one.

In the paragraph on a fresh-water rhizocephalan in our last week's issue, the *Records of the Indian Museum* is quoted as *Records of the British Museum*.

OUR ASTRONOMICAL COLUMN.

The Bright Meteor of April 30.—Mr. Harrison Hill, of Abbey Road, N.W., writes to say that he also observed the brilliant meteor which was seen, as reported in these columns last week, by the Rev. T. E. R. Phillips. At midnight on April 30 Mr. Hill's attention was arrested by a sudden and bright light, which appeared to be a large star, in the S.W. sky. This object increased rapidly in size and apparent brightness, and then disappeared. Although Mr. Hill has frequently observed "shooting stars," this meteor especially impressed him by reason of its lack of apparent motion and its exceeding brightness.

The Spectrum of Nova Lacertæ.—A comprehensive study of the spectrum of Nova Lacertæ is published in No. 194 of the Lick Observatory Bulletins by Prof. W. H. Wright. Spectrograms were secured early in January with spectrographs attached to the 36-inch and 12-inch refractors, but subsequent observations were prevented by a protracted storm which set in after January 6. Altogether, some 140 wave-lengths are given as positions of lines, or as maxima, minima, or limits of bands. As remarked by Prof. Wright, the interpretation of this complex structure of the spectrum is a difficult problem in which great caution must be used. There is one point to which he directs specific attention, however. In the comparison iron-spark spectrum the air lines appear as usual, and show a large measure of agreement with many of the bright-band maxima in the star. This is shown by a table comparing the nitrogen wave-lengths given by Exner and Haschek and Neovius with the stellar wave-lengths. But it should be noted that the strongest nitrogen line, λ 3995, is absent from the star spectrum, as are also some of the fainter lines in the spectrum of the gas; neglecting the lines of intensity two and less, there is, however, a striking agreement except for some discrepancies in wave-length such as might easily occur in the measures of the involved nova spectrum. This is interesting and suggestive, but, as Prof. Wright says,

the existence of nitrogen in the star can hardly be said to be proved.

Bright bands, possibly related to two found in gaseous nebulæ, were seen in the January spectra of the nova, and a spectrogram taken on March 30 shows that the nova had then arrived at the nebula stage; bands at or near λλ 4861, 4959, 5007, 5752 ±, and 6563 were recorded.

THE RADIAL VELOCITY OF α CYGNI.—The study of thirteen spectrograms taken at the Pulkowa Observatory confirms the variability of the radial velocity of α Cygni, first discovered at the Yerkes and Lick observatories in 1910. In No. 38 of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo* Herr G. Neuimin publishes the data and results he obtained from the measures, and directs special attention to the fact that the velocities deduced from eighteen metallic lines vary considerably and consistently from those obtained from the measures of the three hydrogen lines Hδ, Hγ, and Hβ. The range of velocities, relative to the sun, as derived from the metallic lines, is from −17·6 to +2·47 km., and from the hydrogen lines −21·1 to +5·5 km.; the mean difference between the two sets of velocities, from seven plates on which both sets were measured, is +9·1 ± 1·21 km. per sec.

Prof. Belopolsky confirmed this result by independent reductions, using seven iron, two each calcium and magnesium, one helium, and four hydrogen lines. Apparently the helium line agrees with the hydrogen lines in differing consistently from the lines of the various metals; the results show a mean difference, metallic − hydrogen, of +7·1 ± 0·9 km. On two of the spectrograms the calcium lines H and K are apparently double.

THE DISTRIBUTION OF VARIABLE STARS.—Plotting the positions of 678 variable stars given in the *Annuaire du Bureau des Longitudes* (1909), M. Anestin, of Bucharest, finds the known agglomeration in the Milky Way and the condensations in Aquila, Lyra, Cygnus, Sagitta, Cepheus, and Cassiopeia. Near the N. pole of the galaxy, between 10h. and 12h. R.A. and +20° to +40° declination, there is but one variable as compared with twenty in a fourth the area in Aquila and Lyra. Long-period variables show a tendency to grouping, but the irregular variables are more evenly distributed except for an agglomeration in Cygnus.

In the southern hemisphere, 664 variables crowd towards the galaxy, but between 6h. and 10h. R.A. there appears a space almost devoid of them, which covers part of the region, 6h. 30m. to 14h., also devoid of novæ. The region thus avoided by the temporary and variable stars is, as M. Flammarion pointed out, the least complex and least dense large area of the Milky Way (*L'Astronomie*, April, p. 184).

THE VARIATION OF S ARÆ.—No. 3, vol. xxxiii., of *The Astrophysical Journal* (April, p. 197) contains an interesting paper by Dr. A. W. Roberts, in which the author propounds a theory to account for the peculiar light-curves of such "cluster-variables" as S Aræ. The general features of this type of light-curve are short period, a long stationary minimum, a very sudden rise to maximum, and a leisurely decline to minimum. After carefully studying the variation of S Aræ, Dr. Roberts suggests that such a light-curve may result from a combination of two distinct variations. The primary curve would be that of a Cepheid variable, depending upon an intrinsic variation of a bright star. The superimposed curve would be that of an Algol variable, and the theory demands that this shall be caused by the eclipse of the very bright, but relatively small, satellite by a larger, dark primary; the satellite is the Cepheid variable. There are various objections to such a theory, but the main observed facts are in favour of it. The great variation of the smaller star might be explained by the fact that the distance separating the pair is very small; thus the smaller companion may be revolving in a path which carries it through the rarer atmosphere of the larger star, the absorption of this atmosphere accounting for the change in apparent brightness.

THE "ANNUAIRE ASTRONOMIQUE" FOR 1912.—The Royal Observatory of Belgium is to be congratulated upon getting this useful *Annuaire*, for 1912, published so early, for although it necessitates omissions from the *revue* section, it facilitates the work of a number of the practical astronomers the book is intended for. The comprehensive list of observatories is omitted from this issue, but is to be republished every two or three years. In addition to the usual tables, ephemerides, "phenomena," &c., there are valuable articles on the tides, the universal time system, and, in a supplement bound with the *Annuaire*, Dr. Stroobant's work on the recent progress of astronomy.

THE ROYAL SOCIETY CONVERSAZIONE.

THE gentlemen's conversazione of the Royal Society was held in the society's rooms at Burlington House on Wednesday, May 10. The fellows and guests were received by Sir Archibald Geikie, K.C.B., president of the society, and many objects and experiments of scientific interest were exhibited. During the evening the Hon. R. J. Strutt gave a lecture on the afterglow of the electric discharge and on an active modification of nitrogen, and Mr. Joseph Barcroft lectured on adaptation to high altitudes in relation to mountain sickness. Experiments were shown by Prof. Strutt to prove that the well-known "afterglow" of Geissler tubes containing air is a phosphorescent flame, produced by the reaction of nitric oxide and ozone formed in the discharge. It was shown that nitrogen gives rise to a different kind of afterglow. The latter is regarded as resulting from the formation of an active modification of nitrogen, which slowly reverts to the ordinary form with luminosity. It was also shown that acetylene is spontaneously inflammable in this active nitrogen, and burns to cyanogen, the flame showing the characteristic spectrum of that gas.

Following our usual custom, we give a summary of the official description of exhibits, related subjects being here brought together for convenience of reference.

The Astronomer Royal.—(1) Model of orbit of Jupiter's eighth satellite. The model shows the path of the satellite around Jupiter from 1908 to 1916 as predicted by Dr. P. H. Cowell from the observations made in 1908 and 1909. The orbits of satellites VI. and VII. and of the inner satellites are also exhibited to scale and in their proper planes. The scale is 80 inches equal 1 solar unit, or 1 inch equals 1,160,000 miles. (2) Globe showing the motions of the two main star streams. The model has been constructed to show how an examination of the directions of motion of the stars reveals the presence of two great streams of stars. The statistics of the motions in different parts of the sky are summarised by the diagrams on the globe; it can be seen that for each region there are two "favoured directions" of motion in which the stars move in greatest numbers. These directions are traced on the globe, and converge to two apices. *The Director, Khedivial Observatory, Helwan, Egypt.*—Photographs of Halley's comet taken with the 30-inch Reynolds reflector by Mr. H. Knox Shaw. The photographs exhibited cover the period from April 16 to June 10, 1910. *Lowell Observatory, Arizona, U.S.A.*—(1) Photographic negatives of Halley's comet taken at the Lowell Observatory, May 4 to June 5, 1910. (2) Plates of slit spectrograms of Halley's comet. (3) Plates of slitless spectrograms of Halley's comet. Three important deductions follow from the photographs and spectrograms:—(i) The identification, by Dr. Slipher, of the three chief bands in the comet's spectrum as those which Mr. Fowler has shown to be the bands of carbon monoxide when under very low pressure. (ii) The totally diverse gaseous constitution pointed out by Dr. Slipher between the emissive constituents of the head and tail—the bright gases of the one being strong where those of the other are weak, and *vice versa*. (iii) Measurements by Prof. Lowell on knots in the photograph showed an accelerated velocity away from the head, as follows:—

	Angular distance from the nucleus to the point measured in the tail	Velocity of the point of the tail away from the nucleus
Knot 1	1° 28′	13·6 miles a sec.
Knot 2	3 12	17·2 ,, ,,
Knot 3	4 36	10·7 ,, ,,
Knot 4	6 15	29·7 ,, ,,

This, taken in connection with the spectrograms, disclosed

the significant fact that the accelerated knots were composed, to the extent of 75 per cent. of gases, not of solid particles, and that, therefore, *molecules* not only could be, but actually were, repelled by the action of the sun—contrary to current theory. *The Royal Astronomical Society.*—Series of photographs of nebulæ taken by Prof. G. W. Ritchey with the 60-inch reflector of the Mount Wilson Observatory, California, in 1910. *Mr. A. Fowler, F.R.S.*—Spectrum photographs showing the composition of the tails of comets. The spectra of the tails of comets exhibit a number of double bands, which the photographs prove to be identical with bands obtained from vacuum tubes containing carbon monoxide at a pressure of about 0·01 mm. An additional band, due to nitrogen, was present in comet Morehouse. *Solar Physics Observatory, South Kensington.*—(1) Spectroheliograms of the sun. Obtained on Friday, April 28, 1911, about six hours before the time of total eclipse at Vavau, and on Saturday, April 29. Composite pictures are shown of the prominences on the limb and the flocculi on the disc, taken in K_2K_3 (calcium) light. (2) Diagrams illustrating the southern hemisphere surface air circulation. (i) Scheme of general suggested circulation. (ii) Curves showing time difference of pressure changes. (3) Observations of Halley's comet at Fosterdown, Caterham. (i) The temporary observatory showing the three instruments used: 9-inch Henry prismatic camera, 10 feet focus, with one prism of 45° angle; 2-inch quartz calcite prismatic camera, 18 inches focus, with one prism of 30° angle; 6-inch Dallmeyer doublet camera, 4 feet focus. (ii) Plate showing single and double nucleus of comet, drawing of visual spectrum, and photographic spectrum. (4) Photographic laboratory spectra. Showing the flutings of titanium, vanadium, and chromium, employed in the reduction of the spectra of Antarian stars α Orionis, ο Ceti, α Scorpionis, &c.

Prof. R. W. Wood (Johns Hopkins University, Baltimore).—(1) Fluorescence and resonance spectrum of iodine vapour, with monochromatic excitation. Development of band spectrum by presence of helium. Light from a mercury arc is focussed at the centre of a large glass bulb, highly exhausted, and containing a small crystal of iodine. The iodine vapour shows brilliant fluorescence, and the spectroscope shows resonance spectra excited by the two yellow and the green mercury lines, which can be observed separately by interposing absorbing screens between the lamp and the bulb. In a bulb containing iodine crystals and helium at 2 mm. pressure, excited in the same way, the spectroscope shows the band spectrum of iodine superposed on the resonance spectrum. The collisions with the helium molecules apparently effect a transfer of energy from the excited electron system in the iodine molecule to all the other systems. In helium at 10 mm. the band spectrum alone is seen, as in the case of iodine vapour *in vacuo* excited by white light. (2) Echelette diffraction gratings. Gratings ruled with groove of known form on gold-plated copper by a crystal of carborundum. Used for work in the infra-red, and for experimental determination of the energy distribution in the spectrum in relation to the wave-length and the form of groove. The oblique faces of the grooves show a curious oblique image by reflection when the incidence is perpendicular to the plate. *Mr. Eric S. Bruce.*—Photographs and prints descriptive of types of dirigibles. The exhibit is descriptive of various types of airships on the lighter-than-air principle. *Mr. W. H. Dines, F.R.S.*—Working model of winding gear used for kite-flying at Pyrton Hill. *Prof. P. V. Bevan.*—Anomalous dispersion in metallic vapours. Anomalous dispersion at the red lines of potassium. The dispersion is produced by the method well known through the experiments of Prof. R. W. Wood with sodium vapour. Dispersion is also shown at the two violet lines of rubidium.

A. W. Clayden.—An actinograph or radiation recorder. The pen records the difference between the temperatures of two similar bimetallic spirals, of which one is blackened and exposed to radiation, while the other is bright and is shaded by a polished tin cover.—*Sir Henry Cunynghame and Prof. Cadman.*—(1) Contrivance fitted to miners' safety lamps for the detection of fire-damp. The contrivance consists of a small piece of asbestos soaked in carbonate of soda, which can, at will, be introduced into the flame of the lamp without the necessity of lowering it. The presence of small percentages of gas is immediately indicated by the appearance of an orange-coloured cap of the same character as appears when a wire, charged with soda, is introduced into a Bunsen gas flame. (2) A differential hygroscope (Sir Henry Cunynghame). The device consists of two thermometers, one with a wet and the other with a dry bulb. Instead, however, of being placed apart as usual, the stems of the two are brought into juxtaposition. They are not equally divided, but are so arranged and divided that when the top of the column of one of them sinks below the top of the column of the other, any desired hygrometric state of the air is at once seen by simple inspection without any scale or reference to any table, and irrespective of the temperature.

Messrs. Elliott Brothers.—The Anschütz gyro-compass. A practical application of a gyrostat as a mariner's compass. The apparatus consists of a gyrostat so suspended that its axis points to the true north, thus avoiding the necessity of any considerations of magnetic variation. The "directive force" is considerable, and on that account the apparatus can be made use of to transmit its indications to various points in a ship. *Mr. A. Mallock, F.R.S.*—Model of a "detached escapement" for pendulum clocks. The pendulum is free, in the sense that during the swing it makes no intermittent contacts with any solid. Near the end of each swing an electric contact is made by a fine wire dipping in a mercury cup. The current then established passes through the coils of an electromagnet, which, by means of a "remontoir" working a reciprocating lever, causes a very weak spring to act so as to maintain the oscillation. Constant density in the air surrounding the pendulum is approximately secured by the covering bell glass, the edge of which dips in a deep but narrow annular canal partly filled with mercury. An alteration of 1 inch in the height of the barometer alters the density of the enclosed air by about one part in a thousand. *Sir William Ramsay, K.C.B., F.R.S., and Dr. R. W. Gray.*—A micro-balance. This balance, made essentially from the designs of Steele and Grant, registers about 1,20,000th of a milligram. It is comparatively insensitive, one at University College being more than ten times as sensitive. The plan of adding small weight was worked out at University College; it consists in altering the apparent weight of the air in a sealed quartz bulb, suspended from one arm by a silica fibre, by altering the pressure of air in the balance-case. It was with a balance of this type that the density of niton was determined with less than one-tenth of a cubic millimetre. *Mr. J. J. Manley.*—Analytical balance with protected beam. The beam of this balance is completely enclosed by an auxiliary inner case, which is made of magnalium and fitted with plate-glass shutters. Beneath the base-plate of the case, baffle-plates are attached to the pan-suspensions and pointer. These baffle-plates intercept and deflect any convection currents ascending from the experimenter's hand, and so prevent them from striking the beam. By these combined devices, very great uniformity in the temperature of the balance beam may be maintained. *The National Physical Laboratory.*—A simple apparatus for measuring small thicknesses and displacements (exhibited by Mr. E. H. Rayner). *Dr. A. O. Rankine.*—A method of measuring the viscosity of a small quantity of gas. *The National Physical Laboratory.*—Portable potentiometer for temperature measurements with thermo-couples (exhibited by Dr. W. Rosenhain and Mr. S. W. Melsom). *Mr. Alfred W. Porter, F.R.S.*—An anomaly in the lagging of wires and pipes. A sheath consisting of a bad thermal conductor (like asbestos or glass) surrounding a sufficiently narrow hot body assists the escape of heat instead of retarding it. This effect is shown by means of a platinum wire heated electrically. Parts of the wire are covered with glass. Where the cover is the wire keeps quite cool (at about 100° C.) even when the bare part is at 1000° C. Examples of lagged steam-pipes are also exhibited.

Sir William Crookes, O.M., F.R.S.—Collection of old radiometers and otheoscopes. These experimental instruments were made by the exhibitor during his researches on repulsion resulting from radiation, and were used to illustrate the papers when they were read before the Royal Society in the years 1875–8. *Sir James Dewar, F.R.S.*—Radiometer acting by the pressure of mercury vapour given off by the liquid between the ordinary temperature and

$-25°$ C. Radiometer, in concentrated beam of electric arc, stopped by charcoal liquid-air vacuum, and started again by mercury vapour at a pressure of about one fifty-millionth of an atmosphere. Activity again arrested on freezing out the mercury vapour in liquid air. *Mr. Francis Fox.*—(1) Radium bromide from pitchblende found in Trenwith Mine, St. Ives Consolidated Mines, St. Ives, Cornwall. (2) Specimen of rich pitchblende ore from the mine. *Mr. C. T. R. Wilson, F.R.S.*—Exhibition of the tracks of ionising particles in gases. (1) Tracks of α particles from radium through air. (2) Tracks of ionising particles produced by X-rays in air. The trail of ions left by each ionising particle is made visible by condensing water upon the ions. *The National Physical Laboratory.*—Ionisation in the electric furnace (exhibited by Dr. J. A. Harker, F.R.S., and Mr. C. G. Eden). *Prof. J. Norman Collie, F.R.S.*—Tubes showing electric discharge through neon. (1) Tubes showing the electric discharge through neon at high pressures. (2) Table showing the canal rays in neon. *Mr. C. W. Raffety.*—Enlarged photographs of the forms assumed by the brush discharge in air at reduced pressures. *Prof. E. Wilson and Mr. W. H. Wilson.*—(1) An improved high-tension discharge apparatus. (2) A high-tension electrostatic wattmeter (Prof. E. Wilson). *Prof. J. A. Fleming, F.R.S.*—Experiments showing visibly the oscillatory discharge of a condenser by Hemsalech's method, and its magnetising action on finely divided iron cores. *Mr. S. G. Brown.*—(1) Telephone relays. (2) Model of electrical stethoscope.

Prof. A. Liversidge, F.R.S.—(1) Series of sections of gold nuggets and photographs to illustrate the same. (2) Specimens and sections of Australian meteorites, and photographs. *Prof. W. J. Pope, F.R.S.*—Photomicrography in natural colours. Photomicrographs of rock sections, chemical preparations, and crystal interference figures are exhibited. The photographs were taken between crossed Nicol prisms by the Dufay process, in which the colours of the objects are reproduced. *Prof. E. G. Coker.*—Interference colours produced by transparent materials under stress. A beam of plane or circularly polarised light is passed through a plate of xylonite cut into any selected shape and loaded in any convenient manner. The material when stressed behaves like a doubly refracting crystal, and the two rays, into which the incident beam is divided, produce interference colours when passed through a Nicol's prism. The stress distribution may be inferred from the colour fringes produced. *Prof. J. Eustice.*—Experiments on stream-line motion in curved pipes. By means of filaments of coloured water, it is shown that when water is flowing from a straight to a curved pipe some of the filaments approach the sides of the pipe and cross from the outside to the inside of the curve, close to the walls. Several colours are used in the glass pipes, and the interlacing of the filaments caused by the vortex motion is clearly exhibited. *Mr. C. E. Larard.*—Twisted, cylindrical, and castellated metal specimens. *Mr. J. E. Marsh, F.R.S.*—(1) Experiments showing the separation of a homogeneous solution into three layers when the solution is warmed. (2) Solutions of certain salts in ether not miscible with excess of ether.

Prof. W. M. Thornton.—The electric charges associated with vegetable cells. When an electric current is passed through a weak emulsion, in water, of typical animal and vegetable cells, such as blood corpuscles, yeast, bacteria, and unicellular algæ, the animal cells appear to be driven to the positive pole, the vegetable cells to the negative, provided that the latter are from fresh, active growths. The movement reverses with the direction of the current, and is dead beat. *The Director, Royal Botanic Gardens, Kew.*—Cushion plants and their seedlings. The exhibit includes specimens and photographs of the balsam bog of the Falkland Islands (*Azorella glebaria*, A. Gray, Umbelliferæ), with a series of living seedlings raised in the Royal Botanic Gardens, Kew. *The John Innes Horticultural Institution.*—(1) "Chimæras" and Winkler's graft-hybrids, from Prof. E. Baur (Berlin). (2) A case of coupling in Pisum, between roundness of seed and power to produce tendrils, in the ratio 63 : 1 : 1 : 63. *Mr. A. D. Hall, F.R.S.*—A biological factor in soils limiting the activity of bacteria in producing plant food. Bacteria play an important part in the production of plant food in the soil from the accumulated organic residues; indeed, when other things are equal, the fertility of the soil is closely connected with the amount of bacterial activity. It has been shown, however, that a factor exists in ordinary soils limiting the activity of bacteria; this factor is biological, and appears to consist of large destructive organisms. When soils are kept in moist, warm conditions and well supplied with organic matter, as in a greenhouse, there is a marked accumulation of the limiting factor; a similar accumulation occurs in the soils of sewage farms. On the other hand, dry soil conditions are unfavourable to the factor. Heating the soil to 55° C., prolonged drying at lower temperatures, or treatment with various antiseptics such as toluene, kills the factor and leads to a marked increase of bacterial activity. In field and greenhouse soils there is a large production of plant food, and in sewage-farm soils an increased rate of decomposition.

Prof. H. E. Armstrong, F.R.S., and Dr. E. F. Armstrong.—The action of stimulants (hormones) in promoting enzymic activity. The specimens shown are in illustration of results described in recent communications on the functions of hormones in stimulating enzymic change in relation to narcosis and the phenomena of degenerative and regenerative change in living structures, and on the functions of hormones in regulating metabolism. Like the barley grain, leaves are shown to be provided with protective differential septa through which strong acids, salts generally, and substances such as the sugars do not pass, but which are freely permeable by organic vapours, weak acids, ammonia, and a few salts (mercuric chloride, &c.). The passage of the excitant into the leaf is shown in the case of the common laurel (*Prunus laurocerasus*) by the liberation of hydrogen cyanide, and in the case of the spotted Japanese laurel (*Aucuba japonica*) by blackening due to the decomposition of the glucoside aucubin. The active substances are for the most part non-electrolytes, which have little, if any, chemical activity. *Prof. R. T. Hewlett and Mr. J. E. Barnard.*—(1) The bactericidical action of light produced by a quartz mercury vapour lamp. Experiments on the bactericidical action of light indicate that a quartz mercury vapour lamp, in relation to its current consumption, is the most economical source at present available. The most actively bactericidical region in the carbon arc spectrum is that portion of the ultra-violet between λ 3280 and 2260. These radiations are produced freely by the mercury arc, and the action extends still further, practically to the limit of transmission by quartz. Owing to the almost entire absence of heat radiations in the mercury arc, any arrangement for heat absorption becomes unnecessary. This is an advantage of considerable moment, as any such method at present in use substantially increases the necessary exposure. (2) Apparatus for disintegrating bacterial and other organic cells. The apparatus consists of a metal containing vessel, in which a number of steel balls are placed, and which is caused to rotate. The balls are kept in position at the periphery of the vessel by a central steel cone, which, by suitable means, is prevented from rotating. Grinding action takes place between the steel balls and the inner surface of the vessel. The efficiency of the method is high, as after subjecting bacteria to the grinding process for from fifteen to twenty minutes, very few, if any, whole cells remain. Even those that are apparently whole have evidently parted with their cell contents, as may be demonstrated by the difficulty of staining them by any recognised bacteriological method. *Mr. Henry Crookes.*—Photographs and living cultures of *B. phosphorescens*, showing the germicidal action of some metals. Nutrient gelatin-agar is poured into Petri dishes containing small pieces of metal; when the medium has set, the surface is infected with *B. phosphorescens*. After twenty-four hours the bacteria grow luxuriantly, except in a zone surrounding the piece of metal, which remains entirely sterile. The extent of this *death-zone* varies with different metals. *Prof. M. C. Potter.*—Electrical effects accompanying the fermentative activity of yeast. The apparatus shown consists of a glass jar containing a porous cylinder, and into each of these are introduced solutions of glucose of equal concentration. Two platinum electrodes are placed one in the jar and one in the porous cylinder, and on the introduction of yeast into one of the solutions, the whole constitutes a type of galvanic cell. *Mr. S. G. Shattock and Mr. L. S. Dudgeon.*—(1) Resistance of *Bacillus pyocyaneus* to drying *in vacuo*. Experi-

ments devised to ascertain how far this factor might be *per se* lethal to bacteria in insterstellar space. A growth of *Bacillus pyocyaneus* raised from a thin film of a culture (made in peptone water) spread on glass and kept dried *in vacuo* for four months. The vacuum was produced by Sir James Dewar's method (a bulb of powdered charcoal surrounded by liquid air, after exhaustion by pump); after five days the vacuum was maintained by sealing off the tube. Light was excluded throughout. The bacillus when dried in the air (light excluded) dies within three months. The behaviour of this bacillus *in vacuo* is exceptional. Its maintenance of vitality corresponds with that of certain seeds under similar conditions. (2) Microscopic sections of urinary calculi from the human subject.

Hon. N. C. Rothschild.—Model of *Xenopsylla cheopis*, the tropical plague flea. *Mr. F. Enock.*—Photomicrographs of new species of British Mymaridæ. The insects comprised in the subfamily Mymaridæ are ovivorous in their habits, laying *their* eggs in those of various Homoptera and Coleoptera. Hitherto only thirty-five species have been recorded. The photomicrographs are part of the hundred to one hundred and fifty new species (many as yet unnamed) collected or bred during the past thirty-five years. *Sir W. B. Leishman, F.R.S.*—A parasite found in cases of infantile splenic anæmia. In cases of this disease, occurring in Tunis, Italy, Sicily, Malta, Portugal, and elsewhere, a protozoon—*Leishmania infantum*, Nicolle—has been found by C. Aicolle and others. It resembles closely the parasite of kala azar—*Leishmania donovani*, Laveran—and that of Oriental sore.—*Leishmania tropicum*, Wright. The disease is extremely fatal, and appears widespread in the Mediterranean littoral. It has recently been proved to be identical with the fatal disease of children known as "ponos," which occurs in some of the islands of the Grecian Archipelago. The parasites have also been found in dogs, and it is probable that they are transmitted from the dog to the child by the bite of some insect. *The Lord Avebury, F.R.S.*—(1) Moth from Peru (Caligo) imitating an owl. (2) Elytron of beetle (Pachyrhynchus). (3) Butterfly from Borneo (Ornithoptera-Brookeana) mimicking the tips of the leaflets of a pinnate leaf emerging from the deep shade of a tropical forest; the midribs of the leaflets and the serratures of the edges are well represented. *Mr. H. Eltringham.*—Colour drawings illustrating African mimetic butterflies. *Prof. Poulton, F.R.S., Mr. C. A. Wiggins, Mr. W. A. Lamborn, and Mr. E. G. Joseph.*—Recent observations on mimicry, protective resemblance, &c., in African and South American butterflies and moths. *Dr. Deane Butcher.*—Osmotic growths. Osmotic growths are mineral productions simulating the forms of organic life. They are obtained by sowing a mineral seed or nucleus in a concentrated inorganic mother liquor. The nucleus reacts with the liquid to form an insoluble gelatinous precipitate at the surface of contact. This semi-permeable extensible membrane is distended by the osmotic pressure within, and grows by a process of intussusception, branching and putting forth terminal organs as it reaches a solution of lesser concentration. Osmotic growths were first described by Prof. S. Leduc in his work on "The Mechanism of Life." *Dr. G. H. Rodman.*—(1) Stereo-radiographs of monkey and tortoise. (2) A set of transparencies illustrating the development of the X-ray tube.

The Cambridge Scientific Instrument Company.—A new large sliding microtome. This instrument is a very powerful one, and will cut sections of superficial measurements up to 150 by 120 mm. (6 inches by $4\frac{3}{4}$ inches) through decalcified bone or cartilage. *Dr. W. J. Dakin.*—Sections showing stages in the sporogony of a new coccidian parasitic in the whelk. *The Marine Biological Association of the United Kingdom.*—(1) The culture of marine diatoms as food for developing larvæ. Some of the difficulties in the way of rearing marine larvæ in the laboratory have been overcome by keeping them in sterile sea-water and feeding them with cultures, as pure as possible, of suitable diatoms. (2) A collection of living marine animals from the neighbourhood of Plymouth. *Dr. W. S. Bruce.*—Deep-sea invertebrates: new or rare species taken by the polar ship *Scotia* in Antarctic seas during the Scottish National Antarctic Expedition (1902–4). *Mr. C. Tate Regan.*—Sketches illustrating instantaneous colour changes in sea-perches from the Bermudas. The sketches show colour phases observed in the New York Aquarium; these fishes are constantly changing their colour and markings; this is accomplished by the expansion and contraction of chromatophores, or pigment cells.

Mr. A. W. Clayden.—(1) Footprints from the Permian sandstones at Poltimore, Devon. Numerous footprints have been discovered during the last two years in the sandstones mapped in the Survey maps as Lower Sandstones They are of two types. Neither can be exactly matched from any of the known localities at which footprints of Permian age have been found, either in Great Britain, America, or Germany. They bear, however, a general resemblance to those obtained at Corncockle Moor and Penrith, though differing in detail. *Mr. R. W. Hooley.*—Skeleton of *Ornithodesmus latidens*, a pterodactyl from the Wealden shales of Atherfield, Isle of Wight. *Mr. W. Taylor.*—Remains of fossil reptiles from the Triassic sandstone of Lossiemouth, Elgin. *Prof. W. M. F. Petrie, F.R.S.*—Roman portraits, first century A.D. These portraits are painted with coloured wax upon thin panels of cedar. On some a fresh coat of paraffin has been now added for security. They were placed over the faces of the mummies and bandaged down round the edge. They are from the same cemetery, at Hawara, Egypt, as those in the National Gallery, a site now exhausted by the British School of Archæology in Egypt. *Dr. Vaughan Cornish.*—Photographs of surface waves. *Dr. Tom G. Longstaff.*—Mountain photographs.

THE IRON AND STEEL INSTITUTE.

THE annual general meeting of the Iron and Steel Institute opened on May 11 under the presidency of his Grace the Duke of Devonshire. The meetings were held at the Institution of Civil Engineers. The Bessemer gold medal for 1911 was presented to Prof. Henri Le Chatelier, of Paris, who attended for this purpose. The Carnegie gold medal was awarded to Mr. Felix Robin, who has conducted researches on the wear of steels and their resistance to crushing. Carnegie research scholarships have been awarded to Messrs. W. M. Guertler, of Berlin, G. Hailstone, of Birmingham, R. M. Keeney, of Colorado, U.S.A., and G. Dietrich Röhl, of Freiberg, Saxony. Messrs. J. Newton Friend, of Darlington, and T. Swindon, of Sheffield, have had additional grants made to them to enable their researches to be extended and completed.

Sixteen papers in all were presented for discussion; the principal points dealt with in a few of these are given below.

Dr. J. E. Stead contributed some notes on the welding up of blow-holes and cavities in steel ingots. The evidence advanced shows that, if the blow-holes in steel ingots are subcutaneous, *i.e.* under the skin and having no opening to the atmosphere, and the heating of the metal is sufficiently high, say 1000° C. and above, the cavities will weld up completely on being rolled or forged, provided they contain no foreign matter. It is doubtful whether pipe cavities can be so readily welded. The upper ends of the pipes in ingots are open to the gases of the heating furnace, and the cavities become coated with oxide scale, which prevents the metallic surfaces from coming into contact. If the pipe is deep and is bridged over at intervals with diaphragms of solid steel, it is not improbable that welding below these bridges might be effected, provided that the imprisoned gases become forced back into the steel and do not form layers of highly compressed gas between the steel surfaces, and so prevent these surfaces from coming into direct contact. Prof. Howe has suggested that forged steel blooms should be heated for a long time to above the welding point, so as to complete the reabsorption of the gas. This is based on two assumptions: first, that the gases of the cavities are capable of being forced by pressure into the hot steel and of becoming occluded there; secondly, that what gas is not so forced into the metal will diffuse into it during prolonged heating at a high temperature. Prof. Howe's suggestion calls for experimental evidence as regards the quantity of mixed gases or of any gas which can be forced by pressure into solid steel, and also as regards how much of it will come out again on removal of the pressure, and it is understood that a research has

been undertaken with the view of settling these important points.

Messrs. E. F. Law, W. H. Merret, and W. P. Digby have studied welds, and in their paper present the results of their investigations. Defining a weld as the actual fusion together of similar or allied metals, the authors have carried their investigations into the region of the characteristic microstructure of both good welds and unsuccessful attempts to produce welds, a subject on which there has hitherto been very little work done. No matter what the process may be by which two metals are welded together, there must always be an area, more or less sharply defined, of altered molecular construction. The authors show that each process of welding has its own hall-mark. For example, it is possible to say whether an electric weld has been made by an arc or by a resistance method from the evidence afforded by polishing and etching alone. Without annealing to restore the original structure, acetylene and water-gas welds have each their own marked characteristics. Resistance welds are seemingly less prone (with the exception, perhaps, of acetylene welds) to oxidation, but the extrusion of the metal renders good working, while the metal is still plastic, of supreme importance. Arc welds are most prone to oxidation, and many will hesitate to rely on such a process in those positions where corrosion is likely to occur. When the welded metal is not likely to be subjected to corrosion, the excellent fusion of the metal renders the method commendable. Flame welds should receive adequate working and manipulation while in their heated condition. Water-gas welds may be abnormal through the use of oxidising flames; acetylene welds certainly require annealing to break down the crystalline structure in the vicinity of the weld.

Prof. H. C. H. Carpenter has continued his investigations on the growth of cast irons after repeated heatings. His principal results up to date may be summarised as follows:—phosphorus tends to diminish growth; sulphur is never present in commercial cast irons in sufficient quantity to have more than a small influence on growth, which is, however, in the direction of retardation; manganese always retards the rate of growth, and diminishes the absolute amount in the majority of cases. Dissolved gases have no influence on the growth of an iron containing more than 3 per cent. of silicon; if the silicon does not exceed 1 per cent. they may be responsible for a growth of at least 10 per cent. The simplest and most rapid test for forming an opinion as to the growth that is liable to take place in any particular grey iron is to estimate the silicon, and then read off the approximate growth from the following table:—

Silicon, per cent.	Approx. growth, per cent.	Silicon, per cent.	Approx. growth per cent.
1·00	15·0	2·50	31·0
1·25	18·5	2·75	32·5
1·50	21·5	3·00	34·0
1·75	24·5	3·25	35·5
2·00	27·0	3·50	37·0
2·25	29·0		

If the iron contains 0·3 per cent. of phosphorus and upwards, the growth will be from 2·5 to 4 per cent. lower than the above figures, and if more than 0·5 per cent. of manganese is present, the rate of growth will be diminished and the amount of growth somewhat lessened. An alloy containing 2·66 per cent. of carbon, 0·587 per cent. of silicon, and 1·64 per cent. of manganese, showed no signs of growth after 150 heats, but, on the contrary, a slight contraction, viz. about 0·13 per cent. It is a tough material, and its mechanical properties were improved by this treatment. It begins to freeze at about 1340° C., and appears to be a suitable material for annealing ovens, rolls, fire-bars, and the grids of muffle furnaces. Probably it could be used for ingot moulds in an iron foundry without cracking.

The influence of impurities on the corrosion of iron is dealt with in a paper by Mr. J. W. Cobb. Interpreting the results of the author's experiments on the basis of the electrolytic theory of corrosion, it may be stated that pure iron is definitely electro-positive to most of its impurities. Among such impurities were found phosphide, sulphide, carbide, oxide, and silicate of iron. With carbon (graphite) the effects were particularly marked. All the iron alloys tried (excepting ferro-manganese) were also electro-negative to pure iron. With the sulphide and silicate of manganese little or no current flowed. Manganese and 80 per cent. ferro-manganese were found definitely electro-positive to iron. Every piece of commercial iron showed electrical effects with any other, and the effects between portions of the same piece were always sufficient to induce corrosion when the other conditions were satisfied. The presence of an impurity determines so many corrosion centres for iron, and so its influence depends more on quality and distribution than on quantity; thus a more homogeneous iron, even if chemically less pure, may be more highly resistant to corrosion. Other papers bearing on corrosion were contributed by Mr. P. Longmuir and by Messrs. J. Newton Friend and J. H. Brown.

Mr. W. H. Hatfield gives experimental results of the influence of vanadium upon the physical properties of cast iron. As an instance where vanadium has increased the life of locomotive cylinders, a case is quoted where cylinders made of cast iron not treated with vanadium wore 1 32-inch per 100,000 miles, whereas vanadium cast-iron cylinders showed only microscopic wear after running 200,000 miles. The present experiments show that additions of vanadium have a definite influence upon the physical properties of cast iron, and that this influence is mainly that of assisting the carbon to persist in the combined state. The persisting carbides, physically, do not differ materially from the normal carbides found in the cast iron; owing, however, to the actual presence of much of the vanadium in the carbide, that carbide is rendered more stable.

Messrs. A. McWilliam and E. J. Barnes give records of a lengthy series of experiments on the influence of 0·2 per cent. vanadium on steels of varying carbon content.

A paper on the chemical and mechanical relations of iron, chromium, and carbon is contributed by Profs. J. O. Arnold and A. A. Read. This paper is in continuation of the work of the authors already published, and gives an account of a number of experiments to determine the composition of the carbides separated from a series of annealed steels containing various percentages of chromium, the percentage of carbon being practically the same in each. The mechanical properties of these alloys under static and alternating stress, and their microscopic features, have also been investigated.

Iron-silicon-carbon alloys are dealt with in a paper by Dr. W. Gontermann. Some of the work performed at the Institute of Physical Chemistry at Göttingen has already been published, and the present report contains further particulars. The paper contains many diagrams and photographs of models showing graphically the properties of this series of alloys.

The magnetic properties of some nickel steels, and notes on the structures of meteoric iron, form the subject of a paper by Messrs. E. Colver-Glauert and S. Hilpert, of Berlin. A 5 per cent. nickel steel is hardest (magnetically) when quenched in the neighbourhood of 600° C. Quenching from higher temperatures results in a softer material. The changes which occur during thermal treatment of a 25 per cent. nickel-iron alloy are of a far more complicated nature than has been thought previously. At high temperatures there probably exists a product which may be preserved by rapid quenching, and is then strongly magnetic, and persists to the temperature of liquid air. This product does not exist in the region between about 600° C. and 900° C. There is very little connection between the magnetic properties and metallographical structure. There is no sharp magnetic change point for this alloy below zero, but the permeability gradually increases as the temperature decreases from about −50° C. to −180° C. The magnetic properties of a 33 per cent. nickel-iron alloy are only very slightly affected by thermal treatment. The microstructures of commercial nickel steels are practically the same as those of meteoric iron.

Messrs. A. McWilliam and E. T. Barnes complete their series of papers on steel with another on the properties of heat-treated 3 per cent. nickel steel.

Messrs. F. A. Daubiné and E. V. Roy, of Auboué, France, give an account of a process for the desiccation

of air by calcium chloride. The authors have investigated the appliances necessary for drying large volumes of air, and an appliance has been installed at the Differdauge Steelworks, Luxemburg, where it is now in normal working. In this process, the volume of air to be dried is made to traverse a mass of calcium chloride by means of a fan. Water is circulated through pipes bedded in the calcium chloride for the purpose of carrying away the heat generated by the absorption of water by the chloride. The hydration of the calcium chloride is arrested when the outside pellicle of the broken pieces commences to liquate, and a regeneration operation is employed for the purpose of rendering the calcium chloride capable of being employed for desiccating fresh volumes of air.

THE INTERNATIONAL PHILOSOPHICAL CONGRESS AT BOLOGNA.

THE fourth International Congress, which met at Bologna under the presidency of Prof. Enriques, was formally opened on April 6 by the Duke of the Abruzzi. It has been by far the best attended of the series, the total number of members being more than five hundred, and has been most hospitably entertained by the committee and the various municipalities. The general tone of the debates was much more cordial than usual, and the congress was fortunate even in its conclusion, for the next day a general strike was declared in the town and province.

It is difficult to say what exactly we should expect from such gatherings. It is clear that they can never produce any definite result; but the contact of personalities does sometimes bring into clearer light the existence of general tendencies of thought which otherwise might not have been so definitely perceived. This congress did bring to light the existence of such a tendency, and this was the quite evident decline in the importance of "system" in metaphysics. Philosophy does seem to be steering away from its traditional form. It is beginning to form a more fluent and a less rigid and systematic conception of truth. The working out of this tendency is connected with and was most clearly shown in the discussions of what really formed the main problem of the congress, the one it has spent the most time over—that of the relations between philosophy and science. This problem practically resolves itself into the question as to whether philosophy has any right to an independent existence, and it is perhaps one of the surest signs of the renaissance and vitality of the subject that it can discuss such a question with enthusiasm. This key-note of the congress was struck by Prof. Boutroux in his opening speech. Charming though this was in manner, it was not remarkable for profundity of thought, and offered no more original solution than that science, quite legitimately for its purposes, considered the world impersonally, and that it was the business of philosophy to reintroduce for a complete synthesis the element which science left out.

The same subject formed the theme the following day of a paper by that picturesque personality, Fra Gemelli, monk, biologist, and editor of the *Revista Nee-Scolastica*, which drew a reply from Prof. Hans Driesch, in which he explained the scientific use of his conception of entelechy, as distinct from Aristotle's more metaphysical use. The same subject continued to be discussed each day, until the debate finally culminated in the lecture, that was awaited with the greatest curiosity, that which was given by Prof. Henri Bergson, who is perhaps the most discussed and the most interesting philosopher in Europe at the present time. The main point he tried to establish in his *conférence* was that there were two different, and indeed inverse, ways of acquiring a knowledge of reality, the one that of scientific analysis, and another which he described as a kind of intuition, which should be the method of philosophy. Unfortunately, however, this is not the conception that philosophy has formed of itself. It has always attempted to use the same method as the science of its day; it has always attempted to do for the world in general what particular sciences have done for particular fields. It has conceived itself as the complete science, and therein lies the reason of its failure.

This is true historically; Greek philosophy is nothing but the extension into a different field of the method which prevailed in the science of the times, that of geometry. We get a similar phenomenon in modern philosophy. For the static geometrical concepts of the Greek, substitute the conception of scientific law, extend this to the general problem of reality as the Greeks did geometry, and you get the predominant types of modern philosophy. Always you get philosophy pursuing the same method as that of science, that of intellectual analysis, and having the same ideal, that of a complete science of existence. Now, said Bergson, philosophy, so long as it persists in following this method, is doomed to disappear, for it being obviously not wanted in the field of any particular and successful science, it must pursue its activities in the fields where science has not yet penetrated, *i.e.* in the field of the unknown; and this is not a very secure position for it, for as soon as science begins to penetrate the same field, and there is a contradiction between its conclusions and the conclusions of philosophy, it is philosophy that must give way, not science.

The only future of philosophy, then, lies in a recognition of the fact that it must pursue a different method entirely to that of science. It must give up the attempt to give a complete intellectual representation of the cosmos. There remains the allied question of the place of system in philosophy. Looking at the extraordinary complicated constructions of the great systematic philosophers, they certainly seem to have been animated by the conviction that they were creating a science of the real. But, said Bergson, that is only superficial appearance. If you study, say, Spinoza long enough, you will find that the whole elaborate system was merely the language by which he expressed one perfectly simple intuition, a thing which would be stated in one sentence if you yourself had been in a similar state and could at once recognise it. Here comes, then, the absurdity of explaining a philosopher by his sources—you only by that method catalogue the material by which he expressed himself. The important and central thing in a philosopher is a kind of intuition akin to that of the artist, and differing fundamentally from the kind of activity you get in science.

To get to the detailed work of the congress, particularly the work done in the various sections of logic, theory of science, esthetic, ethic, general philosophy, and psychology, one can only say that it was very abundant and very unequal, considerable so far as the magnitude of the subjects raised was concerned, and very little so far as actual results obtained go. This sterility was in great part due to the defective organisation of the congress and to the persistent keeping to the tradition of a free choice of subjects and free individual communication, with the result that there is never time to really discuss in a serious way the subjects raised. For this reason the most interesting work of the congress was done at the general meetings in the afternoon, and we refer here to the lectures which attracted the greatest attention.

The mathematician Henri Poincaré examined the question which has been raised by Boutroux and certain other philosophers as to whether the laws of nature may change. In a world which evolves continually are the laws, *i.e.* the rules under which this evolution takes place, alone exempt from all variation. Such a conception could never be adopted by the man of science without denying even the possibility of science, but the philosopher has the right to pose the question. Imagine a world in which there was no difference of temperature. Certain laws would be discovered by the inhabitants, such as, for example, that water boils at a certain fixed pressure. Suppose, now, that in course of time this uniform temperature changed, all the laws would now change; water would boil at a different temperature, and so on. Now, however perfect might be the conductivity for heat of this planet, it would doubtless not be absolute, so that one day a physicist of genius might with his delicate instruments detect these imperceptible differences. A theory might then be erected that these differences of temperature had an effect on physical phenomena, and, finally, some bold speculator might affirm that the mean temperature of the world had varied in the past, and with it all physical laws. May there not be some physical entity as yet as entirely unknown to us as was temperature to the inhabitants of this

imaginary world, which might vary and so create in the same way a change in all the laws?

Poincaré found something analogous to this, at any rate, in the ideas now being brought forward on the subject of mechanics, and which were later in the congress put forward by Prof. Langevin, whose name is known in connection with work in radio-activity. It is now asserted that the laws of mechanics, once considered absolute, are not so. They must be changed, or at least enlarged. They are only approximately true for the velocities to which we are accustomed, and cease to be so for velocities comparable to that of light. One might say that, as a result of the constant dissipation of energy, the speed of bodies has much diminished, since their activity gets transformed into heat. Thus remounting back to the past, one would find an epoch when velocities comparable to that of light were not uncommon, and when, as a consequence, the classical laws of dynamics were not true. But if, on the other hand, we consider these laws as only approximate laws, and consider the laws of motion of molecules as the true laws, we can keep our faith in the immutability of laws in general. There is not, then, a sole law that we can enunciate with the certainty that it has always been true in the past. Nevertheless, there is nothing to hinder the man of science from keeping his faith in the principle of immutability, since no law can descend to the level of a secondary law without being replaced by another law more general and more comprehensive.

Prof. Durkheim, the celebrated sociologist, examined the question of "judgments of value" and social ideals. How do they arise? They cannot be accounted for on utilitarian principles, for they are often in direct conflict, not only with individual, but even with collective utility. They assert values which go beyond the practical. Must we, then, assume that the ideal is of a different nature from the world of fact. By no means. The ideal values are created in periods of great excitement, such as, for instance, the Renaissance and the French Revolution, when life for a time turns aside from the merely useful. Whilst the intenser life of such periods must of necessity soon die down, the judgments of value and the ideals they create survive into the periods of greater tranquillity, and it is from this that the apparent contradiction between the ideal and world of fact is born.

Prof. Ostwald, the exponent of "energetics," put forward a curious hypothesis in his paper "La Volonté et sa base physique" on the connection between the second law of thermodynamics and the mental phenomena of will. He started from general considerations drawn from Comté's and his own classification of the sciences. The notion of the antecedent and more general sciences finds a regular and systematic application in the subsequent and more special ones, while at the same time these latter require, in addition, the use of new conceptions. There is, for example, a mathematic and a geometry of chemistry, but not a chemistry of mathematics or a biology of physics. He then examined in this light the conception of energy. It appears for the first time in the domain of the physical sciences, and for that reason, while it has no application in the more general sciences of mathematics and logic, it should play an auxiliary part in biology, psychology, and sociology. The laws of the lower sciences cannot adequately explain the phenomena dealt with by the higher, but they provide the framework inside which the latter must work. How does this work out in detail? What meaning have the laws of energy applied to mental life? Just this—that whatever else mental life is, it has to work inside the limits of the second law of thermodynamics. Each individual is occupied all its life with the task of making circulate through its own body a part of the general course of "free" energy on its way to energy of a lower intensity; and further, as only part of this energy can be usefully employed, the rest being wasted in heat, so whatever else mental life may be it must first be directed towards getting as much out of this dissipation as possible. In the effort to increase this percentage, to save energy, comes, in Ostwald's opinion, the whole phenomena of the will. He does not pretend that the second law is an adequate explanation of all mental process, but it is the conditioning framework inside which all the rest must work. It is the dominating fast of mental life. It is this which makes the tremendous importance of the will. All human activity is devoted to get the most out of this limited energy. (Incidentally, one may note the resemblance to Mach's conception of science as a process of economy of thought.) It is this conception of the "degradation of energy" which forms the basis of all the processes in which Schopenhauer saw manifestations of the fundamental will.

The English element at the congress was very small, being responsible for only eleven papers out of a total of 200. Among these the most important was Dr. Schiller's paper on error, which provoked, as any exposition of pragmatism always does at these meetings, a most lively discussion. There was also a paper by E. S. Russell on vitalism, and an interesting little note by Miss Constance Jones sketching out a new law of thought, which attempted to lead logic out of the barrenness of the law of identity, and which she enunciated in the phrase "Every subject of predication is an identity (of denotation) in diversity (of intension)."

The next congress will be held in London in 1915, under the auspices of the University, and it is hoped that this will create a greater interest in these meetings than has heretofore been the case in this country.

RESEARCH AT THE NATIONAL PHYSICAL LABORATORY.[1]

THE representative character of the work done at the National Physical Laboratory is well shown by the eight papers in the volume before us.

Nos. 1 and 2 are by Dr. Chree, and are entitled "Some Phenomena of Magnetic Disturbances at Kew" and "Discussion of Results Obtained at Kew Observatory with an Elster and Geitel Electrical Dissipation Apparatus from 1907–9."

No. 3 is the ninth report to the Alloys Research Committee of the Institution of Mechanical Engineers, on "The Properties of Some Alloys of Copper, Aluminium, and Manganese," by Messrs. Rosenhain and Lantsberry. This is a voluminous paper, and occupies more than half of the entire volume. It is the direct outcome of the eighth alloys research report on the properties of the alloys of copper and aluminium. The study of any ternary system of alloys is a work of considerable magnitude. As the authors remark (p. 65), "If we suppose for the sake of comparison that the study of alloys to the extent of one for every range of 2 per cent. in composition constitutes a sufficiently complete investigation of any system, then in any series of alloys of two metals, such as copper and aluminium, the study of some fifty alloys would meet these requirements, while the corresponding degree of completeness in the case of a ternary system would require the study of no less than 1250 alloys." Very few industrial alloys, however, belong, strictly speaking, to a binary system. The majority are ternary, or even more complicated mixtures, and it is therefore of great industrial importance as well as of scientific interest that the study of such systems as the above should be undertaken.

The authors have not attempted to cover the entire field, but have contented themselves with experimenting on the addition of manganese to the most promising binary mixtures revealed in the eighth alloys report, which are situated at the ends of the system.

At the copper end they have found that certain ternary alloys present advantages over the best binary alloys, these consisting chiefly in a "higher yield point . . . a slightly higher ultimate stress and an undiminished ductility," in the static tests. A hot-rolled bar of a bronze containing approximately 10 per cent. of aluminium and 1 per cent. of manganese gave an ultimate stress of 42 tons per square inch with 30 per cent. elongation. In the dynamic tests, however, there is very little to choose between the binary and ternary systems. Three alloys were found to offer remarkable resistance to abrasion, and in this respect considerably surpassed ordinary tool steel, and as they machine quite readily they might very well be tried in cases where this property is of primary importance, e.g. in the form of turbine blades which have to withstand high velocity steam. As regards constitution, the authors have found that

[1] The National Physical Laboratory: Collected Researches, Vol. VII. 1911, pp. iii + 228.

"within the limits of the alloys studied, the constitution of the ternary alloys very closely resembles that of the binary alloys of aluminium and copper; manganese influences the properties of the alloys in a manner somewhat similar to that of aluminium, but at a different rate."

At the aluminium end the results have been less favourable. The most promising alloy appears to be one with 3 per cent. of copper and 1 per cent. of manganese, which in the form of a chill casting gave a tensile strength of 12 tons per square inch and an elongation of 13·5 per cent. on 2 inches. In the form of rolled bars, however, the authors say, "there does not appear to be any advantage in using the ternary alloys as compared with the alloys of aluminium with copper alone."

The remaining papers are as follows:—

(4) "Report on the Progress of the National Experimental Tank," by Dr. R. T. Glazebrook.

(5) "On the use of Mutual Inductometers," by A. Campbell.

(6) "Comparative Life Tests on Glow Lamps," by C. C. Paterson and E. H. Rayner.

(7) "On a Method of Counting the Rulings of a Diffraction Grating," by G. W. Kaye.

(8) "The Expansion and Thermal Hysteresis of Fused Silica," by G. W. Kaye.

In view of the extensive application of fused silica or quartz glass to physical and chemical operations, the last-named paper is of considerable interest. A curve is given from which the mean coefficient of expansion over any desired range between $-190°$ C. and $1100°$ C. may be derived. From this curve it appears that two change-points exist, one at $-80°$ C., the other at about $1000°$ C. As regards linear hysteresis, the author concludes, "Silica over a range of $0°$ C. to $400°$ C. has nothing to fear in comparison with either Invar or Jena thermometry glasses. . . . There is practically nothing to choose between the different kinds of fused silica." A silica standard metre is being completed at the laboratory.

H. C. H. C.

SPECIALISATION IN UNIVERSITY EDUCATION.

THE March issue of *The Johns Hopkins University Circular* contains an account of the celebrations in connection with the Commemoration Day of the University held on February 22. Dr. James Bryce, the British Ambassador to the United States, was the principal speaker, and in his address discussed the tendency to over-specialisation in university education. Mr. R. Brent Keyser, the president of the Board of Trustees, read a statement of the plans for the development of the new site for the University. Nine years ago, he said, at the time of the raising of the Million Dollar Endowment Fund of 1902, the University received also the gift of the Homewood property. This property, under the deed of gift, is to become the permanent home of the University when, in the judgment of the Board of Trustees, the interest and welfare of the University permit. A plan for development has been provided which will admit of growth and alteration to suit the changing needs of future years. To-day we have been given, he continued, means to accept the offer of 50,000*l*. from the General Education Board, and the total amount pledged, part of it already paid in, amounts to nearly 240,000*l*. With great wisdom, the General Education Board, the aim of which is to help the cause of education of the whole country, has provided that at least 100,000*l*. of this amount shall be retained as a permanent endowment, the income only to be used, so that the institution might not be crippled in its real work by the expenditures incident to large building operations, and by the greatly increased expense which will come from living in such an enlarged environment.

Mr. B. H. Griswold, jun., chairman of the committee on the endowment and extension fund of 1910, said 1500 gifts, ranging from one dollar to 20,000*l*., totalling nearly 240,000*l*., and substantially every dollar of it from Maryland, with the exception of the gift of the General Education Board and contributions of non-resident alumni, had been secured. Apart from the original gift of the founder and apart from all legacies, the citizens of Maryland and the alumni of the University, before the last appeal was made and answered, had bestowed, by direct gift, upon the University since its foundation more than 600,000*l*. The exact amount contributed to date to the 1910 Endowment and Extension Fund is 238,635*l*. Of this sum, 50,000*l*. was given by the General Education Board, 48,000*l*. by the trustees of the University, 60,000*l*. was subscribed by the alumni, and the balance of more than 80,000*l*. was given by those to whom we have given the simple but honourable degree of "Friends of the University." A few special gifts may be mentioned: there is one of 4000*l*. to the department of romance languages, one of 2000*l*. for the Edmund Law Rogers fellowship, and 2000*l*. for the Hutzler library.

Mr. Bryce's address applies equally to British as to American universities, and it is here reprinted in an abridged form.

A remarkable feature of the thirty-five years over which we look back is the wonderful development of the various departments of human knowledge, and especially those which are concerned with the sciences of nature, into special branches, each of which has been tending to become more distinct from the others. So far from finding ourselves approaching the end of human knowledge, we find that the more we know the more remains beyond to be known, and that the realm of the unknown seems to be always increasing with every addition to our knowledge. It is as though the path which we are following were always diverging into a number of different paths which tend to separate from one another, and lead us into untrodden solitudes to which we see no end. Within the recollection of most of us, new branches of science have made good their place, and have become recognised as separate fields of inquiry, and along with this it has befallen that the great majority of scientific inquirers now, so soon as their general scientific education has been completed, begin to devote themselves to one particular branch of investigation and throw their whole energy into pushing it forward. A man is now not a "natural philosopher" in the old sense of the term, but belongs to some one of the specific branches into which natural philosophy has become divided. The same thing has happened in those practical arts which depend upon the application of science. They, too, have multiplied by division, and thus new practical professions have grown up, which were scarcely thought of forty years ago.

The same thing has of necessity happened in university education. We have now in all organised universities professors of a large number of distinct branches of knowledge, which were formerly lumped together as being one branch under one professor.

So also among the students the tendency is for those who have advanced some way to begin to devote themselves to one particular line of study and investigation. Both the teacher and the student are naturally fascinated by the prospect of discovery. The professor likes best to lecture upon the subject in which he is pushing forward his own investigations, and the student is able to find in them the most attractive field of experimental research.

This sort of specialisation has become inevitable, but there is a consequence attached to it which has seemed almost equally inevitable, namely, that part of the time which was previously given to general study, to a knowledge both of natural science in general and of other subjects, has now had to be devoted to this special study. The field of nature is unlimited. Human curiosity is unlimited. But human life and the capacity for using our time and our powers in the acquisition of knowledge remain within very narrow bounds.

Accordingly, the problem which to-day confronts us in all universities is how to find time both for these specialised studies, which have become so much more absorbing, and also for a survey and comprehension of the general field of human knowledge which is necessary in order to make the university graduate a truly educated and cultivated man, capable of seeing the relations of his own particular study to others and of appreciating the various methods by which discovery is prosecuted. This problem of reconciling special with general study, although most urgent in the sciences of nature, shows itself in what may be called the human subjects also.

However, the difficulty I am referring to arises chiefly

in the sciences of nature. These are now tending to overshadow all other studies, partly perhaps because the practical applications to which they are turned have become very numerous and of immense industrial importance for men and nations, and partly also because we are all fascinated by the progress of discovery, and are so eager to attain certitude that we are disposed to turn from those inquiries in which complete certitude is unattainable to those in which we can find an absolutely firm basis in the laws of nature; and it is in the natural sciences that the subdivision and specialisation of which I have been speaking has gone furthest.

Accordingly, the problem to which I have referred has two aspects. It raises the question of a mastery of the principles of the sciences of nature in general as against a highly specialised study of some one department in those sciences. It also raises the question of the respective claims of the study of physical science, or some branch of it, as against the claims of what may be called the human sciences, or, if you prefer it, human subjects.

What do we mean by general intellectual cultivation as opposed to special knowledge? Without attempting a complete definition—nothing is more dangerous than a definition—I will suggest a description. We mean such a knowledge of the main facts and distinctive methods of various branches of human knowledge as give a general idea of the relations of each branch to other branches, that is to say, of what truth and certitude mean in different departments of study, and what are the various paths by which truth may be reached or approached. If you asked me to indicate what this would include, I should make some such answer as this. In the sphere of natural science, it would include a knowledge, not necessarily wide, but sound and exact so far as it went, of some deductive science such as geometry, and of some science of observation such as a branch of natural history, geology, for instance, or some department of biology, or of such a science as chemistry. On the human side, it would include a knowledge of one of what may be called the abstract subjects, such as psychology or logic or ethics, and of one of the observational subjects such as economics or politics. It would include a knowledge of the principles of language, and of at least one foreign tongue, ancient or modern, preferably an inflected tongue; and, finally, it must include the record of human effort and development through the past, that is, history, which shows us how man has grown from what he was in the past to be what he is in the present, and holds out hopes of what he may be in the future. Without at least an elementary knowledge of these, no man is properly equipped for a life of study and thought, or for those branches of practical life which require a wide intellectual outlook. It is not necessary to-day, as it would have been fifty years ago, to argue that every educated man should have some knowledge of deductive science and of the observational and experimental sciences of nature.

Specialisation is not only inevitable for the progress of discovery, but in many minor ways excellent. It is a splendid thing for a great university like this to have among its professors men, each of whom is abreast of the highest development of some particular line of inquiry and knows how that line of inquiry ought to be prosecuted, so that it holds within its own walls, so to speak, an accumulated mass of various knowledge, representing what the world has yet attained. The scientific specialist makes interesting company—when I have a chance I always try to get beside him at dinner—because he is able to tell us what we seek to know of the progress of discovery in the growing sciences, and we have only to ask him to get at once, without the labour of consulting books, the latest results in the clearest form. The scientific investigator, moreover, seems to have, on the whole, the happiest kind of life that is now possible. Does he know how happy he is? Engaged in the discovery of truth, he has for his helpers all others engaged in the same pursuit, and knows that all his labours are working towards a noble and useful end. He is free from the vexations that beset the business man or the lawyer or the politician. If he has not a happy life, granted good health, it is probably his own fault, for what is finer than to be, as Bacon says, *minister et interpres naturae*?

Admitting all this, and much more that might be said on behalf of specialisation, it is nevertheless right to present to you some dangers that seem to arise from the immense extension of the specialising tendency and from the predominance, in particular, of the study of the natural sciences to the exclusion of other subjects. The phenomena of nature may no doubt be slowly changing, and as we know that even among those bodies which we call the fixed stars the positions of the stars towards one another alter, so oxygen and hydrogen may be different now from what they once were, and the proportion of the elements in the compound bodies may alter. The sciences of nature are occupied with that which is permanent and unchangeable. They deal with those laws which we believe, so far as our knowledge goes, to be immutable, to have been operative in the past, and likely to be operative in the future, as they are operative now. He who is entirely occupied in studying these unchanging laws does not learn thereby how to deal with that which is mutable and transient. But the mutable and the transient include, not only most of what concerns our daily life, but the whole immense field of knowledge which covers the human subjects. The realm of ideas, beliefs, theories, feelings, institutions, habits, in fact the whole realm of human thought and conduct, belongs to the sphere of the transitory and changeable. In investigating this realm, we have to walk by methods which are not only not the same, but are even more difficult than those which belong to the sciences of nature. The investigation of probability is more perplexing and less satisfying than those inquiries at the end of which stands certain and immutable truth. Those who try to apply the same formulæ and methods to the human subjects which they apply to nature are in danger of failing, as Herbert Spencer, for instance, failed when he entered the field of history and that of political or social phenomena.

Sixty years ago people complained, and complained justly, of the narrowness of those, even of some eminent men, who had been trained entirely on the old scheme of education, which largely consisted in grammatical studies, and especially in a knowledge of the ancient languages. Men otherwise highly gifted and instructed who had been so trained often failed to appreciate the interest and value of the study of nature, and showed a strange incapacity to understand its methods. Francis Bacon has warned us against that absorption in a particular set of ideas, that prepossession in favour of one particular view which he classes among the *Idola Specus*, the phantasms of the cave which surround the man who sits in the dark recess of his own line of thought unillumined by the light of the broad sky. So now the devotion to any special study, whether in the sphere of natural science or not, tends to narrow the mind and prevents the faculties from attaining their highest development. Many of the greatest discoveries have arisen from bringing together facts and ideas drawn from different regions the relations of which had not previously been discerned. The more you extend the range of knowledge, the more you increase the chances of such discoveries. Most of the great men to whom the progress of science is due were not trained as specialists, but had minds that ranged far and wide over the field of knowledge.

Someone has said that the chief end of education is to stimulate curiosity, to make a man ask about all things familiar or unfamiliar, the how and the why, to discover matter for inquiry in things which other people have passed over without thinking of the problems they suggest, to retain that activity and versatility and freshness which are the most characteristic marks of a forceful and creative intellect. Is it not wonderful how many things were overlooked in the past which now we feel to need investigation, and may there not be things now that ought to be investigated which we are passing over as familiar? The ancients must have noticed the difference in the aspect and structure of different kinds of rock, for instance. The differences between gneiss and limestone, between basalt and slate, stared them in the face. They saw fossil shells in the strata. But it did not occur to them to seek the explanation of these things, and geological science is not yet two centuries old. The wider the range of a man's interests, the more susceptible he is to ideas of many

kinds, the greater is the pleasure which life can afford him, the better can he contribute to the progress of the world both by stimulating others and by himself pointing out the way in which advances can be made. A university has to think, not only of forming specialists, but of making these specialists better by giving them a wide range of knowledge, and still more of sending out men who sustain the level of taste and insight in the whole community and are fit to be its intellectual leaders.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—A public meeting under the auspices of the University Eugenics Society will be held in the new lecture-room, Emmanuel College, by permission of the master and fellows of the college, on Monday, May 22, at 8.30 p.m. The Rev. Prof. Inge, D.D., Dean Designate of St. Paul's, will give an address on "Some Social and Religious Aspects of Eugenics."

OXFORD.—The preamble of the Statute exempting students in natural science and mathematics from examination in Greek passed Congregation on May 16 by 156 to 79.

LONDON.—Presentation Day was on Wednesday, May 10. The Chancellor (Lord Rosebery) presided, and an unusually large number of graduates were presented. A precedent was established this year by the presentation of cadets of the Officers' Training Corps who had gained War Office certificates or proceeded to commissions in the Army. The principal's report showed that the total admissions to the University in 1910–11 were 4255, compared with 4053 in the previous year; internal students, 4350, compared with 4185; and total candidates in examinations leading to degrees or diplomas, 12,681, compared with 12,787. The number of degrees or diplomas granted was 1222. Reference was made to extension of university professoriate, following the appointment of a large number of board of advisors. Among individual benefactions during the year, the most important were those of Sir Francis Galton for eugenics (40,000*l.*), Mr. Henry Dixon for scientific investigations (8000*l.*), Dr. Charles Graham for medical and pathological research (33,500*l.*), and Sir Felix Semon for laryngology (1040*l.*). The report also referred to the notable development of student activities—military, athletic, and social. Lord Rosebery, in a short address, appealed for more adequate accommodation for the central premises of the University and for increased financial support from the authorities and city companies.

IT has been decided by the council of Armstrong College, Newcastle-upon-Tyne, to establish a professorship of philosophy at the college, and to appoint an additional demonstrator in physics.

The Lancet announces the appointment, by the Lord President of the Privy Council, of Sir Donald MacAlister, K.C.B., principal of Glasgow University, as his representative on the International Committee for Postgraduate Medical Instruction.

THREE scholarships in naval architecture have been instituted at the University of Liverpool by the General Committee of Lloyd's Register of Shipping. Each scholarship is of the value of 50*l.* a year for three years, and one will be vacant annually. The first election will take place this year.

Two cases of importance to persons taking part in competitive examinations were settled at the Bow Street Police Court on Saturday last. The defendants were tutors at a coaching establishment, and therefore debarred from taking part in the examinations of the Royal Society of Arts. Notwithstanding their ineligibility, they duly competed under assumed names and gained prizes. The Royal Society of Arts, being anxious that their examinations should be inviolate, and to make it clear to all that people are not allowed either by the rules of the society or the law to compete in examinations in a way which is detrimental to other candidates, took action in the matter, and they are to be congratulated on the result, the defendants being found guilty and punished.

ACCORDING to *Science*, at its recent session the legislature of Kansas voted approximately 200,000*l.* for the State Agricultural College at Manhattan for the next biennium. The funds provide for one wing of an agricultural building, with a detached laboratory for the cutting and curing of meats. The first wing of the new building is to cost 25,000*l.* Two more wings are to be added as the money is voted, each complete in itself. The legislature also provided a special fund for various objects, including money for experiments in the western part of the State in cooperation with the Federal Government; for soil surveys, also in cooperation with the United States Government; for experiments in producing improved wheat, corn, and other crops. The college has this year approximately 2500 students, more, it is said, than are enrolled in any similar institution in the world. The cost per student in this institution in 1910 was 21*l.*

WE learn from *The Belfast News-Letter* that the Library and Technical Instruction Committee of Belfast contemplate making a collection of kinematograph films of educational value for public exhibition in that city. Mr. F. C. Forth, the principal of the Technical Institute, a week or two ago gave a very successful introductory demonstration of the advantages of the kinematograph for teaching the character of various operations and movements that students may perhaps never be able to see for themselves, and which are but poorly represented by the simple lantern-slide. Among the films shown there were illustrated metallurgical works, a visit to Niagara Falls, cheese mites, a fresh-water hydra, rotifers, the circulation of protoplasm in the water weed, the circulation of blood in a frog's foot, chameleons feeding, toads fighting, and the development of a flower.

ON July 14 the King will open the new buildings of the University College of North Wales, which have been completed at a cost of about 112,000*l.*, exclusive of the site, which was presented by the citizens of Bangor. Of the total cost, rather under 10,000*l.* remains still to be collected, and the sums already received include 16,800*l.* from Carnarvonshire, 18,350*l.* from London, 1350*l.* from the staff, and 3500*l.* from old students. The quadrangle of buildings, which is flanked on three sides by the classrooms and offices, has been completed on the fourth side by the Great Hall specially presented by Sir Pritchard Jones. The removal of the arts classes to the new buildings has given increased accommodation to the science departments, and among the gainers the agricultural and forestry departments may be noted. That theory and practice are not always inconsistent is evidenced by the large number of prizes secured by the former department at agricultural shows.

THE council of the Institution of Civil Engineers has made arrangements to hold a conference on the subject of the education and training of engineers on June 28 and 29 at the institution. The subject-matter to be discussed at the conference will be dealt with in three groups, namely, general education, scientific training, and practical training. Among other topics which will receive consideration at the meetings may be mentioned:—the extent to which mathematical and scientific subjects should share with other subjects of literate education the attention of schoolboys who intend to enter later the engineering profession; the question of specialised entrance examinations for university and college courses of study in engineering science with a view to the curricula to be followed, and also of the inclusion in the latter of courses in modern languages; the relation of practical training to college study—whether, or to what extent, before, sandwiched, or after its conclusion; the position and uses of engineering laboratories in relation to education at college; the value of a university degree in engineering science in relation to professional competence; the requirements of practical training in works, with the necessary complement of scientific study; practical training in workshops or on works of construction, with special reference to training in the engineer's office; the relation of engineering employers and colleges from the point of view of the practical training of college students; workshop training as a preliminary to practical training in other branches of engineering.

A COMPLIMENTARY banquet to Prof. H. E. Armstrong, F.R.S., took place at the Hotel Cecil on Saturday, May 13. Although intended, in the first instance, to take the form of a demonstration of affectionate regard on the part of his old students, it was soon found necessary to extend the scope of the celebration, which thus became the occasion for one of the largest scientific gatherings of recent years. The toast of the guest of the evening was proposed by the chairman, Prof. W. J. Pope, F.R.S., and was seconded by Mr. Maurice Solomon. The guests included Sir William Crookes, Sir James Dewar, Sir Chas. Lawes, Profs. H. B. Baker, A. Brown, Clowes, Crossley, Divers, Henderson, Kipping, and Wynne, Messrs. W. Barlow, G. T. Beilby, H. T. Brown, Cross, Hall, R. Messel, R. L. Mond, F. B. Power, and J. E. Stead amongst the chemists; engineering was represented by Profs. Perry, Dalby, Mather, and Sumpner; education by Principal Miers, Mr. R. Blair, Dr. J. H. Cowham, Prof. R. A. Gregory, Mr. A. L. Soper, and Mr. C. M. Stuart; law by Mr. W. Phipson Beale, K.C.; and literature by Prof. M. A. Gerothwohl. On two occasions the Chemical Society has met in order to celebrate the jubilee of five of its past presidents, but we believe that only one similar gathering has previously been organised by a group of chemical students in honour of their professor. The success of the enterprise was most gratifying; "Central" students of every year, from the date of the opening of the college to the present day, united with chemists and others from all over the country, to the number of 230, in honouring one whose influence has been felt and valued by an exceptionally wide circle of admirers and friends.

THE following regulations with reference to the newly founded prize in memory of Lord Kelvin have just been issued by the University of Glasgow:—(1) The prize shall consist of a gold medal of the value of 10*l.*, together with the balance of the income of the capital fund accumulated during three years. (2) The adjudicators shall be the principal, the professor of natural philosophy, and the professor of mathematics. (3) The prize shall be awarded by the Senatus, on the recommendation of the adjudicators, at intervals of three years (the first period beginning with 1911) to the author of a thesis or published work in natural philosophy, including therein mathematical and experimental physics, which has been submitted and approved for the degree of Doctor of Science during the period, and which gives evidence of original research worthy in the opinion of the adjudicators of this special distinction. (4) In making their recommendation, the adjudicators shall have regard to the written reports presented to the faculty of science by the examiners and additional examiners appointed under Section X. of University Court Ordinance No. XXVI. (5) Not more than one award shall be made in each period of three years, and the prize shall not be divided. The adjudicators may, if they think fit, recommend that for a particular period of three years no award be made, and, in that case, the income of the prize shall be added to the capital fund. (6) The Kelvin prize and the William Jack prize shall not be awarded to the same person. (7) After the year 1920 the regulations may from time to time be modified by the Senatus, with the approval of the University Court, provided always that the prize shall continue to be awarded to graduates of the University for special distinction in original research relating to mathematical and experimental physics.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 11.—Sir Archibald Geikie, K.C.B. president, in the chair.—C. T. R. **Wilson**: A method of making visible the paths of ionising particles through a gas. The paths are made visible by condensing water upon the ions immediately after their liberation, an expansion apparatus being used which works without appreciable stirring up of the air. The trails of ions formed by the α particles from radium have in this way been made visible and photographed, very dense and sharply defined rays of cloud being formed on expansion. Air exposed to β rays gives clouds consisting mainly of faint straight threads radiating from the source; these have not yet been photographed. In air exposed to γ rays, the cloud is again in the form of straight threads traversing the cloud chamber—the tracks of β particles from the walls. The cloud formed in air exposed to Röntgen rays is entirely concentrated in minute streaks and patches. A photograph shows these to consist mainly of fine threads not exceeding a few mm. in length, and generally far from straight, probably the tracks of kathode rays produced in the air by the X-rays. The whole of the ionisation would appear, as Bragg has already suggested, to be effected by the kathode rays derived from the X-rays.—W. H. **Dines**: The vertical temperature distribution in the atmosphere over England, and some remarks on the general and local circulation. This paper gives an account of the results of some 200 observations made in the British Isles in the years 1908, 1909, and 1910 on the temperature of the upper air. It discusses the annual variation of the temperature up to 14 kilometres, and shows that the annual range remains fairly steady, with a total amplitude of about 12° C. up to 11 km., above which the range suddenly drops to 3°, and the times of the maxima and minima go back two months. The question of the daily variation at great heights is then discussed. The relation between the temperature at various heights and the height of the barometer at the surface is dealt with, and it is shown how over a low-pressure area with the barometer below 740 mm. the temperature of the first 8 km. is very low, reaching at 7 km. a value of nearly 10° C. below its average value, and that above 10 km. it is considerably above the average. In the anti-cyclonic parts the conditions are reversed, and it is warm below and cold above. The height at which the isothermal region is met with in summer and winter and in times of high and low barometer is then referred to. A statement with regard to the existence of similar conditions that have been found to exist on the Continent is also given. In the second part of the paper various theoretical considerations are taken into account. It is shown that if an extensive and strong wind exists in any part of the atmosphere, warm air will be found somewhat below it on its right hand, and cold air above it on the right, with converse conditions on the left, and it is pointed out that this agrees with the distribution of temperature that is found to exist at the various levels of cyclones and anticyclones.—Prof. W. N. **Hartley**: Some mineral constituents of a dusty atmosphere.—Dr. H. Stanley **Allen**: The path of an electron in combined radial magnetic and electric fields. The path of an electron in a radial electric field superposed on a radial magnetic field is found to lie on a circular cone the vertex of which coincides with the magnetic pole. If the surface of the cone is developed into a plane, the trace of the path is a conic section with the vertex as focus. The solution in the particular case in which there is no electric field has been given by Poincaré; the path is then a geodesic line on the surface of the cone, and, of course, becomes a straight line when the cone is developed. In cases which can be realised experimentally, the developed path is hyperbolic, and does not in general differ greatly from a straight line. An account is given of some experiments carried out to illustrate the theory. The first observations were made with a focus tube in which the antikathode was the pole of an electromagnet. The phenomena observed are easily explained in terms of the theory. Other vacuum tubes were prepared in which a fine pencil of kathode rays could be produced by means of a Wehnelt kathode. In a radial magnetic field the stream of electrons assumed a spiral form, and a number of photographs were obtained showing the spiral paths on a cone of revolution.—Dr. R. A. **Houstoun**: The absolute measurement of light—a proposal for an ultimate light standard. A thermopile cannot be used for the measurement of candle-power, because it gives the same value to the energy of every wave-length, invisible as well as visible. The author has, however, found by spectrophotometric investigation in the ultra-violet, visible, and infra-red parts of the spectrum that if a filter consisting of aqueous solutions of copper sulphate and potassium bichromate in a particular strength in glass cells be placed before the thermopile, then this filter stops the ultra-violet and infra-red entirely, and lets through a fraction of each wave-length in the visible spectrum pro-

portional to its visibility. In other words, it weights each radiation according to its visibility. The voltage on a tantalum lamp was varied over a wide range, and its candle-power as read by thermopile and filters agreed well with the readings of a photometer. Owing to the high sensitiveness of the galvanometer required, the method is not suitable for commercial application, except perhaps for integration photometry, when a number of thermopiles might be connected in series with the one galvanometer. The importance of the method lies in the fact that it provides a satisfactory basis for heterochromatic photometry independent of the Purkinje phenomenon at all intensities. The author therefore proposes to use it for defining the unit of light intensity. He would define the latter as that source, the total intensity of radiation from which at a distance of 1 metre after passing through his filters would be x ergs/sq. cm., sec. For the standard candle x should be about 0·8.—Prof. A. C. **Dixon**: Harmonic expansions.

Royal Microscopical Society, April 19.—Mr. H. G. Plimmer, F.R.S., in the chair.—E. J. **Spitta**: Low-power photomicrography, with special reference to colouring methods.—E. J. **Spitta**: Report on Grayson's rulings.—E. J. **Shepherd**: The reappearance of the nucleolus in mitosis. This was an addendum to the author's previous paper, communicated in April, 1909, on the disappearance of the nucleolus in mitosis. In the present communication the author said that with a view to ascertain how and when the nucleolus makes its reappearance, the diaster stage is the one which calls for most careful study and observation. At or about the time of the formation of the dispirem, and before the diasters have lost their characteristic shape, a looping in the chromatin is observed, the number of loops varying in each daughter nucleus. It is in these loops that the nucleoli will appear, but it must not be inferred that a nucleolus will appear in each loop, as there are frequently more loops than nucleoli. The latter make their appearance when the division of the cell is well marked, and when the interzonal fibres have generally disappeared. From the results of his research, the author was of opinion that the nucleolus is a product of the chromatin injected into the loops by a process which can best be described as a "streaming in" process. A full account of the technique of staining and methods adopted, &c., which have led to the above conclusion, will be found in The Journal of the Royal Microscopical Society.—J. **Murray**: Second portion of a report from the Shackleton Antarctic Expedition of 1909 on the Canadian rotifera. Forty-two species (all bedlloids) were collected among mosses. They included five new species, *Callidina asperula*, *C. canadensis*, *Mniobia obtusicornis*, *M. montium*, and *Harbrotrocha maculata*. There were also a number of peculiar varieties of other species. *Callidina asperula* has since been found in Ireland by the Clare Island Survey. Twenty-seven bedlloids were previously recorded for the United States. Six of these occurred in their collections, so that the number of bedlloids now known in North America stands at sixty-three species, but a number of these were of doubtful value. Among the rarer Canadian species were *Philodina australis* (Australia and Canada), *Callidina speciosa* (British Guiana and Canada), *C. zickendrahti* (Russia and Canada).—Señor Domingo **de Oureta**: A new piece of apparatus for photomicrography, with the microscope in the inclined position.

Geological Society, April 26.—Prof. W. W. Watts, F.R.S., vice-president, in the chair.—A. **Wade**: The Llandovery and associated rocks of north-eastern Montgomeryshire. The area dealt with is near Welshpool, and comprises part of the Severn Valley and the whole of the Vale of Guilsfield. In the succession worked out, the Ashgillian and the Valentian are distinguished for the first time, while the distinction between the Wenlock and the Ludlow beds is brought out by means of graptolite zones. The stratigraphical succession is shown by traverses. The district is shown to be transitional in character between neighbouring districts on almost every side. The structure of the area is that of an anticline with "keystone" faulting. The two boundary-faults of the arch have considerable downthrows. An account is given of the Welshpool Dyke. The glacial geology of the area is described, three series of deposits being observed:—(1) a high-level series; (2) a low-level series; and (3) a stratified series. The Guilsfield Valley is shown to have been occupied by a glacial lake, and the reversed drainage of the Cefn-Yspn Brook is shown to be connected with a "col" through which the overflow water drained.—Dr. J. D. **Falconer**: Geology of northern Nigeria. The protectorate covers an area of about 255,000 square miles, over half of which crystalline rocks are exposed at the surface. Hard, banded gneisses of an Archæan type are intermingled with quartzites, phyllites, schists, and gneisses of sedimentary origin, so as to suggest that the two series, while originally unconformable, have been later affected by a common folding and foliation along axes predominantly meridional in direction. The two series have also been pierced by igneous intrusions of a granitic type. Folded and faulted rocks of Cretaceous age are found. These Cretaceous rocks are overlain unconformably by a horizontal series of sandstones, grits, conglomerates, and ironstones, which in Sokoto province contains intercalations of Middle Eocene limestone. Volcanic activity occurred during Tertiary times, and gave rise to fields of basaltic lava in Bauchi and Bornu, as also to numerous puys of trachyte, phonolite, olivine-basalt, and nepheline-basalt throughout southern Bauchi, Muri, and Yola. Repeated minor oscillations during the latter part of the Tertiary era culminated in the elevation of the Bauchi plateau, the depression of the Chad area, and the establishment of the present river-system.

PARIS.

Academy of Sciences, May 1.—M. Armand Gautier in the chair.—B. **Baillaud**: Remarks on the "Annales de l'Observatoire de Paris" containing the observations made in 1892.—P. **Villard** and H. **Abraham**: A direct-reading electrostatic voltmeter for very high potentials. A simplified voltmeter capable of giving accurate readings up to potentials of 300,000 volts.—E. L. **Bouvier**: The Pycnogonides of the *Pourquoi Pas?* This group is well represented in the Antarctic regions, more species being found there than in the Arctic regions.—M. **Jarry-Desloges**: *Résumé* of the physical observations of the planet Mars made in the opposition 1909–10, with remarks on the quality of the telescopic images in various regions. The appearance and disappearance of the white polar cap corresponds with a fixed Martian date. No regularity, however, can be traced as regards the changes in form and shade of the dark spots, which, especially in the equatorial regions, do not appear to be related to the seasons. No evidence could be obtained of the existence of a liquid state resulting from the disappearance of the white polar substance.—Jules **Drach**: Determination of the lines of curvature of the Fresnel wave surface.—J. **Hadamard**: The fundamental solution of partial differential equations of the parabolic type.—L. **Godeaux**: Linear congruences of conics.—MM. **Claude**, **Ferrié**, and **Driencourt**: Radio-telegraphic comparisons of chronometers by the method of coincidences between Paris and Bizerta. It has been definitely established by these experiments that radio-telegraphic comparisons by the method of coincidences are capable of giving the difference of time between two chronometers 1000 miles apart, and with an accuracy of at least 0·01 sec.—C. **Raveau**: Interference fringes from a linear source of light.—M. **Estanave**: Photographs with changing colours. A description of a method of obtaining a photograph the colours of which change according to the angle of observation.—M. **Aubert**: Thermo-diffusion.—Walter **König**: The displacement of ultramicroscopic particles produced by very rapid sound shocks. A theoretical explanation of some experimental results recently described by MM. Henri and Lifschitz.—M. **Pomey**: The propagation on a telegraph line of the current due to a constant electromotive force.—Jean **Perrin**: The determinations of molecular magnitudes. A criticism of several methods based on Stokes's law. For the charge of the electron, the value $4·24 \times 10^{-10}$ is regarded as more probable than the usually accepted $4·8 \times 10^{-10}$.—Jules **Roux**: The charge of the electron. Determinations on sulphur particles lead to the value $4·17 \times 10^{-10}$.—A. **Blanc**: The ionisation produced by phosphorus.—Georges **Moreau**: The ionisation of salt vapours by a corpuscular radiation.—F. **Leprince-Ringuet**: Study

of the state of insulation of an alternating network by means of voltmeters interposed between a pole and the earth.—Jacques **Duclaux**: The application of the kinetic theory to the study of the phenomena of catalysis.—Œchsner **de Coninck**: Determination of the molecular weight of uranyl, UrO_2. The reduction of H_2UrO_4 by pure hydrogen at a red heat led to a molecular weight of 270·66 for UrO_2, as against 270·5 deduced from the atomic weight 238·5 for uranium.—H. **Henriot** and M. **Bouyssy**: A method for measuring the impurities in a confined atmosphere. Metallic vessels containing a freezing mixture of ice and salt were suspended in the room, the ice being melted and weighed. The amount of reduction of a solution of potassium permanganate and chromic acid was determined, and this taken as a measure of the impurity of the atmosphere.—MM. **Taurel** and **Griffet**: The determination of the proportion of combined sulphur in a mixture of different forms of sulphur.—Frédéric **Aronssohn**: The mineral composition of the bee. Fifteen elements were determinable in the ash, including arsenic, copper, manganese, and zinc.—Jean **Pougnet**: The action of the ultra-violet rays upon the green pods of vanilla. Ultra-violet light produces the odour of vanilla in fresh green pods; manganese salts accelerate this action.—Lucien **Daniel**: Biometrical researches on a graft hybrid between the pear and quince trees. After six years' cultivation, no flowers have been produced on this hybrid. A study of the leaf dentition shows the influence exerted by the subject on the graft.—A. **Marie** and Léon **MacAuliffe**: The height and general morphology of French women.—MM. **Landsteiner, Levaditi,** and **Prasek**: Attempts to transmit scarlatina to the chimpanzee.—C. **Vaney** and G. **Tainturier**: The degenerescence of some larval forms of *Hypoderma bovis*.—Carl **Störmer**: The results of photogrammetric measurements of the altitude of the aurora borealis at Bosekop during February and March, 1910.

MELBOURNE.

Royal Society of Victoria, March 9.—Prof. E. W. Skeats, in the chair.—J. **Mann**: Papuan timbers, some of the properties of six species. These, known as Ulabo, Tamanau, Alaga, Madave, Kokoilo, and Ilimo, are now being exported. Mechanical tests for strength, and for calorific value, charcoal, and ash were made, and the results are tabulated. Ulabo, which is a dark heavy wood, is of engineering value and white-ant proof, while the others are useful for general joinery and, being well coloured and figured, for cabinet work.

MENDELISM AND BIOLOGY.

Mendel's Principles of Heredity. By W. Bateson, F.R.S. Pp. xiv+396. (Cambridge: University Press, 1909.) Price 12*s.* net.

THE time has come when a preliminary attempt may be made to forecast the position which Mendel's discovery will occupy in the history of biology, and when the widely divergent attitudes which have been taken up towards Mendelian principles may be profitably considered.

The reviewer is in the present case relieved of the duty, which usually falls to his lot, of indicating the nature, scope, and value of the contents of the book before him; for, whether we agree with Mr. Bateson or not, sceptics and adherents alike consider that his book is the fullest and most authoritative exposition of the results which have been achieved by those who have worked on the lines laid down by Mendel. These results may throw no light on the nature of heredity or on any problem which it has pleased the imagination of biologists to invent; but, be this as it may, the book before us is the source from which the fullest and most trustworthy information in regard to these results is to be sought, and no attention need be paid to the criticisms of those who are not intimate with its contents. Whatever the Mendelian doctrine is, here it is, for better or for worse.

To estimate the significance of this book we must, therefore, assign this doctrine to a place in the scheme of biology. The degree of success which will attend the efforts of any given person to perform this task will be inversely proportional to the faculty possessed bv him of imagining that he may be mistaken. If he lacks this faculty altogether, complete success, so far as he is concerned, is assured, and the Mendelian hypotheses will either be set down as the correct picture, drawn now finally, once and for all, of the hereditary processes underlying the phenomena which they were invented to explain, or as the fantastic imaginings of unfortunate biologists who are unwilling or unable to take the whole of the available evidence into account. To us, who foster and preserve some of the attributes of childhood, these two extreme views appear no more than naïve and elementary, the utterances of men who, in the current phrase, "know their own minds." We cannot believe that in every department of the Mendelian hypothesis the explanation offered does more than approximate to that picture of the underlying processes which will ultimately be agreed upon as representing them as accurately as they ever can be represented. Still less can we believe that the Mendelian hypothesis is wide of the mark altogether, and bears no relation at all to the phenomena which it attempts to explain. How true a representation it is, can only be determined by subjecting its component hypotheses to rigorous experimental tests. Our own opinion, to which, however, we attach little weight, inasmuch as the experiments designed by us to effect this test are only, as yet, begun, is that the majority of the hypotheses will stand these tests well.

We may now pass from the question as to the truth of the Mendelian principles to that of the bearing of these principles on those products of the imagination which we agree to name "great biological problems," such, for instance, as the "nature of heredity" and the "origin of species." The former question must, we suppose, be regarded as a real one, but, of course, not one any answer to which will ever be regarded as the final one. But the latter involves so many notions, only remotely representing phenomena, and so many generalisations which are manifestly *interim* ones, that the discussion of its relation to Mendelian principles becomes a mere exercise in dialectic offering no prospect of ever so slight a progression in the direction of a clearer vision of actuality.

Let us deal first with heredity. The problems of heredity which are debated at the present day exist only for those who adopt that view of life which insists on the disparateness and circumscription of the units to the succession of which the continuation of the stream of life is due. To those, on the other hand, who think that the cutting up of this stream into individuals (which, so far as we can see at present, do certainly appear to be discreet) is an unwarrantable insistence on a secondary feature; and who think that the difference as regards the livingness of the objects of their several interests between a man who is not satisfied with observing less than, say, ten consecutive generations of a living thing and a man who dissects a rabbit, is as great as, and of the same nature as, the difference between a man who dissects a rabbit and a man who collects stamps —to these the favourite problems of heredity do not exist at all, though the material out of which these problems have been constructed is the chief object of their attention.

With regard to the light thrown by Mendelian results on the question of the origin of species. The idea that the process of specific differentiation is akin to that of Mendelian segregation will doubtless serve as a fertile incentive to investigation for years to come. But to suppose that evolution is due to causes which can be compared to the shuffling of marbles in bags seems to us to be an idea which throws no light on any problem, save on that of the value of the insight of those who are not ashamed to confess that they entertain it.

The strictly phenomenal or impressionist aspect of specific differentiation must be attacked by means of the instrument which Mendel has put into the hand of biologists—the analysis of the organism into its constituent characters by experimental breeding. But to suppose that the Mendelian method does any more than indicate the lines along which the attack on this particular problem is to be made betrays, in those who make this supposition, a high degree of that naïve sanguineness as to the powers of the human intelligence which constitutes, at the present day, the most formidable obstacle blocking our approach to a true vision of life and evolution.

O

BRITISH MARINE WORMS.

Ray Society: A Monograph of the British Annelids. By Prof. W. C. McIntosh, F.R.S. Vol. ii., part ii. Polychæta. Syllidæ to Ariciidæ. Pp. 233–524+23 plates. (London: Dulau and Co., Ltd., 1910.) Price 25*s.* net.

THIS volume constitutes a further instalment of Prof. McIntosh's large monograph of British Polychæts, and its publication raises the hope that the entire work will be completed in a few years. The families described are amongst the most interesting and the most familiar to naturalists, yet they have probably never received such detailed treatment as is here accorded, with the result that we now have such a survey as Huxley first planned when he undertook professional work. The variety and beauty of this section of the British fauna will be a surprise to most naturalists.

The most interesting points in the volume are the assumption of the "epitokous" stage among the Nereids, and the phenomenon known as "Palolo."

During their asexual or "atokous" stage, Nereids are provided with similar lobes and bristles on every segment, but when the breeding season ensues many species of this family undergo a metamorphosis. The head and eyes enlarge, the posterior two-thirds of the body grows out segmentally into new lamellar feet, and these in turn develop long swimming bristles. In this "hetero-nereis" or "epitokous" phase, the two sexes often differ in colour and in habits, and in at least one species there are again two castes of males. The behaviour no less than the appearance of these animals now finds a new expression. Up to this period, Nereis has lived a sluggish life in a burrow. Now as hetero-nereis, he or she strikes out for the open sea, swimming easily and gracefully by rhythmical contractions of the paddles, and discharging broadsides of ova or of milt into the water. This effort is probably the final act of a career, for, carried away by the act of discharge, these pelagic Nereids may rupture and die.

On this subject the veteran naturalist of St. Andrews has gathered together his own vast stores of information and also those of his fellow-workers. He traces the development of this metamorphosis in all available instances, and collates a great amount of information, not only as to British, but concerning all Polychæts that exhibit this phenomenon.

With regard to palolo, this Fijian word has reference to a peculiar swarming of Polychæts at the surface of the sea. At Amboina, round Japan, on the coast of Florida and Samoa, swarms of Eunicid worms suddenly appear at definite times and disappear as suddenly as they came. The interest of their advent is increased by its coincidence with a certain phase of the moon in two months of the year, October and November in some places, March and April in others. Several genera exhibit this habit of swarming on two or three definitely fixed nights if the weather be clear. By the following morning not a trace of them is to be seen.

Still more remarkable are the details of the process. During the preceding twelve months these Annelids have led a sedentary life, hiding as far as is known in crannies or burrows in rock and coral. No sooner, however, is the moon at full in March or in October, as the case may be, than these Eunicids turn round in their burrows, twist off their tails, and send them wriggling on to the surface, the head end meanwhile remaining in the burrow. The whole mature population simultaneously perform the act, with the result that the neighbouring water acquires an appearance not unlike that of vermicelli. These severed tail ends are provided with special ocelli, and swim away laden with ova or with milt, which they discharge with every contraction. In a few minutes disruption is complete, and hence by sunrise the act is over. Meanwhile the head-ends, ensconced in their burrows, are already making scar-tissue, and in time regenerate the missing portion.

Such in brief, though, of course, subject to local modifications, is the meaning of this expression, and we now ask is there a British palolo, or have we anything of this nature on our coasts? The monograph before us gives no certain answer. True, there is a British *Lysidice punctata* at Guernsey, closely allied to a species that acts palolo elsewhere, but at present such swarming, if it occurs, has escaped observation. As to this and many other features of habits, coloration, and development, there is still a wide field for research amongst Polychæts. We trust that the publication of this monograph will stimulate to fresh observations on this interesting group.

Rather unwillingly, a word of criticism must be added, and it is to repeat a request made in the review of the preceding section that appeared in this journal in 1908. It was there urged that the family name of each species should be placed as a headline to one of the two facing pages, preferably the left, and we would also ask for an outline classification in each part as issued. For working purposes the absence of these two simple devices creates an extraordinary amount of trouble, and the reviewer is, after careful search, still far from clear as to the classification of, for example, the Eunicidæ.

In conclusion, the magnificent plates of coloured figures reflect the greatest credit on everyone concerned in their production. Plate liii., for instance, representing *Nereis virens* in all its three feet of beauty is a wonderful picture. Prof. McIntosh is to be heartily congratulated on the completion of such a large section of this great work.

F. W. GAMBLE.

CHEMISTRY FOR MINERS.

Elementary Chemistry for Coal-mining Students. By Prof. L. T. O'Shea. Pp. ix+319. (London: Longmans, Green, and Co., 1911.) Price 6*s.* net.

THE object of this little book is to furnish coal-miners with a knowledge of as much of the science of chemistry and of its applications as they are likely to find useful in their everyday work. Its contents are thus naturally divisible into two sections, the first giving an outline of chemical principles, and the second a rather more detailed account of such portions of the subject of coal-mining as depend more especially upon the above principles.

Such a book undoubtedly raises the question whether it is advisable in the interests of the students to lay before them only fragments of a complete science, even though it be admitted that the particular fragments that are most likely to be useful to them in their after-career have been selected with care and discrimination. On one hand, it may be urged that it is better for the coal-miner to have a rudimentary knowledge of chemistry than to have none at all, and that unless the amount of science required of him is cut down to the lowest possible limits, he will have none of it, whilst on the other we have the obvious dangers that attend a limited knowledge of any subject, and in the present case more especially the risk that the man who has mastered such a book as Prof. O'Shea's will think that he has got a real grasp of the science of chemistry and will remain in ignorance of the vast field that this book does not profess even to touch upon. No chemist needs to be told that a book that treats only of the chemistry of certain of the metalloids must necessarily present only a very imperfect outline of the principles of modern chemical science, and there would probably be a pretty general consensus of opinion that, if possible, it would be far better for the mining student to learn the elements of chemistry as an abstract pure science from a book on chemistry, and, having mastered these, then to be taught what portions of that science he has to apply to the problem of his daily work.

Prof. O'Shea has evidently come to the conclusion that the latter method is the less practical, and no doubt there is very much to be said for his view; it must be admitted that the coal-miner who thoroughly masters his little book will benefit greatly thereby, and will certainly obtain a fairly clear understanding of many of the phenomena that he meets with in the pit. The first chapters give an outline of the leading principles of chemical combination, and of the physical and chemical properties of oxygen, nitrogen, air, hydrogen, water, sulphur, carbon, and the oxides of carbon, including a useful chapter on flame and the safety lamp; then follow a number of chapters on the application of the facts thus set forth, on coal, coking, and the recovery of by-products, on explosives, and on gas and dust explosions; the book concludes with some brief chapters on certain chemical and physical calculations, which will prove useful for the proper understanding of certain parts of the subject. Prof. O'Shea has done his work well, and has evidently selected his material with great care and judgment, and with a sound appreciation of the needs and limitations of the coal-miner. He has also taken care to express himself throughout in plain, simple language, and it may be suspected that it is to the desire for simplicity that a certain amount of slipshod writing in the book is due, as, for example, in such expressions as "one of the most improved forms," "a purely dust explosion," &c.; a somewhat flagrant case is the definition of the atomic weight of an element as "a number which represents how much heavier its atom is than the atom of hydrogen," where the author obviously means "how many times as heavy."

It is difficult to see why Prof. O'Shea should insist that nitro-glycerol is the more correct name for nitroglycerine; the latter is a thoroughly well-known and generally accepted trivial name, and if he wants chemical exactitude, he should have used the strictly correct form, glyceryl tri-nitrate; it is now generally recognised that nitro-glycerine and gun-cotton are not, as Prof. O'Shea states, nitro-compounds, but nitrates. In the same way exception may well be taken to the statement that coal occurs in "veins." Such inaccuracies, though they are undoubtedly blemishes in an otherwise very well-written book, do not, of course, detract seriously from its value as a whole, and will presumably be corrected in a future edition. Prof. O'Shea may fairly be congratulated on having produced a little book that gives, within a convenient compass, a great deal of information that will prove extremely useful to all coal-miners, and be found to render very great assistance to the class for which it is more particularly intended. H. L.

ANOTHER BOOK ON EVOLUTION.

Phases of Evolution and Heredity. By Dr. David Berry Hart. Pp. xi+259. (London: Rebman, Ltd., 1910.) Price 5*s.* net.

THIS book is not written by a man red-handed fresh from an encounter with nature. If his hands needed washing before he wrote, it was to remove the dust of books. Would that the water could have removed the taint of much reading also. The notion that the truth must be sought in books is still widely prevalent, and the present dearth of illiterate men constitutes a serious menace to the advancement of knowledge.

The author of this book constitutes an exception to the law that the more certain a man is that he is right the more probable is it that he is wrong. Dr. Hart lays stress on the fallibility of the human intelligence. He realises that he may be mistaken. And he is. The title-page of his book bear these words:

"Every seeker after Truth is dependent on the knowledge of his Age. He must, therefore, shape his coat according to his cloth, and expect a misfit. The words of Cromwell to the General Assembly of the Scottish Church should ever ring in his ears: 'I beseech you, in the bowels of Christ, think it possible you may be mistaken.'"

The book deals with "Mendelism," "Biometry," "Mnemism," "Observation Bee-Hives," "Evolution in Religion," and "Men who have Revealed Themselves."

The obstacles which, according to Dr. Hart stand in the way of our acceptance of the Mendelian hypothesis seem to us wholly illusory. He does not see why segregation should not occur in F_1, and asks the following questions, which seem to us quite easy to answer. "1. Why, if this explanation be true, do we get all the plants of the F_1 tall-dwarf crossing, tall, and not talls and dwarfs in the 1:2:1 ratio?" [*Answer:* Because the only one kind of union between gametes can take place, namely tall×dwarf.] "2. The recessive quality reappears in F_2. Is it not, then, equal to the dominant?" [*Answer:* Yes, if you like.]

"Clearly it is only temporarily recessive." [Precisely.]

"3. How is the recessive element expressed in F_1? It has not disappeared, as it reappears in F_2 unaltered. It is not expressed in the 'soma' of the plant: Where is it?" [*Answer:* In its germ cells.]

Dr. Hart's amended Mendelian scheme on p. 43 may be all right, but we cannot understand it, and we know of no experimental evidence for the assertion that there are three kinds of zygotes in F_1, a tall-tall, $\left\{\begin{matrix}\text{tall}\\\text{dwarf}\end{matrix}\right\}$tall, and a dwarf-tall. The reader must examine Dr. Hart's argument for himself.

The account of biometry is not very illuminating.

"Galton," we are told, "formulated certain laws, which are important—that of filial regression, for instance; but the most widely known one, Galton's law, setting forth the supposed fractions making up the full heredity in the individual, is of great importance, and has been specially fought over since Mendelism began to exert its sway over Evolution. . . . We may therefore, using Mendel's term of unit-character, say that, according to Galton, offspring inherit one-half of their unit-characters from their parents, and the most of the other half from the grandparents and great-grandparents."

And, again:—

"The amount of hard work bv biometricians in accumulating measurement-facts and noting minute variations is enormous. We get a good illustration of that in some of the late Francis Welldon's [*sic*] work. This eminent biologist was a most eminent follower [!] of biometric work, and . . . we see how Welldon spent himself, sometimes successfully and sometimes unfortunately, it must be said unsuccessfully, in arduous observations, unremunerative as yet in scientific deduction."

We cannot agree with this definition of biometry in the glossary at the end of the book, "Biometry is concerned with accurate measurements of 'organs,' their relations, and the laws governing their occurrence." It grieves us not to be inclined to praise this book, for the author is so manifestly earnest. But earnestness is not a sufficient qualification for authorship, and we cannot persuade ourselves that the book meets a long-felt want.

PHANTASMS OF THE LIVING.

Théorie Physico-chimique de la Vie et Générations Spontanées. By Prof. Stéphane Leduc. Pp. 202. (Paris: A. Poinat, 1910.) Price 5 francs.

PROF. LEDUC is not one of those who exaggerates the apartness of life. He thinks that the differences between an animate and an inanimate system are differences of degree, not of kind. It is in vain, he says, that one seeks for any exclusive characteristic of living things; it cannot be found in development, or nutrition, or irritability, or growth, or organisation, or reproduction. One discovers in living creatures only those physical forces which operate in the not-living world; biology, indeed, is part of the physico-chemistry of fluids. These conclusions are based partly on general reasoning, which appears to us fallacious, and partly on an interesting series of experiments, of which some illustrations may be given. A solution of 5 to 6 per cent. pure gelatine is spread on a slide; on this at regular intervals of 5 to 6 mm. one places by means of a pipette drops of ferrocyanide of potassium; these diffuse and meet and dry, giving a result like a tissue. The "artificial cells" pass through three stages of organisation, equilibration, and decline—ending, of course, in "death."

With a little ink and water one can conjure up all sorts of phantasms, some of them yielding very striking suggestions of karyokinesis. Periodic precipitations due to waves of diffusion may result in the artificial production of mother-of-pearl, which we can well believe, but we are not impressed by the "curious analogy" between some of the forms and "articulate animals." One of the figures is a little like a squashed scorpion, but is this sort of thing useful?

Prof. Leduc contributes an interesting short history of the biological study of osmotic phenomena, referring to Nollet, Rose, Traube, Harting, Quincke, and many others, and he gives a number of remarkable figures —the precise nature of which is in most cases left unstated—showing his own osmotic creations, produced by placing a fragment of calcium chloride in a saturated solution of carbonate of potash or tribasic phosphate of potash, or in similar ways. A fruitful solution to work with consists of 60 gr. of silicate of potash at 33°, 60 gr. of saturated solution of carbonate of soda, 30 gr. of saturated solution of di-basic phosphate of soda, and distilled water to make up a litre. Into this are placed fragments of chloride of calcium, and remarkable osmotic growths result. Some of the pictures of these and similar growths are mushroom-like, others worm-like, others coral-like, others shell-like, others mould-like, others leaf-like, and when a number are grouped together on a plate the effect is very quaint.

There can be little doubt that a study of these growths may in the course of time throw some light on the *rôle* of osmosis in organic growth. We think, however, that the author is going far beyond his results when he says that these osmotic growths exhibit "nutrition, assimilation, elimination, and irritability." The need of proof-reading is so conspicuous in this volume that we must direct attention to it. We read of Ernest Hœckel, Ulenhuth, Buttler Burke de Crambridge, Bütschli, and so on; there are three or four errors in the title of a book by Rhumbler; and we see a German word with an accent. These are minute details, but they are congruent with the impetuous superficiality of the main thesis of the book.

IRRIGATION WORKS.

Notes on Irrigation Works. A Course of Lectures delivered at Oxford under the auspices of the Common University Fund. By N. F. Mackenzie. Pp. ix+111. (London: Constable and Co., Ltd., 1910.) Price 7*s.* 6*d.* net.

THESE lectures in book form have as their author an engineer whose competency to deal with his subject is sufficiently established by the fact that he was selected to be Under Secretary

for Irrigation to the Government of India. The duties of that office, coming after a career of practical work on irrigation schemes, would give that breadth of view with which a lecturer on so wide a subject as "Irrigation Works" should be endowed.

The irrigation works described in this book include more than the material works of irrigation, such as channels for irrigation and drainage and works of regulation. "Notes on Irrigation *Work*" would seem to be a more appropriate title. For, besides discussing weirs and irrigation channels—irrigation works properly so-called—the author describes what may be termed the embryonic growth of an irrigation project—that is, the preliminary surveys, studies, and calculations, which mark stages of development in the incomplete project. The final chapter, moreover, explains the revenue duties of the canal engineer of India. The canal engineer of Egypt is fortunate in escaping the harassing duties of revenue management, which in India are part of an irrigation officer's duties.

A separate chapter deals with the development of irrigation in Egypt since 1884 in a concise and comprehensive summary, and concludes with a short reference to possible future schemes. With this exception and a few references to works in Egypt under the head of weirs, the author has wisely drawn his illustrations from works in India with which he is personally acquainted, and treats his subject generally from the point of view of India. He thus avoids a fruitful source of error. The "eminent authority" whom he quotes as misconceiving the cause of the failure of Narora weir, leant too heavily on the broken reed of an official report, and fell into error for want of first-hand knowledge of the subject which he was using as an illustration. Mr. Mackenzie, with more caution, gives his opinion "with all reserve" as to the cause and manner of the accident. He may be right, but, as he points out, the local engineers decline to commit themselves to a positive opinion. There is, at least, one more theory of the cause of the accident, which has not yet appeared in print. Whatever the real cause may have been, the discussion, which has followed on the accident to the Narora weir and to which the author makes his contribution in his book, has been fruitful in establishing sounder principles upon which to base the design of weirs than had been recognised before.

A chapter on the design of irrigating channels is chiefly concerned with the important matter of silt deposit in the small distributing channels in the delivery zone of an irrigation system; but the method of water distribution on the rotation system is also described in general outline. An introductory chapter refers to the performance in the distant past and the promise in the near future of irrigation in Mesopotamia; also to the conditions which create a need of irrigation and drainage, and to the good effects of moderation and to the evil effects of excess in either.

The book is written in good, plain English, and is free from unnecessary technicalities, as lectures addressed to students should be, and as, indeed, all lectures might well be. The substance of the book is sound instruction, and irrigation engineers, as well as students, will find much useful knowledge in it, clearly expressed and convincingly demonstrated. A careful perusal of it would be a valuable preparation for a more detailed study of irrigation works and administration, either by books or by actual practice.

THE CRYSTALLINE SCHISTS.

Die Kristallinen Schiefer. Eine Darstellung der Erscheinungen der Gesteinsmetamorphose und ihrer Produkte. By Prof. U. Grubenmann. Zweite Auflage. Pp. xii+298+xii plates. (Berlin: Gebrüder Borntraeger, 1910.) Price 20 marks.

ORIGINATING in a course of lectures at Zürich, based largely on the author's own researches among the crystalline schists of the Alps, Prof. Grubenmann's book has already made for itself a place in petrographical literature. The two parts, general and special, issued separately in 1904 and 1906 respectively, are in the new edition included more conveniently in a single volume; but the general plan of the work remains unchanged, and the additions found here result merely from the growth of material during the last five years. Thus, in the first part, there is some revision of those sections which deal with the application of physico-chemical principles, and some interesting illustrations of original sedimentation, mixed injection, &c., are drawn from recent work in Finland and Scandinavia. The additions made to the second part of the book are perhaps more important, including a large number of chemical analyses, and some simplification of the classificatory scheme.

The general principles of Prof. Grubenmann's treatment are already known to petrologists. His classification is based primarily upon chemical composition. No distinction is made between metamorphosed sediments and metamorphosed igneous rocks, for it is urged that, even if their original characters are not wholly obliterated, metamorphism has set so marked a stamp upon them that the new characters supersede the old in significance. The author adopts Osann's chemical classification, originally devised for igneous rocks alone, and in this way arrives at twelve groups of crystalline schists. In each group there is made further a threefold division corresponding with different zones of depth, where the conditions as regards temperature and pressure are presumed to differ in an important degree. This division, an amplification of Van Hise's conception, is described as a "physical-geological" one; but, since the actual depths of the several zones are not the same in different groups of rocks, the geological significance is merely of a limited scope.

The distinction made between crystalline schists and "contact-rocks," which latter are excluded from consideration, seems to us an artificial one, and is difficult to defend in a scheme professedly based on the actual characters of the rocks. Barrow has shown that the great metamorphic aureoles of the Scottish Highlands can be divided into three zones, having sillimanite, cyanite, and staurolite as their

characteristic minerals. Here it is clear that the formation of one or other of these silicates depended solely on temperature, and in no wise on depth; but in the book before us sillimanite figures as a distinctive mineral of the deepest zone, and cyanite and staurolite of the middle zone. We are led to suspect that the author has overrated the influence of pressure as a factor in metamorphism. Such experimental data as we possess go to show that even very high pressures may not displace greatly the temperature-limits of stability of the rock-forming silicates.

Apart from such considerations, more or less theoretical, the work is a mine of valuable information. The classification at least serves its purpose as a standard of comparison, and the systematic treatment of the structures of crystalline schists will be especially useful. A. H.

PLANT LIFE OF MARYLAND.

Maryland Weather Service. By F. Shreve, M. A. Chrysler, F. H. Blodgett, and F. W. Besley. Vol. iii., The Plant Life of Maryland. Pp. 533. (Baltimore, U.S.A.: Johns Hopkins Press, 1910.)

THE weather service of the American State of Maryland, maintained by the Johns Hopkins University, Maryland Agricultural College, and the United States Weather Bureau, receives a broad interpretation. The first volume of the series dealt with the physiography and meteorology of the State, the second presented the results of many years' study of the climate and weather of Baltimore and vicinity, while the third is connected with the former in so far as vegetation is dependent upon physiography and climatic conditions. The main purpose of the present volume is to present an ecological description of the vegetation, which is demarcated into three zones. The coastal zone spreads inland as far as the "fall-line"; thence to a contour line of 1500 feet extends what is designated as the "midland" zone, and a mountain zone comprises land above that altitude. The term, "fall-line," it may be noted, is nowhere explained; reference to another source shows that at the junction of the Cretaceous or Cenozoic with older formations the rivers have falls or rapids.

The division into these three zones is suggested by the occurrence in the central counties of many species having a wide range, coupled with the appearance of a conspicuous southern floral element in the coastal zone, and an appreciable admixture of northern elements in the mountain zone; these facts throw some light upon the historical sequence of events. As for the details, these are well elaborated, and due consideration is given to the limits imposed by soil constitution, both physical and chemical, and by topography. Climatic conditions are extremely favourable to tree growth, so that forests are important in each of the zones. Originally extensive forests of white pine and pitch pine existed in the western part of the State, but now the white pine is limited to isolated specimens. The converse process is seen in southern Maryland, where scrub pine spreads over land cultivated before the Civil War; this is a first stage that is altered by the incursion of oak, and later by hickory. Apart from the forests, the various marsh regions in the coastal zone are interesting, also the serpentine barrens and Susquehanna gravels in the midland zone. To make the survey more complete, sections are devoted to agricultural and forestry matters, and an account of the floristic geography with a list of plants is supplied by Dr. F. Shreve. The text is illustrated by a considerable number of excellent photographs and by a few maps that would be more useful if the scale were larger. The volume is highly creditable to Dr. Shreve and his associates, and will take rank with the best local ecological studies.

OUR BOOK SHELF.

Salvarsan or 606 (Dioxy-Diamino-Arsenobenzol): its Chemistry, Pharmacy, and Therapeutics. By Dr. W. H. Martindale and W. W. Westcott. Pp. xv+77. (London: H. K. Lewis, 1911.) Price 5s. net.

IN this little book, the authors summarise all the essential information contained in the numerous publications that have appeared up to date on the Ehrlich-Hata remedy for syphilis. "Salvarsan" is the trade name given to the compound—which is chemically dioxy-diamino-arsenobenzol—synthesised by Ehrlich and his collaborators, and first introduced under the designation "606." Ehrlich has for some time past been studying the effects of various anilin dyes and organic compounds of arsenic on trypanosomes and other protozoan parasites. In quick succession he brought out more or less effective remedies, such as trypan red for bovine piroplasmosis (Texas fever), atoxyl and arsenophenylglycine for trypanosomiasis of man and animals, and, finally, "606" for spirilloses, diseases caused by spirillar micro-organisms, such as relapsing fever and syphilis.

S. Hata, of Tokio, conducted researches with "606" on the spirochætes of relapsing fever in rats and mice, and subsequently on the spirillosis of fowls. The drug was found to be extraordinarily efficacious, and it was an obvious further step to try it on syphilis, another spirochæte disease, with correspondingly successful results. Mercury has been used for centuries as a remedy, the one remedy, for syphilis, but a proper course of treatment with it extends over months, and it is impossible to make many patients realise the necessity for this, and hence the disease relapses, with, in many instances, dire results. With salvarsan, however, it is claimed that a single dose will in many instances effect a cure, an enormous advantage.

There can be little doubt that in salvarsan we have a most potent remedy for the cure of syphilis, though whether it will do all that has been claimed for it time alone can show. Unfortunately the drug is toxic, and requires to be administered in a special manner; it is not altogether free from danger in particular cases, and is contra-indicated in some of the worst forms of syphilis, *e.g.*, when the nervous system is involved. In the book under review, the authors give complete directions for the preparation and administration of the drug, and epitomise the precautions to be taken and the contra-indications for its use, and it should prove a very useful guide for the practitioner. Summaries of some of the principal contributions on the remedy are included, and a full bibliography is appended. R. T. H.

Outlines of Zoology. By Prof. J. Arthur Thomson. Fifth edition, revised. Pp. xxii+855. (Edinburgh, Glasgow, and London: H. Frowde and Hodder and Stoughton, 1910.) Price 12*s.* 6*d.* net.

IN the case of a book written by such an experienced writer and teacher as Prof. Thomson, and especially at the appearance of a fifth edition, there is little room for critical comment. The qualities that have made this work such a successful handbook are well known to generations of Scotch students; the conciseness of its information, the caution of its statements, and the clearness of its comparisons. Even in its older form this text-book was notable for its close texture, for the compact nature of its information. Now that all the bearings of modern work upon its topics have been incorporated, it is a rendering not only of the outlines of zoology, but of much of the "corpus" of zoological knowledge, and he would indeed be a full man who could really possess the store of information, both old and new, that is contained in its pages.

Almost the only general criticism we have to make is the inadequacy of the treatment of the cœlom-theory. This important and difficult subject has recently been expounded so clearly in Prof. Sedgwick's text-book of zoology, and is of such fundamental importance that the fragmentary presentation in the book before us is a matter of regret, affecting, as it naturally does, nearly every division of the animal kingdom. The discussion on Echinoderm larvæ on p. 278 fails through such a want of what Moseley, we believe, described as "morphological grip." The "absence of the apical sense-organ" mentioned at the bottom of that page is surely an oversight. The apical plate is well developed in Echinid larvæ, and even bears eye-spots.

The text has been most carefully revised. Very few mistakes have been overlooked, but two call for mention. One of the most recently discovered insects —Acerentomon—is figured, a welcome sight, on p. 362, and is described there as being without antennæ, though antennæ are figured and described in the legend. The other occurs on p. 235, where, in the second paragraph, the word "sexes" is written "series." Such minute defects are, however, of little account. A notable feature of this edition is the large number of new figures.

Étude sur l'Assurance complémentaire de l'Assurance sur la vie. Avec de nombreux développements sur les Assurances contre la Maladie et l'Invalidité. By P. J. Richard. Pp. iv+118. (Paris: A. Hermann et Fils, 1911.) Price 3.50 francs.

THERE has lately been a movement among insurance companies in various parts of the world to combine with ordinary life insurance benefits dependent upon sickness, so that in the event of incapacity no premiums are payable, and sometimes an annuity is received. This movement has led to the mathematical investigation of the underlying principles, and the subject has proved attractive to one or two writers, owing, perhaps, to its complexity, for it is necessary to deal with the probabilities of death, sickness (permanent and temporary), and recovery, all of which vary with the age and occupation of the life assured, as well as with the time that has elapsed since the person was medically examined for insurance. M. Richard, in his recent publication, evolves the formulæ that might be used, and gives specimen tables to enable us to form an idea of how the premiums might be calculated, although, as he points out, we have not sufficient statistical data to enable us to use his formulæ satisfactorily.

The best solution of the problem is probably the statistical one which sets out on one hand the payments made to the offices, and on the other the various benefits allowed to the insured. The subject is, however, at present too new on its practical side to enable us to use this solution, and until experience provides us with data, M. Richard's neatly-printed little book will prove interesting to those who are concerned with actuarial problems in theory and practice, and have perhaps already been attracted to the subject on which he writes by the earlier work of Schaertlin and a few other writers.

Recueil d'Œuvres de Léo Errera. Physiologie générale. Philosophie. Pp. xiv+400. (Brussels: H. Lamertin; London: Williams and Norgate, 1910.)

THE late Prof. Errera was possessed of an inherent faculty for analysing subtle problems by a process of concise, logical argument, and this faculty is particularly apparent in his treatment of certain of the general physiological subjects discussed in this fourth volume of collected papers. One of the best instances is supplied by the notes arranged for a course of lectures debating the existence of a vital force in plants. Two lectures on sleep were delivered before an audience composed largely of doctors. The view put forward by the author that sleep is induced by the formation of toxic bodies was opposed by several doctors present, but was not refuted.

Three papers only can be classed as direct contributions to botany, although arguments are deduced from the plant world in all of them. One of these discusses the question whether acquired characters can be inherited, and answers it in the affirmative on the strength of cultural experiments with *Aspergillus niger*, carried out by Dr. Hunger in the Botanical Institute at Brussels. Another paper dealing with the struggle for pre-eminence as exemplified by the growth of lateral branches of a conifer when the main stem is destroyed, was read before the British Association at the Cambridge meeting in 1904. Two essays on the individual and the assertion of life are published for the first time. The papers generally manifest a copious knowledge and ready application of the latest scientific facts, and botanists in particular will appreciate the arguments and views expressed with regard to spontaneous generation and the existence of a soul in plants.

Wild Flowers as They Grow. Photographed in Colour direct from Nature. By H. Essenhigh Corke, with descriptive text by G. Clarke Nuttall. Pp. vii+197. (London: Cassell and Co., Ltd., 1911.) Price 5*s.* net.

THE first point of interest in this volume is supplied by the coloured illustrations, which are the outcome of photographs taken from nature direct by the Lumière process, and reproduced by a four-colour printing operation. Most of the colour tones are well rendered, notably the yellow and green of the primrose, the blues of the harebell flower, and the blended colours of the bee orchis; only the yellow colours of the dandelion and toadflax are distinctly incorrect. From a combined natural and artistic point of view the wild strawberry is excellent, as are several others, especially when it is considered that an exposure of minutes is required for taking the photographs. In the accompanying letterpress Mr. Nuttall presents a clear and precise description, adapted for general readers, of the chief features of biological interest observable in the twenty-five plants selected, and comments on the popular names, superstitions, and other such details. The text and illustrations together form an attractive volume, and the cost is moderate.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Discovery of the Teeth of Palæolithic Man in Jersey.

AT the close of last year Messrs. E. T. Nicolle and J. Sinel reported (*Man*, December, 1910, p. 185) some of the results of an exploration of a Palæolithic cave-dwelling situated in the cliffs of St. Brelade's Bay, on the south coast of Jersey. Amongst the mammalian bones found on the floor of the cave, Dr. A. Smith Woodward and Dr. C. Andrews recognised remains of the woolly rhinoceros, the reindeer, and two varieties of horse. Abundant evidence of former hearths and numerous flint implements were found with the bones. Nine human teeth were also found, and it is to the nature of these I wish now to direct attention. The exploration of the cave was continued by Mr. R. R. Marett, reader in social anthropology, Oxford University, who is now preparing for publication a full account of the various "finds" made in the Jersey caves. By his courtesy I was given an opportunity of examining the human teeth, which are to be fully described by Mr. Francis H. J. Knowles. Three of the teeth, all of which are fossilised, but in an excellent state of preservation, belong to the upper jaw—a second left premolar, a first right and a second left molar; the six teeth from the lower jaw are a canine, first and second premolar and second molar of the left side, a second incisor and second molar of the right side. It is thus possible to reconstruct the dentition of this individual —for clearly all are from the same set—with a fair degree of accuracy. The recognition of each member of the series was made easy by their close resemblance to the teeth of the Heidelberg mandible, usually regarded as the oldest example of Pleistocene man yet discovered in Europe. The teeth of the Gibraltar cranium, which is probably a very primitive and early example of the Neanderthal type, were also of assistance. In many features the teeth of the Krapina men are recalled. There can be no doubt that the St. Brelade individual to whom these teeth belonged must be ranked as one of the most, if not the most, primitive of the examples of the Neanderthal type yet discovered.

When the Heidelberg mandible was found in 1907 embedded in the Mauer sand beds, at a depth of nearly 90 feet, anthropologists were surprised by the fact that while the crowns of the teeth did not greatly exceed modern dimensions, the mandible itself was so massive as to recall the form found in the orang and gorilla. The important fact brought home to us by the Heidelberg discovery was that the outstanding feature of the teeth of Pleistocene man, as compared with those of modern man, are the size and character of the roots of the teeth, not the size or character of their crowns. The stout roots and massive mandible indicated the roughness and toughness of the food, and the huge muscular strength exerted in mastication. Now, as regards the characters of the roots, these now found in the cave of St. Brelade exceed all human teeth previously discovered. Although the crowns of the teeth are smaller than those of the Heidelberg mandible, the roots are in most cases absolutely, and in other cases relatively, greater in their diameters, and indicating a smaller but still more powerful mandible in the St. Brelade individual.

The characters of the roots of the St. Brelade teeth may be seen from the adjoining figure. Two of the teeth are represented, A, the left lower canine from its proximal or mesial aspect, and B, the second lower molar, also from the same point of view. Typical specimens of the same teeth in a modern European are shown in A′ and B′. The difference in thickness is striking; the length of the roots is nearly the same. So specialised are the tooth roots in Neanderthal man that Klaatsch and Adloff exclude this race from the ancestry of modern man. In the specimens figured of the second lower molars, both St. Brelade and modern, the two roots are fused, but the process of fusion is absolutely different in the two. In the Brelade specimen the roots have become so hypertrophied and strengthened that they have come together as a result of overgrowth; in the modern molar the roots have dwindled and atrophied and become approximated by a process of retrogression. In the anthropoids, as in well-developed molars of modern man, the roots are well developed, separate, and spread. The roots of the first molars of modern man thus resemble those of the anthropoid, whereas the typical molars of the Neanderthal race appear to differ absolutely from the anthropoid type. At first sight it appears as if Klaatsch and Adloff must be right in tracing the root-forms in the molar teeth of modern man to a primate ancestor, and in excluding the highly specialised roots of Neanderthal man from the ancestry of the molars of modern man. In this I think they are wrong, for were retrogression to overtake the masticatory development of the Neanderthal type of man, then the apparent fusion of the roots would vanish, and they would again appear as separate structures as in the well-developed molars of modern man. This stage of retrogression can be seen in the teeth of the men of Spy. When we speak of the Neanderthal race we must remember that it probably endured throughout the Pleistocene period, one covering several hundred thousand years, and that we must expect to find many forms. The Spy men appear to belong to the latter part of the period; the Heidelberg and Brelade men to the earlier.

The teeth of Pleistocene man are highly specialised as regards their roots, a character in which they altogether depart from the anthropoid form. The change in root form

is best explained by the supposition that the human method of mastication had been evolved from the anthropoid long before the end of the Pliocene period. The peculiarity of the human method of mastication is the side to side or grinding movement of the lower jaw; in the anthropoid the movement is a crushing or cutting movement. The great canine teeth are implanted as maxillary guides to prevent any side to side action and ensure that the mandible will not slip or "skid" when the powerful muscles of mastication are at work. The human method of mastication was only possible when the canine teeth began to sink, as in the female chimpanzee, almost to the level of the other teeth. That the human canines were once anthropoid in form there can be no doubt; their embryological history leaves room for no other opinion on this point. When, however, the side to side movement in mastication was evolved, the implantation of the teeth had to be strengthened to meet the side to side strain. It is that stage which is preserved for us in Pleistocene man. It is very remarkable that in modern times the side to side movement has disappeared in highly civilised races, and the former cutting bite, ensured by the lower incisors passing up behind the upper, has appeared. With the improvement in food in more modern times, the usual primate form of tooth roots reappeared. In the St. Brelade dentition the first lower premolar is highly specialised, as is the case in the anthropoid; its specialisation originally depended on the fact that it had to serve as the opponent of the massive upper canine. The discovery, made under the auspices of the Société Jerviaise, thus not only serves to show the extension of the Neanderthal type to the Channel Islands, but supplies most important facts bearing on the evolution of man.

A. KEITH.

Botanical Research at Peradeniya.

IN *The Times of Ceylon*, April 12, is published a communication, dated June 20, 1910, from the Governor of Ceylon to the Secretary of State for the Colonies on the question of a Department of Agriculture for that colony. With the proposals put forward in that memorandum we are not concerned, but there is one feature in connection with it against which we cannot but strongly protest. Appended to the memorandum are certain notes by Mr. Dunstan, of the Imperial Institute, of which one runs as follows:—

"Owing to the agricultural duties which are now performed by the botanical officers at Peradeniya, and for which they are not specially qualified, no botanical research is being carried on, and the scientific reputation of the establishment, which was at a high level in the days of Thwaites and Trimen, is suffering."

We are confident that this statement cannot be justified. A reference to the Annals of the Royal Botanic Gardens, Peradeniya, founded by Dr. Willis in 1901, gives evidence of the amount of valuable work that has been carried out in recent years. We may mention, without attempting to be exhaustive, the researches of Messrs. Green, Holtermann, Keeble, Lang, Lock, Parkin, Pearson, Petch, Smith, Svedelius, Willis and Wright, which have all been carried out at Peradeniya during Dr. Willis's directorship. At the present time Dr. Willis and Dr. Lock, and Messrs. Petch and Green, are actively engaged in research.

In our opinion there would be a general agreement among biologists that the high reputation of the Royal Botanic Gardens has been fully maintained—to say the least of it—under the direction of Dr. Willis. To the sympathy of the staff with scientific progress, and to their ability in smoothing the way for those who visit the gardens for purposes of research, two of us, who lately stayed there for scientific work, can personally testify.

We are relieved to read that the Secretary of State, in his answer to the memorandum, has not associated himself with the paragraph above quoted. But we feel bound to make some protest against what seems to us to give an entirely misleading impression of the high position, as a centre of research, which Peradeniya has attained, under Dr. Willis's initiative and guidance.

Cambridge University, May.

The Heraldic Yale.

SUPPOSING a traveller on his return from Africa were to tell a friend in the Heralds' Office that he had seen a beast, in general appearance like an antelope, with divided hoofs and a long tail bunched out at the end like an elephant's: having horns, roughly corrugated and protuberant on his forehead like a ram's, though he could not be quite sure as to their form, because he saw him only in profile, and they seemed movable, one sometimes pointing forward and the other backward: further, that he had two enormous tusks and a lower jaw like a goat's, that is, with a long beard.

His friend might take out his pencil and embody what he was told in a rough sketch something like this, Fig. 1, saying, "That's very interesting, for your description of the beast combines all the characters of the heraldic Yale, which some say had an African origin."

Supposing the traveller then strolled round to the British Museum and reproduced, as well as he could, the sketch drawn by his heraldic friend, but, on being cross-examined, was forced to admit that what appeared to him to be tusks might have been the tips of the beast's curved horns, which from another point of view did seem to point different ways: that the upper part of his tail was not covered with short hair only, as in the elephant, but was more bunchy below, and from the animal's manner of whisking it about the bunchiness was exaggerated. Supposing, also, that he was not clear as to the points or protuberances on the top of the animal's head—whether they

FIG. 1.

were the tips of his ears or bases of horns, or both—and that he was led to modify his picture, as in Fig. 2.

His British Museum friend also might say, "That's very interesting, for it is not unlike an African beast known as the gnu, from its native name nju."

Talking the matter over afterwards with a third friend, who was learned in folk-lore, he was told that it was

FIG. 2.

very interesting as an example of how heralds and artists had modified in time the strange form of the gnu into accord with the characters of the only animal of the kind which they did know, namely, the antelope.

T. MCKENNY HUGHES.

Dynamical Enunciations.

UPON Newton's classic definitions and laws of motion various criticisms have been passed by A. E. H. Love, E. Mach, K. Pearson, H. Poincaré, and others.

Some writers emphasise one aspect of the subject, some another, and most are destructive rather than constructive. But, if the full value of this critical work is to reach the ordinary student, it seems desirable that teachers should have at hand some brief statements embodying those central positions on which there is fair agreement in modern thought.

As an attempt in this direction, the following enunciations are, with great diffidence, submitted:—

Law of Motion.—Accelerations occur only in opposite pairs, the ratios of which are constant for given particles.

Definition of Mass.—The masses of particles are positive constants, inversely as their mutual accelerations.

Definition of Force.—Force is the product, mass into acceleration, and has the direction of the acceleration.

Choice of Axes.—Since motion is relative, force and mechanics are relative also. Hence, the foregoing and any problems based upon them should be referred to axes which, in each case, yield a mechanics most appropriate to the phenomena under discussion.

Nottingham, May 12. E. H. BARTON.

I AM much obliged to the Editor of NATURE for giving me an opportunity of commenting upon Prof. Barton's letter. In the second edition of my book on "Theoretical Mechanics" I have expressed my ideas on the subject at such length that it is unnecessary to go into details here. It may suffice to say that the first two of Prof. Barton's proposed enunciations seem to me to be too abbreviated to be of much value. To anyone who understands the theory of mechanics, as explained by the writers whom he cites, such statements could be of little use, while to anyone who does not they might be misleading. The third enunciation does not distinguish between force and the quantity which Routh called "effective force" and I call "kinetic reaction." The distinction appears to me to be important. The fourth enunciation would seem to permit an undesirable degree of freedom in respect to the choice of a reference system. I do not wish to suggest that Prof. Barton means by his brief enunciations something different from what I mean in my book, but rather to point out that such brevity as he aims at may be inconsistent with clearness in the statement of principles. One way of bringing the results of modern critical discussions concerning the laws of motion within the reach of the "ordinary student" would be to publish a short tract, on the same scale, say, as Maxwell's "Matter and Motion." In such a tract summary enunciations could be accompanied by adequate explanations. Would not this be better than providing teachers with a set of enunciations?

May 18. A. E. H. LOVE.

Further Experiments with the Gramophone.

I HAVE just seen Prof. McKendrick's letter in your issue of April 20, describing the experiments he has made with a view to improving the quality of the notes reproduced by a gramophone.

Some five or six years ago, when I was working at the auxetophone, I tried a number of similar devices, and, to a very large extent, succeeded in getting rid of the objectionable hissing and scratching sounds.

One of the horns I tried consisted of a wooden tube of rectangular section and gradually increasing area, which was doubled backwards and forwards on itself in the shape of a flat zigzag, and was practically identical with the metal horn illustrated in your paper.

In the end I found it was best to use a coiled metal trumpet of large size and gradually increasing area and about 48 feet long, in which I introduced several right-angled and "U" shaped bends; further, I fitted a "T" shaped tube close to the reproducer, which made a considerable improvement in the quality of the tone. The longer sound waves passed through this "T" shaped bend with little loss, but the very short waves, which caused most of the scratching, were absorbed at the bend, especially if the blank end of the "T" was filled with cotton wool or some other similar substance, or if an inner sliding tube, with the end closed, was introduced into the blank end of the "T," and pushed in, so as to throttle the sounds at the bend.

I also fitted a flexible joint between the needle and the actual reproducer, which further eliminated these high-period vibrations. This flexibility was obtained by giving the joint very large clearance, and filling the space in between with a highly viscous substance.

I found considerable improvement, as well, in the tone when a paper diaphragm, or when moderate quantities of paper, linen, &c., were put in the trumpet.

In conclusion, I might say that my own experiments quite bear our Prof. McKendrick's opinion on the importance of using suitably shaped trumpets in order to obtain pleasant natural reproductions of musical tones and of the human voice. CHARLES A. PARSONS.

Heaton Works, Newcastle-on-Tyne, May 17.

German East African Dinosaurs.

WITH reference to your note on the German East African Dinosaurs (NATURE, May 18, p. 390), *Die Woche* of May 6 reproduces an interesting series of photographs of the remains, taken on the site of the excavations.

Matlock, May 20. F. GILLMAN.

BREATH FIGURES.

THE manner in which aqueous vapour condenses upon ordinarily clean surfaces of glass or metal is familiar to all. Examination with a magnifier shows that the condensed water is in the form of small lenses, often in pretty close juxtaposition. The number and thickness of these lenses depends upon the cleanness of the glass and the amount of water deposited. In the days of wet collodion every photographer judged of the success of the cleaning process by the uniformity of the dew deposited from the breath.

Information as to the character of the deposit is obtained by looking through it at a candle or small gas flame. The diameter of the halo measures the angle at which the drops meet the glass, an angle which diminishes as the dew evaporates. That the flame is seen at all in good definition is a proof that some of the glass is uncovered. Even when both sides of a plate are dewed the flame is still seen distinctly though with much diminished intensity.

The process of formation may be followed to some extent under the microscope, the breath being led through a tube. The first deposit occurs very suddenly. As the condensation progresses, the drops grow, and many of the smaller ones coalesce. During evaporation there are two sorts of behaviour. Sometimes the boundaries of the drops contract, leaving the glass bare. In other cases the boundary of a drop remains fixed, while the thickness of the lens diminishes until all that remains is a thin lamina. Several successive formations of dew will often take place in what seems to be precisely the same pattern, showing that the local conditions which determine the situation of the drops have a certain degree of permanence.

An interesting and easy experiment has been described by Aitken (Proc. Ed. Soc., p. 94, 1893). Clean a glass plate in the usual way until the breath deposits equally.

"If we now pass over this clean surface the point of a blow-pipe flame, using a very small jet, and passing it over the glass with sufficient quickness to prevent the sudden heating breaking it; and if we now breathe on the glass after it is cold, we shall find the track of the flame clearly marked. While most of the surface looks white by the light reflected from the deposited moisture, the track of the flame is quite black: not a ray of light is scattered by it. It looks as if there were no moisture condensed on that part of the plate, as it seems unchanged; but if it be closely examined by a lens, it will be seen to be quite wet. But the water is so evenly distributed, that it forms a thin film, in which, with proper lighting and the aid of a lens, a display of interference colours may be seen as the film dries and thins away."

"Another way of studying the change produced on the surface of the glass by the action of the flame is to take the [plate], as above described, after a line has been drawn over it with the blow-pipe jet, and when cold let a drop

of water fall on any part of it where it showed white when breathed on. Now tilt the plate to make the drop flow, and note the resistance to its flow, and how it draws itself up in the rear, leaving the plate dry. When, however, the moving drop comes to the part acted on by the flame, all resistance to flow ceases, and the drop rapidly spreads itself over the whole track, and shows a decided disinclination to leave it."

The impression thus produced lasts for some days or weeks, with diminishing distinctness. A permanent record may be obtained by the deposit of a very thin coat of silver by the usual chemical method. The silver attaches itself by preference to the track of the flame, and especially to the *edges* of the track, where presumably the combustion is most intense. It may be protected with celluloid, or other, varnish.

The view, expressed by Mr. Aitken, which would attribute the effect to very fine dust deposited on the glass from the flame, does not commend itself to me. And yet mere heat is not very effective. I was unable to obtain a good result by strongly heating the *back* of a thin glass in a Bunsen flame. For this purpose a long flame on Ramsay's plan is suitable, especially if it be long enough to include the entire width of the plate.

It seems to me that we must appeal to varying degrees of cleanliness for the explanation, cleanliness meaning mainly freedom from grease. And one of the first things is to disabuse our minds of the idea that anything wiped with an ordinary cloth can possibly be clean. This subject was ably treated many years ago by Quincke (Wied. Ann. II., p. 145, 1877), who, however, seems to have remained in doubt whether a film of air might not give rise to the same effects as a film of grease. Quincke investigated the maximum edge-angle possible when a drop of liquid stands upon the surface of a solid. In general, the cleaner the surface, the smaller the maximum edge-angle. With alcohol and petroleum there was no difficulty in reducing the maximum angle to zero. With water on glass the angle could be made small, but increased as time elapsed after cleaning.

As a detergent Quincke employed hot sulphuric acid. A few drops may be poured upon a thin glass plate, which is then strongly heated over a Bunsen burner. When somewhat cooled, the plate may be washed under the tap, rinsed with distilled water, and dried over the Bunsen without any kind of wiping. The parts wetted by the acid then behave much as the track of the blow-pipe flame in Aitken's experiment.

An even better treatment is with hydrofluoric acid, which actually renews the surface of the glass. A few drops of the commercial acid, diluted, say, ten times, may be employed, much as the sulphuric acid, only without heat. The parts so treated condense the breath in large laminæ, contrasting strongly with the ordinary deposit.

It must be admitted that some difficulties remain in attributing the behaviour of an ordinary plate to a superficial film of grease. One of these is the comparative permanence of breath figures, which often survive wiping with a cloth. The thought has sometimes occurred to me that the film of grease is not entirely superficial, but penetrates in some degree into the substance of the glass. In that case its removal and renewal would not be so easy. We know but little of the properties of matter in thin films, which may differ entirely from those of the same substance in mass. It may be recalled that a film of oil, one or two millionths of a millimetre thick, suffices to stop the movements of camphor on the surface of water, and that much smaller quantities may be rendered evident by optical and other methods. RAYLEIGH.

NORTH SEA FISHERY INVESTIGATIONS.[1]

THE third Report on the Fishery and Hydrographic Investigations conducted by the Marine Biological Association under the international organisation is the most interesting yet published. It contains statistical papers dealing with the abundance and migrations of edible fishes in the North Sea; the age and growth-rate of plaice from the same region; and the fishing action of trawl nets with respect to the size of mesh. There are also accounts of the distribution of fish-eggs in the North Sea during the summer, and of the physical conditions of the water of the English Channel, and its contained plankton throughout the year 1906.

The first, and most lengthy, paper in the Report is one of unusual interest and value. In it Miss R. M. Lee has summarised and discussed a series of records kept by the masters of nine Grimsby steam trawling vessels, which fish over the whole of the central part of the North Sea. These records cover the period 1904–8, and represent the results of 14,543 hauls of the otter trawl net, which means about 53,995 hours' fishing. The statistics have been treated most clearly and concisely, and show for each of twenty-three areas into which the whole North Sea has been divided, the monthly average quantities of each of the more important species of marketable fishes caught by the vessels per ten hours' trawling. In order to render these results comparable with those obtained by other statistical workers (Fulton, D'Arcy Thompson, Redeke), the author has calculated factors which enable one fishing unit to be converted into any of the others used.

From these data (which are based on the practical knowledge acquired by a number of very experienced fishermen) Miss Lee has deduced the general distribution of each of the species of fish considered over the whole area of North Sea represented, the migrations from one subarea to others, the spawning movements of the fishes, the variations in density from month to month, and the general change in the productivity of the fishing grounds from year to year. Her paper, and a former one which dealt in a similar way with records kept by a number of Lowestoft sailing-trawler skippers, form a picture of the present condition of the North Sea fishing area which must prove to be of inestimable value for the fishery administrators of the future. If, in the early 'seventies, before steam trawling had become the predominant method of fishing, such a summary by a trained statistician had been made, how much controversy and trouble might have been avoided! Even as it is, a comparison of Miss Lee's results with those imperfect records which we possess of fishery operations in the North Sea in the 'seventies and 'eighties shows most strikingly the change which has taken place, and enables us to realise, to a degree hitherto unattainable, how very great must have been the diminution of the stock of fish inhabiting the North Sea. It is not a question of the decadence of a fishing ground, but rather the fishing-out of an accumulated stock, and the establishment of a new equilibrium, on a lower level, between the natural powers of recuperation of a fish population and the catching power of the British and Continental fishing fleets. And there can be little doubt that, in the absence of concerted measures for cultivation, this equilibrium must settle down to still lower levels. It is sincerely to be hoped that this work may be continued by Miss Lee.

Dr. Wallace has continued his former work on the natural history of the plaice and subjects to detailed analysis, a mass of data representing individual deter-

[1] Third Report (Southern Area), on Fishery and Hydrographical Investigations in the North Sea and Adjacent Waters, 1906–8. [Cd. 5546]. 1911.

minations of length, sex, age, and weight of over 20,000 plaice from various North Sea fishing grounds. The results show clearly that the conditions with regard to nutrition vary from ground to ground, and they suggest that a knowledge of these conditions may, in time, enable fishery authorities to increase the productivity of the North Sea by the "transplantation" of fish from grounds on which the growth is slow to other grounds on which the conditions of life are more favourable. Dr. Wallace's paper supplements that of Miss Lee in that it gives us data which cannot be obtained by ordinary methods of commercial statistics, and which are quite essential for the proper understanding of the latter.

Mr. Todd's experiments on "covered nets" are designed to elucidate the fishing action of the trawl net in respect of the numbers and sizes of fish which escape capture by the mesh employed. The outside parts of the trawl nets used have been covered by other loose nets of narrower mesh, and the fish which have escaped capture by the inner wide-meshed net are intercepted by the outer narrow-meshed net. Mr. Todd tabulates and discusses the results of a number of such experiments.

Mr. Wollaston gives an account of the first cruise made by an English vessel expressly for the purpose of determining, by means of specially constructed nets, the distribution of fish-eggs in the open sea. The cruise was made in June, 1909, in the North Sea, by the vessel *Huxley*, and tables are given which show in detail the results of the experiments made at each observation station, while synoptic charts represent the numbers and distribution of the eggs of certain species of summer-spawning fish present per square metre of sea surface in the neighbourhood of the stations. By far the most interesting part of Mr. Wollaston's paper is that devoted to a description of the methods employed. The net was specially constructed, and its "constants" were calculated so that it was possible to estimate approximately the average volume of water which was filtered through its meshes. Welcome improvements in the methods of preservation of the fish-eggs caught, so as to avoid distortion, and obscuration of finer details of structure have been developed. The author then proceeds to apply the methods of modern biometricians to the analysis of his data. It has hitherto been impossible, in work of this kind, to avoid the confusion of eggs belonging to closely allied species, since in some cases a fish-egg can only be identified by measuring its diameter, and that of the contained oil globule. In some pairs of species these pairs of characters overlap, and it was an error of this nature that vitiated (to some degree) the results of Hensen's famous North Sea cruise of 1895. Mr. Wollaston, however, elaborates a mathematical method whereby the eggs belonging to two such overlapping species can be separated. If in a number of examples of the eggs of one species two measurable variable characters, such as the diameters of the egg and oil globule, be determined, then the frequencies of these two variables can be represented by an equation, which is that of an elliptic "correlation surface." But a group of eggs may include two species allied together in that the diameters of the eggs and those of the oil globules do not differ greatly; nevertheless it is only by these characters that the eggs may be recognised. In such a case the correlation surfaces overlap. Mr. Wollaston then shows that it is always possible, by means of relatively simple mathematical methods, to decompose the compound correlation surface so obtained; and to estimate with a very fair degree of probability the actual numbers of each species of egg in the group. We believe that this method is quite a novel one.

The plankton and hydrographic investigations relate to the year 1906. Mr. Bygrave has given the usual tables recording the distribution and relative density of the planktonic organisms present in the Channel in that year. He shows that the density of oceanic plankton may be correlated with the salinity of the water. The seasonal changes taking place in the abundance of the plankton are also discussed, and the author adopts Brandt's hypothesis, according to which the spring maximum of density of Diatom and Peridinian plankton is the result of the accumulation of food-stuffs in the water during the preceding winter months, while the summer minimum is due to the activity of denitrifying bacteria, which decompose nitrogen compounds, so that the latter cannot be used up by the diatoms.

The hydrography of the English Channel is discussed by Mr. Matthews in a short paper of great general interest. An account, illustrated by charts, of the salinity and temperature variations during the year 1906 is given, and the author then discusses the results of calculations of the mean salinities during the years 1903–9. He shows that in addition to the annual salinity variation, there is a two-yearly periodic change, of such nature that the "even" years are characterised by a high range of salinity variation, while in the "odd" years the range of variation is low. The annual and biennial periods are superposed on a longer one, probably twelve-yearly. These discussions anticipate a further paper, which promises to be one of very great interest.

J. JOHNSTONE.

A ONE-VOLUME NATURAL HISTORY.[1]

TO compress even a sketchy account of the leading types of existing animals into a small octavo volume of just over 560 pages, and that illustrated by a number of relatively large figures, is a task of stupendous difficulty. In the present instance the author has increased the difficulty by introducing—

FIG. 1.—A Chinchilla. From the "New Illustrated Natural History."

probably in accordance with what I believe to be a mistaken notion on the part of publishers—a number of anecdotes, which merely waste space. This may perhaps account for the very imperfect diagnoses of most of the groups and species, which appear in many cases insufficient for their identification by those who

1 "New Illustrated Natural History of the World." By E. Protheroe. Pp. xx+564. (London: G. Routledge and Sons, Ltd.; New York: E. P. Dutton and Co., n.d.) Price 7*s.* 6*d.* net.

are not naturalists, and for whom alone the volume is intended. As is usual in works of this nature, vertebrates claim the lion's share of the volume, the lower groups being accorded only sixty-eight pages, which is, of course, an altogether inadequate proportion of space.

Nevertheless, Mr. Protheroe has succeeded in producing a readable, and certainly a remarkably well illustrated volume, which is calculated to attract a large circle of readers. With the exception of the twenty-four coloured plates, the illustrations are from photographs, some of which are naturally better than others. In some instances the photographs, like the one of a tur (p. 169), are taken from immature specimens, which convey no idea of the adult animal. In other cases, as in the so-called Canadian skunk

FIG. 2.—A Marabou Stork. From the "New Illustrated Natural History."

(p. 95) and dwarf buffalo (p. 162), animals are wrongly identified; while in the figure of a wild ass (p. 155) the reader is left to discover for himself whether it is intended for an Asiatic or an African species, and there is no reference in the text to the figure of an "Australian Rail" on p. 366. As regards the coloured plates, it will perhaps suffice to say that while some are excellent, the others are probably the best that could be produced for the money; but in the figure supposed to represent the black rhinoceros it seems as if the artist had made a "composite" portrait of the African and the great Indian species. Two photographs are reproduced as samples.

As regards the text, this, in addition to much more or less irrelevant matter, is marred by a large number of omissions and errors, of which only a few, and these in the sections on mammals and reptiles, can be mentioned here. In the Insectivora, for instance, no mention is made of Chrysochloridæ, Gymnurinæ, Solenodontidæ, or Potamogalidæ, while the Centetidæ are intercalated between Tupaiidæ and Macroscelididæ, and the reader is left to find out for himself the genus name of the typical representatives of the latter. Space for these omissions might have been found by cutting down the account of monkeys. Among the rodents, Pedetes is still classed with the jerboas (p. 126), and is said to be "a very similar species," while American porcupines are not separated as a family from their Old-World relatives.

Passing to ungulates, it may be noted that Grévy's zebra (p. 156) is stated to range "the Victoria Nyanza regions," whereas its habitat is east and north of that lake; and that not a word is said with regard to the range of the white rhinoceros (p. 152). On p. 169 we are informed that the Alpine ibex is "the most probable forbear of the common goat," and on p. 171 that the takin "is a native of the highest and least-known regions of Tibet." Perhaps, however, the worst misstatement in the book occurs on p. 241, where it is asserted that the opossum family is "remarkable among the marsupiated animals, because it is the only one that is not Australian." Has the author never heard of Cænolestes?

Among the reptiles it must suffice to state that there is no mention of Schlegel's gharial, that the reader is left to find out for himself what part of the globe is the home of the Chelydridæ (p. 404), and that it is scarcely true to say that the tuatera has teeth on the palate (p. 428).

Although the book has merits, I am driven to conclude from the foregoing and other instances either that the author is terribly careless, or that he is not up to his work.

R. L.

PROF. JOHANNES BOSSCHA.

THE career of this eminent physicist has not only been of importance for the advancement of physics, but also of the greatest benefit to the development of exact science in Holland. Born on November 18, 1831, at Breda, Bosscha was initiated in physics by van der Willigen, and entered the University of Leiden in 1850. His eminence as a student in different respects foreshadowed the leading position he occupied in later life. In Bosscha's later observational work the influence of the great astronomer Kaiser is evident. In March, 1852, he took his degree with a dissertation on the differential galvanometer, worked out in the Physical Laboratory at Leiden, then under the direction of Rijke. After a short stay at Berlin, he returned to this laboratory as assistant. Attention was soon directed to him by the vigorous part he took in the great scientific movement in connection with the law of conservation of energy. The most important problem dealt with in his well-known papers on the mechanical theory of electrolysis is the test of Kelvin's calculation of the electromotive force of a galvanic cell from the heat developed by the chemical processes which accompany the current. By determining in absolute measure the electromotive force of the Daniell cell, he contributed to the work which ultimately led to the adoption of the C.G.S. system of electrical units. He gave a solution of multiplex telegraphy, and several rules

and methods introduced by him have passed through the text-books into the electrotechnic practice.

In the time that separates this period of experimental activity from its resumption in 1873 fall ten years devoted to the organisation of secondary education and the reorganisation of the higher technical instruction in Holland, which have proved a great boon to the country. The secondary schools have spread enlightenment everywhere, and, providing everywhere the preparatory instruction necessary for attending the polytechnicum, they laid the foundation for the development which technics have taken in Holland. Equipped as they were by Bosscha's influence with physical and chemical laboratories, they have since attracted to science the greater number of the men of the present generation that have devoted their life to it. Though absorbed in this very successful organising work, Bosscha found time for his discussion of Regnault's measurements, which added much to the value of these classical researches.

Professor since 1873, and director of the Polytechnicum at Delft since 1878, Bosscha found the opportunity to continue his efforts for the reorganisation and development of this institution. He was foremost among those who raised its status to that of a technical university, what it afterwards became officially. Bosscha's clear and fascinating lectures live in the grateful memory of broad circles of his pupils. He was the acknowledged master in criticism of experimental methods. To have felt the influence of his insight, inspiration, and high aims was to be full of admiration and gratitude for one's life. The main scientific work undertaken by Bosscha in this period was in relation with the new Dutch standard metres; an investigation of Fizeau's focussing method was the starting point for a study which led him to the development of a complete theory of centred optical systems. The series of Bosscha's metrological researches will always be regarded as a masterpiece of scientific work of precision.

To uphold Holland's honour in the domain of science was Bosscha's constant aim all his life. Having accepted in 1885 the secretaryship of the Dutch Society of Sciences at Haarlem, he became the soul of this institution. His manifold occupations—it will suffice to mention the reorganisation of the Dutch Meteorological Service—were all directed to the promotion of science, the extension of its influence, and the increase of sympathy for Dutch science abroad. Working to the end of his life with unimpaired power of thought, vivacity of appreciation, and glowing love for what was right, serving science with his enthusiasm and eloquence, he was always honoured by the Dutch physicists as their leader. The last years of his life were devoted to the edition of Huygens's correspondence and works. To his literary talents and his passionate love for historical justice we owe many vivid pictures of past scientific life. As to Huygens, it may be said that he was resuscitated by Bosscha, and no less talents than his were needed to get all from Huygens's hand presented to the scientific world in a form corresponding to Huygens's greatness.

Bosscha's increasing veneration for Huygens was well in harmony with his own searching love for truth, his aristocratic turn of mind, and his profound sense of beauty. He combined great courage and force of mind with an almost childlike simplicity and trustfulness and an infectious optimism. We lose in him a noble, frank character, and a friend to whom one never went without being warmed by his kind affection and stimulated by his faith that the future belongs to the great ideas.

H. KAMERLINGH ONNES.

NOTES.

DR. FREDERIC A. LUCAS has been appointed to succeed Dr. H. C. Bumpus as director of the American Museum of Natural History, New York, and will take office on June 15. The new director, who is now in his sixtieth year, has been chief curator of the Brooklyn Institute of Arts and Sciences since 1904. He had previously served for twenty-two years in various posts in the U.S. National Museum at Washington. As an author he is best known for his books and papers on palæontology and comparative anatomy, as well as on museum methods.

PROF. UGO MONDELLO, director of the geophysical observatory at Leghorn, has accepted the post of director of the Observatorio Regional do Rio Grande do Sul, Brazil.

LORD CURZON OF KEDLESTON has been elected president of the Royal Geographical Society in succession to Major Leonard Darwin. Captain H. G. Lyons, F.R.S., has been appointed one of the honorary secretaries, and Sir G. D. Taubman Goldie, F.R.S., the foreign secretary, of the society.

THE Hanbury medal of the Pharmaceutical Society for 1911 has been awarded to M. Jean Eugène Léger, of Paris. The new medallist is chief pharmacist to the Hôpital St. Louis at Paris, and a member of the committee of revision of the French pharmacopœia.

DR. J. G. FRAZER (author of "The Golden Bough," &c.) has been elected a member of the philosophical-historical section of the Royal Academy of Sciences of Berlin.

WE regret to have to record that at the Paris-Madrid aëroplane race at Issy-les-Moulineaux on Sunday last a deplorable accident occurred, causing the death of M. Berteaux, the French Minister of War, and severe injuries to M. Monis, the French Prime Minister. It appears that one of the competitors in the race, M. Train, finding that neither the engine nor rudder of his machine was working satisfactorily, decided to descend, and in endeavouring to avoid coming into contact with a detachment of cuirassiers and the spectators, dashed into the group of Ministers and their party, who only came into the aviator's view as the cuirassiers rode clear of the group, with the lamentable result given above.

WE announce with deep regret the death, on Saturday last, at the age of eighty-seven years, of Dr. N. Story-Maskelyne, F.R.S.

WE regret to notice the death, which took place on Monday last, of Mrs. W. P. Fleming, the curator of astronomical photographs at Harvard.

THE death is announced of Prof. B. Peter, for many years the first assistant at the Leipzig Observatory. Prof. Peter was born at Weida, in Saxe Weimar, in 1853, and studied medicine at the University of Jena, but his liking for mathematics and natural science led him to accept a position, under Prof. Karl Bruns, at the Leipzig Observatory in 1876. Six years later he was advanced to the position of first observer, and in 1899 was named professor of practical astronomy, holding both posts until his death.

MR. ROBERT SERVICE, who has just died at Dumfries, was one of the best naturalists in Scotland. His profession of nurseryman and seedsman prevented his attending a university, and also involved close attention to business for every working day. Nevertheless, he knew intimately the haunts of every bird in the south of Scotland. Not only so, but he thoroughly understood

mammals, fishes, Amphibia, and reptiles. He was an excellent entomologist, and took an especial interest in bees and the larger Diptera. Most unfortunately, his published papers represent but a very small part of this wide acquaintance with birds and beasts of all kinds. He was never able to afford the heavy cost of publication which must, for some inscrutable reason, always be incurred in Great Britain if a book is of a scientific nature. Much of his work is included in the recent "Birds of Dumfriesshire," by Mr. H. S. Gladstone, but by far the greater part of it is lost. It is by no means unusual for working men to be real naturalists, at least in Scotland; but Robert Service was far more scientific, and had a far wider knowledge than even Edwards and Dick, whose names are known to the general public. He managed somehow to keep abreast of modern authorities, in spite of the difficulties involved by residence in a small country town. His death is a serious loss to the natural sciences in the south of Scotland, and under present conditions it is a loss that cannot possibly be repaired.

The Times announces that enough money having been raised by subscription for the erection of a statue to Captain Cook, permission has been given for the statue to be placed on the Mall side of the Admiralty arch, at the end of the Processional road, on the right hand going towards Charing Cross, and the execution of the statue has been entrusted to Sir Thomas Brock, K.C.B., R.A.

According to *The Pharmaceutical Journal*, a statue to the memory of Priestley is to be erected in the market-place of Birstall, the town of his birth.

The committee of the Robert Koch memorial endowment for the encouragement of research in the subject of tuberculosis has decided to give grants to Prof. Schieck and Dr. Krusius for investigations on tuberculosis of the eyes, to Dr. Weinberg for statistical inquiries relative to tuberculosis, and to Prof. Gaffky for the continuation of his researches. Since the year 1908 the sum of 3600*l.* has been expended by the committee in scientific work.

The new Research Institute of the Cancer Hospital was opened on Tuesday by the Duke of Connaught, who said he hoped that the institute might be the forerunner of wonderful discoveries in combating the disease of cancer, and that success would be the result of the labours of those who should engage in research.

The conversazione of the Royal Society of Arts will be held on Tuesday next—May 30—in the galleries of the British Museum (Natural History), from 9 p.m. to 12.

On Tuesday next Prof. W. W. Watts will deliver the first of two lectures at the Royal Institution on "Charnwood Forest: its Ancient Volcano and its Fossil Landscape"; on Thursday, June 1, Mr. T. Thorne Baker begins a course of two lectures on (1) "Changes Effected by Light," (2) "Practical Progress in Wireless Telegraphy"; and on Saturday, June 3, Dr. W. L. Courtney begins a course of two lectures on "Types of Greek Women." The Friday evening discourse on June 2 will be delivered by Commendatore G. Marconi on "Radiotelegraphy," and that on June 9 by Prof. Svante Arrhenius on "Applications of Physical Chemistry to the Doctrine of Immunity."

The fifty-fourth general meeting of the Institution of Mining Engineers will take place on Thursday, June 1, in the rooms of the Geological Society. The following papers are announced for delivery:—A flame test for the estimation of oxygen and black-damp in naked-light mines, by Dr. J. S. Haldane, F.R.S.; An experiment on the effect of reversing the main air-current, by Mr. J. Bain and Dr. J. S. Haldane, F.R.S.; Notes on contrivances designed to prevent over-winding, with some instances of their failure, by Messrs. W. H. Pickering and G. Poole; The Otto-Hilgenstock direct-recovery process and its application, by Mr. E. Bury. The following papers, which have already appeared in the Transactions, will be open for discussion:—The mining school at Bochum, Westphalia, by Prof. H. Louis; Progress in the use of exhaust seam-power, by Mr. J. Burns; The Elliott-Jones vertical coke-oven, by Mr. T. C. Futers.

An International Rubber and Allied Trades Exhibition will be held in the Royal Agricultural Hall from June 24 to July 14, and on July 3 there will be a rubber conference at which the many problems in connection with the industry will be discussed.

The eighth International Congress of Applied Chemistry is announced to be opened, at Washington, by the President of the United States on September 4, 1912; the further meetings of the congress will be held in New York from September 6 to 13. The congress will be divided into twenty-three sections and subsections, and papers intended for presentation or publication should reach the American committee not later than July 1, 1912.

The preparations of the German Antarctic Expedition were completed at the beginning of May, and on May 7 the *Deutschland* sailed from Bremen. Lieut. Filchner will join the ship in Buenos Ayres in four months' time, whither additional stores and equipment are also being sent. The general plan is to enter the Weddell Sea to the south of South America, and endeavour to establish the relation of the masses of land lying east and west of the South Pole. Great importance is attached to the installation of a land station and its maintenance for so long a period as possible. From this point geographical, geological, astronomical, magnetic, meteorological, and biological work will be carried on by the staff of eleven members of the expedition, who will be here quartered. Four of them will make a dash for the South Pole with Nansen sledges. The ship, the *Deutschland*, is a converted whaler with auxiliary steam of about 300 horse-power, and has been especially fitted with a view to the comfort of the explorers. She is equipped with a wireless telegraph installation, and is taking out three motor vehicles and one motor boat, since motor transport is to be largely employed, though both dogs and Manchurian ponies are also to be utilised.

Speaking in the House of Commons on Wednesday of last week on the Budget proposals, Mr. Balfour asked the Chancellor of the Exchequer to exercise caution in carrying out his scheme for the expenditure of large sums of money on building consumption sanatoria. In the public mind, he said, there had perhaps been an exaggerated enthusiasm for this method of dealing with tuberculosis. There was an idea that this open-air treatment had produced such marvellous results that through it alone tuberculosis could be, if not exterminated, at all events diminished to such an extent that it might be reduced to one of the rare zymotic diseases. He was not sure that the most recent investigations bore out that view. There were very able investigators who took the view, after examining the actual results in this country and in Germany, that so many complete cures must not be expected as was at one time hoped for. He took a sanguine view as to the treatment of tuberculosis, for he believed that science had made great strides and was still destined to make great strides, but

when they came to such large sums as those mentioned by the Chancellor of the Exchequer, it was possible to waste money on permanent buildings which might be better devoted to scientific investigation into the cause of the disease. They must not assume that all that they had to do was to spend money on these sanatoria in order to effect a cure. What was important was that medical science had made great progress, and we required further investigation and perpetual study as to how these people were to be treated when in the sanatoria. One of the greatest benefits, perhaps, of establishing these sanatoria would be in giving expert medical authorities the opportunity of carrying on investigations which would enable them in the future to deal with this disease in a way they were not able to do at present. In reply, Mr. Lloyd George said he agreed that the important thing was to encourage scientific investigation, so as to arrive at the best methods of cure. That was provided for in his Bill. There would be set aside a special fund for the purposes of scientific research. The Government would make use of and assist existing sanatoria, those which had been maintained by voluntary contributions, and even those which were built by private enterprise.

At a meeting of pathologists interested in medical museum work, recently held at the Royal College of Surgeons of England, for the purpose of receiving information upon the International Association of Medical Museums, and with a view to extend the membership and general usefulness of that body in Great Britain, the following resolutions were passed:—(1) That after the arrangements for the meeting of the International Congress of Medicine at London in 1913 are completed, steps shall be taken to arrange for a meeting of the International Association of Medical Museums in conjunction with this congress. (2) That the three great English medical societies, namely, the Pathological Society of Great Britain and Ireland, the Anatomical Society, and the Royal Society of Medicine, be made cognisant of the action of the International Association of Medical Museums, and that cooperation with these societies be attempted with special reference to the publication in their journals of the Department of Exchanges, as well as announcements and short reports of meetings. (3) That one or more correspondents in London be appointed to act as local secretaries.

The Entomological Society of London held a Conversazione on Wednesday, May 17, in the rooms of the Linnean Society, which had been kindly lent for the purpose. The exhibits were very varied, and there was much to interest the non-entomological as well as the scientific portion of the assembly. The "livestock," including Observation Nests of ants with various myrmecophilous insects, shown by Messrs. Donisthorpe and Crawley, larvæ and pupæ of British Lepidoptera by Mr. Newman, fleas with ova, larvæ, and cocoons by Mr. Bacot, and "stick insects" in every stage of development by Mr. Baldock, were a constant source of attraction. Many fellows exhibited interesting and attractive insects of various orders, including eight drawers of mimetic Lepidoptera brought by Prof. Poulton, the three newest European butterflies (*Callophrys avis*, *Pieris manni*, and *Erebia palarica*) by Dr. Chapman, the pick of the results of thirteen years' breeding of *Angerona prunaria* by Mr. Pickett, and a wonderful drawer of gynandromorphs from the Tring Museum. There were several microscopic and photographic exhibits, Mr. Main's stereoscopic photos and Mr. Enock's Mymaridæ deserving special mention, while further variety was secured by Mr. Eltringham's and Mr. Wheeler's water-colour drawings of butterflies, Mr. Prideaux's method of scale-transference, Prof. Image's interesting books, including Stainton's annotated copy of Wood's "Index Entomologicus," the Obligation Book of the Society with its many interesting autographs, and the various relics of Linnæus exhibited by the Linnean Society. During the evening lectures were given, with lantern illustrations, by Prof. Poulton on "Recent Discoveries in Insect Mimicry," and by Mr. Enock on the Tiger Beetle (*Cicindela campestris*).

A communication has been received from the Decimal Association directing attention to a recent report of the council of the British Medical Association with reference to the adoption of the metric system of weights and measures by medical practitioners. This report recommends that both the theoretical and the practical instruction of medical students in pharmacology and materia medica should henceforth be according to the metric system. As regards practitioners who have been trained in the imperial system of weights and measures, the suggestion is put forward that a transitional procedure should be adopted which, while immediately introducing some of the advantages of the metric system, would also facilitate the change from the old system to the new at a later date. Cooperation with pharmacists will be necessary in order to deal with cases where prescriptions are given to be made up by any chemist the patient may choose. It is recommended that the local divisional bodies should, after ascertaining that medical opinion in their district is ripe for the step, arrange a conference with the local pharmaceutical association in order to arrive at a mutual understanding in the matter.

Mr. P. W. Stuart Menteath continues in *Biarritz-Association* his somewhat controversial papers on "Les Gisements metallifères des Pyrénées Occidentales." Despite the title adopted, the work is mainly directed against the too hasty adoption of the theory of recumbent overfolds as an explanation of the facts of mountain-structure. Numerous sections illustrating the author's observations are given in the third part (March, 1910). The fifth part (March, 1911) criticises the views of Pyrenean structure held by M. Dalloni; but the arguments are marred by a certain obsession in regard to "Darwinisme," the evolutionary theory being held responsible for most of the errors of geologists. Perhaps the same obsession explains a mysterious allusion, at the conclusion of part iv., to the reduction of our "facultés légitimes à celles des singes et des perroquets." Where the author emphasises the effects of ramifying igneous injections, associated with mineral veins, in inducing metamorphism, he seems to be on more serious and surer ground.

The *Geologische Rundschau* continues to provide admirable essays on current work and problems in geology, in addition to original papers. The "Besprechungen" themselves are original, in that they consist of critical reviews by specialists. H. Potonié brings together his own results under the head of "Kaustobiolithe" in part vi. of the first volume, p. 327 (December, 1910). In the following part (March, 1911), R. Lepsius urges that the high watershed in Scandinavia lay to the east of the present one in glacial times, and thus allowed of the recognised movements of the ice. He does not approve of the theory of the ice-dome, and prefers to rely on considerable warping and faulting of the country to account for its present general contour and the basins of many of its lakes. Critics may point out the evidence that exists in Jämtland and

elsewhere of the movement of ice over obstacles rising 1000 metres or more above the glaciated valley-floors. W. von Seidlitz describes in the same number the adventurous excursion organised by Axel Hamberg for five members of the International Geological Congress of 1910. The six geologists, in visiting the Sarek Mountains in Lapland, required a train of six Lapps and twenty-four reindeer. The masses of crystalline rocks overthrust on Silurian strata proved of special interest. In volume ii., part ii. (May, 1911), O. A. Welter notices seventy-three recent papers on nephrite.

The fourth annual meeting of the American Peat Society was held in Ottawa in 1910, and the proceedings are recorded in full in the journal of the society issued for January, 1911, and published at Toledo, Ohio. The members look to the future rather than to the present; but the rapid consumption of coal-supplies gives a patriotic importance to those who try to develop the use of peat. Of course, the manufacture of ammonium sulphate also comes under consideration. The Canadian Department of Mines has issued a second edition, with maps and engineering drawings, of Bulletin No. 4, on the "Investigation of the Peat Bogs and Peat Industry of Canada during the season 1909–10." The author is Mr. A. Anrep, jun., peat expert, and valuable papers are translated from foreign sources. That on the Ekelund process for drying powdered peat at a high temperature is likely to attract the most attention.

Mr. C. D. Walcott has carried the history of the indubitable Merostomata back into Middle Cambrian times (Smithsonian Miscellaneous Collections, vol. lvii., No. 2, April 8). Two new genera, Sidneyia and Amiella, are described by him from the Rocky Mountains near Field, on the Canadian Pacific Railway, and are the result of a laborious and systematic examination of the strata. Both genera fall into a new sub-order of the Eurypterida, the Limulava, with four pairs of cephalo-thoracic appendages and simple antennæ, in this resembling the trilobites. Beltina, the fragmental pre-Cambrian form regarded as a Merostome, receives further discussion and illustration, but Redlichia, of the Lower Cambrian of Indo-China, is styled "the oldest Merostome now known."

Museums in America are in the fortunate and enviable position of being able to draw, in addition to their regular State grants, large pecuniary contributions from private benefactors. In the report for 1910, the American Museum of Natural History acknowledges its indebtedness to this source of revenue, the president remarking that while the "income from endowment has not materially increased, the total gifts towards exploration and exhibition exceed those of any previous year in the museum's history." Even so, the financial resources appear unequal to the demands upon them, for it is further stated that "the addition of three new departments since 1907, namely, of Living Fishes and Reptiles, of Woods and Forestry, and of Public Health, has made serious demands upon our income. . . . Thus the increased endowment afforded by Mr. Jesup's bequest, which cannot by its terms be used for any item of maintenance, is offset by these increases." Among the additions to the exhibited collection, mention may be made of a group of Pribilow sea-bears, of which a photograph is given in the report. A special feature of the year was the unusual number of collecting expeditions, of which there were ten to various parts of the United States and fourteen to other territories.

In *The Field* of May 13 Sir Ray Lankester gives, under the title of "The Earliest Picture in the World," an illustrated description of a cylinder of stag's antler found in 1875 in the cavern of Lorthet, near Lourdes, Haute Pyrénées, on which are incised figures of three red deer and several salmon-like fish. The specimen belongs to the Elaphotarandian epoch, when the Arctic fauna was being replaced by the animals characteristic of modern Europe. The author gives a flat picture printed off from the cylinder, and adds two restorations of the missing portions of the figures of the deer. In his opinion, the prehistoric engraver worked from a similar flat picture, and it is further suggested that incised cylinders of this type were used by their makers as "blocks" from which to print impressions on birch-bark and other suitable materials.

To *The Times* of May 15 Dr. Shipley communicates a letter on the so-called "eale" or "yale," in which it is pointed out that the original account was given by Pliny, from whom Topsell seems to have derived the materials for a fuller notice in 1607. These accounts present the animal in a somewhat different guise from those previously quoted. It is described as of the size of a hippopotamus, with an elephant's tail, a black or tanny colour, the jaws of a boar, and two horns, which could be moved independently of each other, of more than a cubit in length. Topsell adds that it was fond of water. Its home was Ethiopia. If the statement as to its size be trustworthy, the only animal that would accord with the description would be an African rhinoceros; and we believe there are legends as to the mobility of the horns of the latter. On the other hand, rhinoceroses were known to the ancients. Whatever be the truth on this matter, it seems impossible to identify the antelope-like or goat-like animals in the arms of Christ's College with Pliny's eale.

According to the report for 1910, the Natural History and Polytechnic Society of Bootham School, York, continues to attract a satisfactory number of working members, the natural history section including sixty-five scholars. Meetings and excursions were held from time to time, and the admirable practice of inducing the members to keep diaries, based on actual observations, has been continued.

The hon. secretary of the Selborne Society informs us that the nesting boxes made from natural logs which the society introduced at the beginning of the year have been very successful. In some cases correspondents (who number well over seven hundred) have had all the boxes which they have put up tenanted, and a special experiment made in the Brent Valley Bird Sanctuary has resulted in possession being taken of all but one of the boxes concerned. The committee of the society has arranged an exhibition of the boxes in the science section of the Coronation Exhibition, and photographs of the boxes, showing the nests within and the birds sitting, will be published in "The Country Home" for June.

The report of the advisory committee for the Tropical Diseases Research Fund for the year 1910 (Cd. 5514, 128 pp.) shows that the campaign against these diseases is being prosecuted vigorously from the several aspects of prophylaxis, treatment and research into the structure, life-history, and modes of transmission of the causal organisms. Prof. Ross and Dr. Thomson have shown that, by the use of improved methods, malarial parasites can be found in the blood in the apyrexial periods, occurring in numbers so small as 20 per cubic mm. Relapses are thus explicable as the result of the usual mode of increase in the number of such parasites; the presence of crescents reproducing parthenogenetically is not essential for the production of a relapse. Dr. Wenyon has given

an account of his investigations, carried out at Bagdad during the summer of the past year, on Oriental sore; his experiments indicate that Stegomyia is under suspicion as the transmitter of this disease. Numerous other important researches, completed or in progress, are reported upon, *e.g.* by Prof. Minchin on trypanosomes and fleas, Dr. Woodcock on Halteridium, Dr. Castellani on a type of bronchitis common in Ceylon, and due apparently to the attack of a new species of the fungus Oidium, Drs. Fraser and Highet and others on beri-beri in the Malay States and Siam.

To the Bulletin of the Johns Hopkins Hospital for May (vol. xxii., No. 242) Dr. Pearce Bailey contributes an article entitled "A Florentine Anatomist." This is no other than that versatile genius Leonardo da Vinci, who planned to write a treatise on anatomy in one hundred and twenty volumes, and left note-books rich in drawings with marginal explanations, and he was the first to acquire an accurate knowledge of descriptive anatomy. A short biographical sketch of Sir Richard Owen is also contributed by Dr. Rohrer, with four characteristic portraits and an illustration of Sheen Lodge, where his last days were passed.

THE catalogue of additions to the library and the list of new garden plants of the year 1910 have been issued as Appendix II. and Appendix III. to the current volume of *The Kew Bulletin*. In the former the printing is confined to one side of the page, so that the titles may be cut out and used as index slips; the latter provides an authentic list of correct names. As in recent years, an outstanding feature of the new garden plants is the predominance of Chinese novelties, although, except for eight species of Rubus, the additions are scattered through numerous genera; the introductions traceable to Mr. E. H. Wilson's last journey are beginning to arrive through the Arnold Arboretum and other sources. Several fine orchids have, as usual, been introduced by Sir Trevor Lawrence; among those which gained botanical certificates were *Megaclinium fuscum* and *Polystachya paniculata* from Africa, and *Dendrobium karoense* and *Bulbophyllum polyblepharon* from New Guinea.

A NUMBER of new records of flowering plants and ferns for the National Park, Wilson's Promontory, Victoria, are noted by Mr. J. W. Audas in *The Victorian Naturalist* (vol. xxvii., No. 11), which raise the total to 600 species. Amongst them are species of Pterostylis, Xanthosia, and Hydrocotyle, an uncommon creeper, *Myriophyllum amphibium* and *Selaginella Preissiana*. The list includes some apparent aliens, such as *Fumaria officinalis, Nasturtium officinale*, and *Spergularia rubra*. Several plants were noted as rapid colonisers on burnt ground, of which *Burchardia umbellata* was the most conspicuous. A succulent form of *Stackhousia umbellata* was found on the beach where the crimson and occasionally white-flowered *Kennedya prostrata*, the "running postman," attracted attention; on the sand dunes, the grasses *Spinifex hirsutus* and *Festuca littoralis* proved their value as efficient sand binders.

AN interesting report on the progress of agriculture in India is issued from Pusa. The improvements in cotton-growing are now making themselves felt in many thousand acres of the great cotton areas in the presidencies of Bombay and Madras and in the Central Provinces, while the plant-breeding work of the United Provinces seems likely materially to improve the crop there. Special mention is made of the wheat-breeding experiments, which have now reached considerable dimensions, and have resulted in the production of varieties better in quality than anything yet grown in India. Progress is also recorded in the reclamation of the salt lands of Sind, and in the rigorous campaign against the palm disease in the Godavery delta, which has resulted in the saving of lakhs of rupees every year. Progress in agricultural education has, however, been slower than in investigation, but the cause is not far to seek—colleges have had to be built and staffs collected before much could be done. But the beginning is made, and good work may be looked for here also.

WE have received copies of the South African National Union Journal, the organ of a society having for its object the encouragement of South African industries. A number of articles are published showing the products that South Africa can supply for which there is a good market, and we note that stress is laid on the importance of keeping up the supplies of maize and of bacon. Mr. Burtt Davy writes on the value of peanuts for human food, and argues that, for the strict fruitarian, peanuts are not only the cheapest, but also the best source of energy.

THE opening up of British West Africa is dealt with at some length in No. 4 of *Tropical Life*. The five colonies S. Nigeria, N. Nigeria, the Gold Coast, Lagos, and Sierra Leone can, it is claimed, produce nearly every important tropical product except perhaps tea and sugar. Much, however, is needed in the way of organisation; trade routes are needed, land laws require amending, and labour supplies have to be arranged. An association has recently been formed with the object of accomplishing some of these objects.

WITH characteristic thoroughness, the Americans are introducing agricultural education into the Philippines. It is less than two years ago that the first agricultural college was started at Los Baños with twelve students, the classes being held in tents, with no appliances, not even blackboards, at first, and with so few seats that the students had to carry their stools about with them. Now it has a hundred students, laboratories, and class-rooms, and by next year will have accommodation for five hundred students. We have received the first two numbers of its journal, *The Philippine Agriculturalist and Forester*, published by the "student body" of the college, and containing interesting accounts of agriculture as it now is, and of possible improvements on present methods.

IN the year 1907 the Jamaica Weather Service, which had been dormant for some years, was resuscitated and associated with the United States Weather Bureau, which placed at its service an electrical recording anemometer by Friez, designated a "triple register." The Kingston Observatory has now published the results of wind direction and velocity between August, 1908, and July, 1909, for each hour and month. The tables show in all months a gradual increase in velocity from midnight to 1h. or 2h. p.m., followed by a decrease. Another prominent feature of the diurnal range is the sudden decrease for a little time just after sunrise, owing probably to the gradual disappearance of the land breeze. By extracting the number of miles from each direction, it is shown that 51·2 per cent. of wind comes from the S.E., and 23·9 per cent. from the north (land wind). The average hourly velocity of the former is 11·2 miles, of the latter only 4·0 miles. The annual resultant derived from the hourly components is E.S.E. ¼ E. 2·5 miles per hour. During the period under review the greatest hourly velocity was 30 miles (factor 3).

AN average rainfall map with isohyets of Victoria compiled from yearly records available for a period of 15 years

and upwards has been received from the Central Weather Bureau at Melbourne. It has been drawn to the same scale as that of New South Wales (published last year), the two forming a comprehensive and valuable rain-chart of the south-eastern portion of Australia. The average rainfall of Victoria is 27·19 in., ranging from 10·80 in. in the Mallee district (north-west) to 68·75 in. in Cape Otway Forest district (south). The map shows an approximate distribution as follows:—40–> 60 in. over an area of 12 thousand square miles; 20–40 in. over $43\frac{1}{3}$ thousand, and < 15–20 in. over $32\frac{1}{2}$ thousand square miles. The great influence of proximity to the mountains and seashore is plainly shown; the abundant rains on the Australian Alps, Cape Otway, and Gippsland ranges being particularly conspicuous.

IN a paper read before the Royal Photographic Society, Mr. Chapman Jones dealt with the relationship between the size of the particle and the colour of the image in the case of lantern-slides developed to show a coloured deposit. The author referred to Zsigmondy's statement that the colour of colloidal solutions has no direct dependence upon the size of the particle, and his suggestion that the cause of the colour is not to be sought for in the sizes of the particles, but rather in the distances between them. Mr. Chapman Jones has investigated the matter, not by the usual ultramicroscopical method, but by enlarging the particles by mercurial intensification. Mercury is added in definite proportions by treating the film containing the particles first with mercuric chloride and then with a ferrous oxalate developer, each treatment adding one atom of mercury to each atom of silver, or of silver and of mercury that is present, the linear enlargement for eight enlargements, the maximum employed, being 7·134. The enlarged particles were then measured by means of a microscope and eye-piece micrometer, the accuracy of measurement being about 5 per cent. The results obtained showed that films that gave the same colour contained particles of approximately the same diameters, particles below 0·10 micron giving no visible colour; particles from 0·10 to 0·13, yellow; from 0·14 to 0·17, orange; from 0·17 to 0·19, pink, brown, or purple; and particles above this size, grey. No connection between the distance apart of the particles and the colour was found, but a measurement of the refractive index of gelatin and calculation of the half wave-length of light in gelatin, showed that the size of the particle giving a definite colour could be taken to correspond approximately with the half wave-length of light the absorption of which would give that colour, the particles being rather smaller than the calculated half wave-lengths. The authors conclusions are that the size of the particle is the determining factor in selective scattering, and that light is scattered by particles that approximate in diameter to half a wave-length of the scattered light.

Himmel und Erde for April 29 contains an article by Prof. B. Donath, of Berlin, on the gyrostat and its technical future. After explaining the precessional motion of a gyrostat by means of the ordinary toy, Prof. Donath gives an account of Schlick's application of the gyrostat to the diminution of the rolling motion of ships, and hints that a similar device may in the future form part of the equipment of the aëroplane. The greater part of the article is devoted to the applications of the gyrostat to mono-rail transport by Brennan and by Scherl, and to the gyrostatic compass by the brothers Anschütz. In the case of the compass, the theory is clearly explained, and views of the various parts of the instrument are given. The author is naturally optimistic as to the future of the compass, but expresses himself more guardedly as to that of the mono-rail.

THE opportunity for the dissemination of nature knowledge offered by the boy scout organisation should not be lost sight of by those who desire to see the study of natural phenomena become more popular in the future than it has been—unfortunately for us and for our boys and girls—in the past. A lecture recently delivered in Leeds by Mr. Elgie was, according to *The Leeds Mercury*, attended by some 400 of the scouts, who paid enthusiastic attention to the lecturer's instruction as to the apparent movements of the stars, their grouping in constellations, and the simpler methods by which geographical direction may be ascertained from observation of the heavens. These same subjects are, we understand, also dealt with by Sir Norman Lockyer, in an additional chapter, in the new edition of his "Primer of Astronomy"; in this chapter the author shows the disposition of the most easily recognised asterisms throughout the year, so that the scout may, on recognising any group of stars, determine at once the cardinal points, and so find his direction. Workers in other fields of science, *e.g.* geology, botany, &c., might usefully give a little time to the simple instruction of the young people already so admirably organised by the general movement.

The Cairo Scientific Journal for April contains a paper on work under compressed air at the Boulac Bridge, read by Mr. Arthur J. Knowles before the Cairo Scientific Society on March 2. The Nile at Boulac is very deep; in places there are more than 66 feet of water at low Nile. The number of men who actually worked in compressed air during the sinking of the piers and abutments of the bridge was 493. One hundred and fifteen cases of illness were dealt with by the doctor, one man being attacked three times, thirteen men twice (one fatally), and eighty-six men were attacked once (three fatally). One case resulted in total deafness, four were fatal, and the remaining cases completely recovered. Two of the fatal cases were due to the heart and circulatory system, one to the lungs, and one to hæmorrhage of the spinal marrow. The majority of the cases were of pains, cramp, slight palsy, and temporary paralysis of limbs and joints. The labourers were all natives of Egypt, supervised by Europeans, but the latter were not in the compressed air for such long periods as the labourers. The author regrets the non-provision by the contractors of a medical air-lock, into which men suffering from the effects of too rapid decompression can be put and recompressed. This remedy is almost universal in English and American practice, and has been attended with great success.

THE Cambridge University Press announces for early publication in the series of "Cambridge Manuals of Science and Literature" "Aërial Locomotion," by Messrs. E. H. Harper and A. Ferguson, and "Electricity in Locomotion," by Mr. A. G. Whyte. The first-named work will contain an introduction by Prof. G. H. Bryan, F.R.S., and chapters on general principles, propellers and motors, stability and control of aëroplanes, model aëroplanes and gliders, aëroplanes, dirigibles, &c., and Mr. Whyte in his volume will give an account of the application of electricity to locomotion and show the present condition of affairs and the developments which may be looked for in the near future. There are to be chapters on the mechanism of the overhead and of the "stud" systems, on electric railways and on electric traction on main line railways. There will also be a discussion of petrol-engine electric power.

THE age of Sir Nathan Bodington, given in NATURE of last week as eighty-two, was sixty-two years.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR JUNE:—

June 1. 5h. 0m. Mercury at greatest elongation W. of the Sun (24° 30′ W.).
6. 15h. 0m. Mars at greatest heliocentric latitude S.
7. 17h. 6m. Jupiter in conjunction with the Moon. (Jupiter 1° 0′ N.).
14. 14h. 16m. Uranus in conjunction with the Moon. (Uranus 4° 35′ N.).
20. 12h. 44m. Mars in conjunction with the Moon. (Mars 0° 12′ N.).
22. 1h. 35m. Sun enters Sign of Cancer. Solstice.
22. 22h. 38m. Saturn in conjunction with the Moon. (Saturn 3° 3′ S.).
25. 9h. 14m. Mercury in conjunction with the Moon. (Mercury 3° 32′ S.).
27. 2h. 38m. Neptune in conjunction with the Moon. (Neptune 5° 28′ S.).
29. 5h. 8m. Venus in conjunction with the Moon. (Venus 3° 40′ S.).
29. 13h. 0m. Mercury in perihelion.

THE TAIL OF HALLEY'S COMET ON MAY 20, 1910.—No. 4496 of the *Astronomische Nachrichten* contains further notes on the question of the direction of the tail of Halley's comet on the evening of May 20, 1910. Prof. Eginitis returns to the discussion, with M. Antoniadi, concerning the appearance of a tail directed *towards* the sun, and suggests that the latter has failed to recognise the exceptional position of the tail, with regard to the earth and sun, at the time, and also its curvature; such conditions would account for the phenomena observed at Athens about which Prof. Eginitis has no doubt and M. Antoniadi contends were impossible.

THE SPECTRUM OF THE RING NEBULA IN LYRA.—Some interesting spectra of the Ring Nebula are published by Mr. Keivin Burns in No. 193 of the Lick Observatory Bulletins. The photographs were taken with a slitless spectroscope attached to the Crossley reflector, in order to determine the spectral type of the central star. Stained and unstained plates were employed, and, in passing, it is interesting to note that a "Cramer Crown" plate stained twenty-one days previously was 50 per cent. faster in the red than a newly stained plate from the same box. The length of the spectrum is only 3·3 mm. between λλ 6560 and 3730, and the width of the image of the Ring is 1·6 mm. in declination.

A comparison of adjacent stellar spectra with the spectrum of the central star showed that while between λλ 6600 and 5800, the latter was only as bright as a 14·2 mag. star of type A or F; at λ 3300 it was as bright as an F-type star of magnitude 12·4. In fact, the spectrum of the central star is relatively stronger in the ultraviolet than that of the bluest of the many Orion-type stars which have been photographed with the same instrument; yet there is not the great difference between the visual and photographic magnitudes of this star that there is generally thought to be. Mr. Burns states that, if isolated, both the central star and the other star within the Ring would be easy objects for moderately large telescopes; he finds their visual magnitudes, by photographic methods, to be 14·1 and 14·7, while their photographic magnitudes are 13·2 and 14·5 respectively. The similarity of the spectrum of the central star to the spectra of central stars, or condensations, in other nebulæ removes any doubt as to its connection with the nebula.

The following radiations were found in the spectrum of the nebula itself:—λλ 3450, 3730, 3870, 3970 (Hϵ), 4100 (Hδ), 4340 (Hγ), 4690, 4860 (Hβ), 4960–5010 (chief nebula line), 5880 (D_3), and 6560 (Hα). Of these, the radiation at λ 3730 is by far the strongest, on the ordinary plate, and is followed by the chief nebula line; the hydrogen lines are relatively faint. The sizes of the rings due to λ 3730 and the hydrogen lines appear to be the same, while those due to the nebula lines λλ 3870 and 500 appear to be smaller. The monochromatic images of the ring show far more detail than a composite image, a fact which suggests that they differ in detail.

PROPER MOTIONS OF STARS BETWEEN +75° AND +80° DECLINATION.—By the comparison of the positions determined at the Kasan Observatory with those given in twenty-two earlier catalogues, Prof. Dubiago has determined the proper motions of some 730 stars, and publishes them in No. 4496 of the *Astronomische Nachrichten*. All these stars occur in the Kasan A.G. zone between declinations +75° and +80°, and the complete results are to appear in No. xv. of the Publications of the Kasan Observatory.

THE GYRO-COMPASS.—A brief description of the gyrocompass, which was exhibited at a recent meeting of the Royal Astronomical Society, appears in the May number of *The Observatory* (No. 435, p. 190). This compass is quite independent of the earth's magnetism, and may therefore be employed in many positions where an ordinary magnetic compass would be useless. It was, in fact, primarily designed for use in polar research, but now proves to be quite unsuitable; it is, however, trustworthy between latitudes 70° N. and S., and is being adopted by several Governments for use in their navies.

The rotating disc is floated on mercury, so that it is free to move in two directions, and the rotation of the earth causes the axis to set itself due north and south. The axis is geared up to an indicator, so that the needle always points N. and S. when the gyro is running. The rotation of the disc is produced by an ingenious electric motor of which the disc forms part, and the inherent tendency to prolonged oscillation is overcome by a most ingenious system of damping by currents of air, the application of the blasts depending upon the amplitude of the oscillation at the moment.

A fuller description of the instrument is given by Mr. G. K. B. Elphinstone in a book, "The Anschütz Gyro-Compass," published by Hugh Rees, Ltd.

ANCIENT OBSERVATORIES IN INDIA.—An illustrated description of the five astronomical observatories erected at the beginning of the eighteenth century by Saway Jay Singh, the Maharaja of Ambhery in Rajputana, is one of the interesting papers in the May number of *L'Astronomie*. M. Ducret, who describes the equipments, states that the observatories were situated at Benares, Muttra, Delhi, Ujjain, and Jaipur, but with the exception of the last named they are in a sad state of ruin. A photograph of the Jaipur Observatory shows huge masonry erections by which the altitudes and azimuths of the celestial bodies could be determined. The installation shows that in 1718–34, when the observatory was erected, the study of astronomy of position was well advanced in India.

THE BRITISH SOLAR ECLIPSE EXPEDITION.

March 30, 1911.

AT the moment of writing we are fifty-five days out from home, and are steaming along steadily in H.M.S. *Encounter* towards the island of Vavau, which we hope to reach on Sunday evening next (April 2). Since leaving Sydney, on March 25, we have experienced a N.E. or head wind all the time, which has somewhat reduced our speed. To-day we are in lat. 25° 20·5′ and long. 174° E., *i.e.* we are well to the north-east of Norfolk Island and to the south of Hunter or Fearn Island.

When boarding the ss. *Otway* at Tilbury on February 3, I was the sole representative of the Solar Physics Observatory's expedition on board, for Father Cortie and Brother McKeon, who joined the ship at the same time, represent the party sent out by the Joint Eclipse Committee. It was not long before I discovered that many cases containing self-recording instruments, books, photographic materials, lantern-slides, &c., for use on the voyage, were not placed in my cabin, and it was only at Port Said that I finally heard by cable that they were all neatly stowed away in No. 2 hatch with hundreds of tons of cargo above them, and therefore inaccessible until Sydney was reached. Fortunately, I had my 5×4 Kodak with me, and supplies of films were easily obtained at Marseilles, Naples and Colombo *en route*.

On the whole, the weather was cold for the time of year on the way out to Australia, and it was only in the doldrums that a high temperature and moisture-laden

atmosphere were felt. I had intended to keep running three self-recording instruments, lent me by Dr. W. N. Shaw, to record pressure, temperature, and the hydrometric state of the atmosphere on the way out and home; but, alas! these were in No. 2 hatch.

We reached Marseilles on February 9, and Mr. F. K. McClean, a volunteer for my party, joined the ship, having travelled overland from London. Unfortunately, we passed Messina at 3 a.m. in the morning, so that the scene of the great earthquake could not be distinguished.

Solar halos were visible daily, and these corroborated the low temperatures we were experiencing. On February 15 Port Said was sighted; it was a beautiful morning, but the air distinctly chilly. The same evening we entered the canal, and took only sixteen hours to get through. In the Gulf of Suez, even with a following wind, it was not hot; in fact, low temperatures were the chief features of the voyage. At Aden my notes state:—"It has been exceptionally cool the whole journey, and especially through the Red Sea."

In the Indian Ocean the temperature began to rise, and the thermometer in my deck cabin, with an electric fan running, registered usually 78°–82° F. at about 11.30 p.m. Colombo was reached on February 25, and although it was somewhat warm on shore, it was nothing to what it was in December, 1897, when I was there on the way out to India for the eclipse of 1898. On the evening of February 26 we had a fine display of lightning. The colour of the flashes was a distinct violet, and each flash, or rather the great majority of them, appeared to quiver, *i.e.* did not seem to be instantaneous, and gave the impression that several flashes passed down the same path in the air. The flashes were, however, too distant to photograph; otherwise I would have recorded their multiple nature by photographing them with a moving camera. The phosphorescence on the water was brilliant that evening (and my cabin temperature 83° F.). I have never been farther south than Colombo before, and so I had been looking forward with considerable interest to reaching the doldrums. I wished to observe and photograph the beautiful cloudscapes which are special to that region.

Monday, February 27, I labelled my cloud day. There were small but superb cumuli sailing over the sky slowly all day. Each cumulus was practically a nimbus, and rain was falling in dense sheets from most of them. The under surface of each cumulus was very flat, and their bottoms seemed to be about 4000–5000 feet high. As we were roughly in latitude 7°, the sun at midday was very high—nearly overhead. Thus the lower portions of the clouds were in deep shadow, and, looking towards the horizon, tier upon tier of their lower portions, due to perspective, made an impressive sight. This day ended with one of the most majestic sunsets I have ever seen. The sun, sinking behind these distant cumuli, rendered them of varied colours. Some were picked out in inky-black with golden edges, while others were tinged with a ruddy hue, with purple for their main mass. Just above the sun, but tremendously high up in the upper reaches of our atmosphere, was a beautiful delicate mass of cirro-cumulus in the form of waves. These exhibited all the colours of the rainbow, and were brilliant in the extreme. A powerful pair of binoculars showed both their structure and colour. Beautiful golden rays also shot up from the sun, making the scene one of perfect beauty. The sight of these rays at sunset are alluded to by sailors as "the sun setting his back stays." After the sun had set, all the clouds became an inky-violet colour, and took all shapes, from French poodles to whales or 4·7 guns. This wonderful sunset was followed next day by an even more perfect sunrise. The sea exhibited that oily look so well depicted by Somerscales—and long rollers were sluggishly passing by making the *Otway* pitch a little. Even the bow way of the *Otway* refused in this oily sea to break, but sped silently away from the ship's side. The horizon at the east, with the distant yet unilluminated cumuli, brought to one's mind spectroheliograph photographs of the sun's limb with the prominences around it, the cloud-forms representing the latter. Gradually the most beautiful dawn began to appear, and the sequence of events during the sunrise seemed to be exactly the reverse of the sunset the night before. In this case the "front stays of the sun" formed a conspicuous feature.

The evenings now were very warm and humid, and my cabin temperatures, at about 11.30 p.m., varied from 82° to 85° F., even with the electric fan running.

FIG. 1.—SS. *Otway* leaving Sydney Harbour for Brisbane. H.M.S. *Encounter* in Harbour (three funnels).

The approach to Australia is not very inspiring, for the coast at Fremantle is very low-lying, both to the north and south. It was here that I first experienced the great kindness of Mr. H. A. Hunt, the Commonwealth meteorologist, during my brief visit to Australia. Knowing that the ship would put in at Fremantle, he arranged for the meteorologist of the Perth district, Mr. Kerr Lewis, to meet me and show me round Perth. But I left the ship to catch the steamer for Perth instead of the train, so we missed each other, and I did not see him until I returned to the *Otway* again in the afternoon. Mr. McClean and I and a Mr. E. C. Anderson, whom I have commandeered as a volunteer observer for our expedition to Vavau, went off and visited the Perth Observatory. It was there we learnt that Mr. Cooke, the director, was away in Melbourne on the Boundary Commission, and we gathered some information about the Australian eclipse party to Vavau also. Mr. Kerr Lewis, the chief assistant at the observatory, very kindly showed us over the observatory, which is in a fine position overlooking the

surrounding country. In recent years the growth of houses in the neighbourhood has been so rapid that its position will soon be spoilt, if it is not already.

The journey from Fremantle to Adelaide was livened by a lecture by Father Cortie on "Comets," and by Mr. McClean on "Flying." To give an idea of the low temperature conditions during this portion of the journey, furs and overcoats were generally worn, and my cabin temperature was about 65° F. When at the Perth Observatory I was informed that the past season in Australia had been phenomenal, the summer having been cold and very wet. This I afterwards found was the case generally for the whole of the southern portion of the continent.

Second Letter.

April 1.

On the morning of March 11 we arrived at Adelaide, and moored alongside the quay. Father Cortie there received a letter from Captain Colomb, the captain of H.M.S. *Encounter*, the ship which had been put on special service to assist both Father Cortie and my party at the eclipse. Captain Colomb informed us that his ship was at present in dry dock at Coccatoo Island at Sydney, and that he would be ready to sail with our party from Sydney on March 25 if that date was convenient. We informed him that this arrangement suited our plans admirably, and at his request we notified him of the amount of our luggage. At Adelaide Mr. Cooke, the Government astronomer of W. Australia, and Mr. Dodwell, the Government astronomer of S. Australia, met us. The Commonwealth Government placed a motor-car at our disposal, but unfortunately our time was so limited that we were unable to make much use of it.

Fig. 2.—Rain Squalls on the Equator.

The journey to Sydney proved most instructive. The region round Ballarat, where we visited my brother, is studded with past and present gold mines. There we were shown over the most up-to-date assaying plant, owned by Mr. Edwards. The following morning a motor run of 100 miles brought us to Bendigo, and we had experience of Australian cross-country roads; in many cases it was a mere track, with no metal at all on it. I was told that I was seeing Australia under very abnormal conditions for that time of year, for instead of scenery of predominating *brown* tints, I was passing through a country as green as any scenery in England. This was due to the exceptional rainfall. At Bendigo we were shown over a battery of 110 stamps. The same evening we left for Melbourne, and the next morning Mr. Hunt, the Commonwealth meteorologist, took us to call on the Hon. King O'Malley, the Minister for Home Affairs. He very kindly welcomed us to Australia, and explained to us the working of his department. Mr. Hunt also showed us over the Meteorological Office of which he is chief. I was in time to see the very efficient system which he has adopted in making his daily forecasts for the whole of Australia. I made the acquaintance of Mr. G. H. Knibbs, the Commonwealth statistician. Next morning (March 15) I visited the Melbourne Observatory. Mr. Baracchi was there full of the question of the Boundary Commission and the coming eclipse, of which he is chief. I renewed my acquaintance with Mr. Baldwin, who some years ago visited the Solar Physics Observatory at South Kensington, and also met Mr. Short, another assistant. I viewed with great interest the great Melbourne reflector, with which I was so familiar from book illustrations. My old friend Dr. Skeats, of the Royal College of Science, but now professor of geology at the Melbourne University, took me off to lunch to meet many of his *confrères*, and then we made a quick tour of the University. This University is growing very rapidly, and arrangements are already in preparation for a considerable increase of the various departments. I had the great pleasure of meeting Mr. Grayson there, who has so successfully achieved the art of ruling very thin lines on glass exceedingly close together—nearer together than those on any gratings yet ruled. He showed me the extremely ingenious methods he was adopting to produce the portions of the mechanism for ruling gratings. The work was of the very highest order, and he accomplishes every portion of it himself. It will be a grand day when we can order large-size ruled gratings from Australia.

On the morning of March 16 Mr. J. Brooks, retired Trigonometrical Survey of New South Wales, and Mr. W. E. Raymond, first assistant, Sydney Observatory, met us at the railway station. Both Mr. Brooks and Mr. Raymond form part of my eclipse party, and both are familiar with eclipse work, as they were with Mr. McClean on his eclipse expeditions to Flint Island and Tasmania. Further, both Mr. McClean and I had been in correspondence with them from England, asking them to make many preparations locally, which they had most satisfactorily carried out. Our total instrumental and camp equipment was increased from 4½ tons to about 6 tons. I had intended to call on Vice-Admiral King Hall and Captain Colomb, of H.M.S. *Encounter*, as soon as possible, but found on my arrival that the former was away in Tasmania and the latter with his ship in dry dock. March 17 was a very busy day. First it was necessary to be down at the wharf to tally off all the eclipse cases as they came out of the *Otway*, though the majority were not going to be moved until late that evening. Then the Lord Mayor of Sydney was going to give us a civic welcome, which was to take place at noon that day. We all assembled at the Mansion House at the time appointed, and were met by Profs. Moors and Pollock, of Sydney University, the Rev. Father Pigot (representing the Eclipse Committee of the Australasian Society for the Advancement of Science), Mr. J. Mangle, the Rev. Dr

Roseby, Dr. Quaife, Mr. Guthrie, Mr. W. E. Raymond, and Mr. Hamlet (representing the British Astronomical Association and the Royal Society).

Prof. Moors, introducing our two parties, remarked that the Australian expedition, which was going to Vavau to observe the eclipse, expected to learn a great deal from us. After Mr. Hamlet's reference to the voyage of Captain Cook in 1770, when he sailed to the South Seas to observe the transit of Venus, and also to the British and Commonwealth expeditions on the present occasion, the Lord Mayor heartily wished all the expeditions success, and instanced the voyages of Sir Ernest Shackleton and Captain Percy Scott as showing what could be gained to science by close study under arduous conditions.

Prof. Pollock expressed the hope that the advent of the present British parties would benefit the scientific workers in Australia and raise and sustain that enthusiasm without which no good work was ever accomplished. Father Cortie replied in an appropriate manner, pointing out that Britishers felt quite at home in Australia, and that such expeditions helped to cement further, if necessary, the friendship between Australia and the Mother Country.

In my reply I laid particular stress on the importance of the occasion for furthering the proposal for a Solar Physics Observatory for Australia. I pointed out the importance of filling up the gap of longitude between Kodaikánal (India) and Mount Wilson Observatory (U.S.A.), and that in Australia the weather conditions were ideal for a large observatory of this kind. I also indicated the important part played by the sun in controlling our terrestrial atmospheric movements, and that a close study of the sun was of first importance to Australians, whose population was so largely composed of those who reaped benefit from the soil. After this pleasing ceremony was over we adjourned to another room to drink the health of the King.

In the afternoon we all went to Coccatoo Island to call on Captain Colomb, the ship being still in dry dock. He greeted us very heartily, and at his request we gave him an account of our programme and requirements.

In the evening we all attended a meeting of the British Astronomical Association, and at its conclusion Mr. McClean, Mr. Anderson, and I went with Mr. Raymond to the observatory to see the show clusters, nebulæ, and double stars of the southern hemisphere.

The following morning was occupied in tallying all the eclipse cases from the *Otway*. These were to be transferred to H.M.S. *Encounter* by steam lighter on Monday, March 20. During the afternoon I boarded the *Encounter* to give Captain Colomb detailed information about the assistance required. I suggested to him the importance of communicating with England as soon as possible after the eclipse in order to inform the home authorities of our results. This he took in hand, and it was arranged that H.M.S. *Encounter* should send a wireless message to H.M.S. *Pioneer* at Auckland, which would be transmitted through to England by cable.

The next day (Sunday, March 19) we all went out by steamer to the beautiful River View Jesuit College, where Father Cortie and Brother McKeon were staying. The rector and the fathers received us in a most hospitable manner. The college is situated away up towards the beautiful harbour of Port Jackson, and is an imposing structure amongst lovely scenery. Since our arrival in Sydney it had been very hot, and the damp atmosphere had made our various duties rather laborious; even the Australians considered it so. The steam to River View was delightful in the extreme, and we were able to gain some idea of the great future such an important port must have. There is very deep water everywhere, and the largest ships can lie alongside any of the innumerable harbours. At River View the very beautiful seismographs, which are in the charge of the distinguished worker Father Pigot, were shown to us. Every detail of these instruments and their functions were carefully pointed out.

The next day (March 20), at an early hour, the steam lighter was alongside the wharf, and Mr. McClean and I went and superintended the placing of the cases in the lighter. Then we steamed away, and with the help of the *Encounter's* crew got all the cases safely stowed away in torpedo flats and other available spots.

This morning I had expected Mr. Hunt to arrive from Melbourne, as I had been requested by the Hon. King O'Malley, the Minister for Home Affairs, through Mr. Hunt, to visit and report on the proposed site for the Solar Physics Observatory near the new Federal Capital site, and Mr. Hunt was to escort me there and back. Mr. Baracci had arranged to proceed to the site from Melbourne, and we were all to meet there. At midday I met Mr. Hunt, and he proposed that we should start the same evening, to which I consented. In the meantime, Mr. Hunt took me to call on Mr. Stephen Mills, the Collector of Customs, who is the successor to Colonel Lockyer (now retired); the latter I met in Melbourne a few days ago. Colonel Lockyer had very kindly given me two letters, one for Father Cortie, which would clear us of any difficulty that might arise in relation to custom duties. These proved very useful, and saved us much anxiety.

W. J. S. Lockyer.

(*To be continued.*)

THE WORK OF THE ROYAL GEOGRAPHICAL SOCIETY.[1]

In looking to the future, it is important to inquire how the society will be able to maintain its reputation and its usefulness in the new conditions of geographical knowledge. It is true that the South Pole is as yet uncaptured, that the map of Arabia is still largely composed of great blank spaces, and that the bend of the Brahmaputra is drawn by guesswork in our atlases. But all these problems will, it is probable, be solved before long, and where then will be the field in which the explorer may hope to win renown by robbing the unknown of its romance? We must sooner or later face the fact that the work by which this society has become best known in the past represents an almost finished chapter in geographical history, and we should sometimes, in preparation for the future, ask ourselves what ought to be our *rôle* when the last leaf in that chapter has actually been turned.

When endeavouring thus to take time by the forelock, we should perhaps in the first place inquire more precisely as to the nature of the change which is now taking place, and as to how soon it is likely to be accomplished. Systematic surveys are, we know, being pressed forward in many parts of the world, of which until recently the maps were produced mainly by the efforts of enthusiastic amateurs, whilst now they are turned out with almost machine-like regularity and precision by Government officials. As to the British Empire, the annual reports of the Colonial Survey Committee show how rapid has been the advance in this direction, and what satisfactory progress has been made, though in certain localities the authorities, in spite of past experience, seem disposed to linger on in a state of comparative topographical ignorance. Outside the British Empire similar changes are taking place, though less rapidly, with the result that when the international map of the world on the scale of 1 : 1,000,000 is completed, as it will be before many years have passed, a large proportion of it will be based on surveys sufficiently accurate to ensure the work holding good for many a century to come, except for the rise of new towns and the alteration in political boundaries. But in spite of all this progress there are likely to remain vast tracts of land, mapped in a fashion, no doubt, but with the details inaccurate and incomplete, where for at least half a century or more from this date the independent traveller will find ample opportunities of adding to the knowledge of the earth we live in. Indeed, for some years to come large areas are likely to exist our knowledge of which can only be increased at the risk of the traveller's life. But although the available topographical information concerning many regions will for long remain very imperfect, yet it is inevitable that the day will come when the whole world will be mapped with fair accuracy, and to that condition of things this society will have to adapt itself.

Nearly all great changes, however, take place gradually, the process of evolution being, as a rule, an advance

[1] Extracts from the address of the president, Major Leonard Darwin, at the anniversary meeting of the Royal Geographical Society, May 22.

made by a great number of small steps; and no sudden geographical revolution need be feared. To move with the times ought not to be very difficult, therefore, and to do so it is mainly necessary to look to the immediate future, or to take "short views of things," to use the words of that wise man Sydney Smith. If this policy be steadily pursued, there need be no cause for alarm for many years to come, at all events; for, as already suggested, plenty of geographical work yet remains to be done. We ought no doubt, in view of the changing conditions, to direct our efforts with more persistence than heretofore in the direction of encouraging travellers to make systematic and detailed examinations of comparatively small areas, and not merely to cover long distances with the result of doing little more than confirm the impressions of previous explorers. Their surveys should be as good as is possible in the circumstances, and the information they collect should be extensive, varied, systematic, and recorded with reference to the needs of the students of science and history, as well as of the man of commerce. In short, the traveller of the future ought to be a trained topographer, or to have thoroughly prepared himself in advance for some definite class of investigation.

As regards internal administration, the aim must be to make the society's house a place where accurate information can readily be obtained concerning all countries, including our own, the information thus supplied being all that could be described as geographical within the most elastic meaning of the word. The acquisition of suitable maps and books should, indeed, in future only be limited by financial necessity, whilst the collection of geographical photographs should be well maintained. No pains should be spared to make our systems of indexes as perfect as possible, a subject to which, as a fact, considerable attention has recently been paid; and with such aids the staff should be in a position to give every assistance to all students wishing to utilise the vast stores of information which the premises should contain. In short, we shall want more maps, more books, more photographs, and a more convenient house to hold both them and the steadily accumulating objects of interest which we own; and if the society continues to grow in usefulness on the lines suggested, we must look forward to the possibility of a material increase being needed in the number of the staff. Moreover, our means of keeping touch with foreign countries should be considered from time to time, to see if they are not capable of improvement. For example, as a single possible suggestion, might it not be worth considering whether British consuls, whilst actually serving abroad, should not be allowed to join our ranks with some special advantages as regards fees? Then, again, partly with the same object of facilitating the supply of information to our fellows, partly with the view of making our collections more generally useful, and partly in order to disarm the criticism made against us of wishing to poach on the preserves of other sciences, it might perhaps be well to allow the fellows of certain other learned societies to use our libraries with the same freedom with which they can now consult the maps in our map room.

As to the work of exploration and investigation for which we are not directly responsible, this should, as heretofore, continue to receive our warmest encouragement and our help when possible.

One other function which this society may always usefully perform, and one which has thus far been too much neglected. Science is cosmopolitan, and certainly the records of this society's proceedings during recent years, where the names of Sven Hedin, Peary, Charcôt, and many other distinguished foreign explorers so prominently appear, prove that this aspect of our duties is not now being overlooked. It is not, however, as it seems to me, in the least inconsistent with a belief in our world-wide obligations to hold that the work done by our fellow-countrymen has an especial claim on our attention, and that one of the aims of a national geographical society should be to keep alive the knowledge of the great deeds of British explorers in the past. Is it not probable that the history of Australia and New Zealand would have taken a very different turn if the work actually done by Captain Cook had been forestalled by some explorer owing nothing to these isles? And yet to that great man no fitting monument has yet been erected. As to Africa, its map should have the names of our fellow-countrymen written all over it if intended to indicate the historical development of that continent—a development due in large measure to British exploration, the history of which we should never allow to die. In the case of thousands of adventurers who set forth to America and elsewhere from these islands in times gone by, and to whose exertions is largely due the fact that English is now the most widely known language on the face of the earth, and that these islands hold in relation to their size an absolutely unique place in the history of the world, it is true that of these men we do not even know their names, though the effect of their exertions yet surrounds us on every side. It is to be hoped, therefore, that there will always exist in this land a body of men banded together with the object, amongst others, of making more widely known what was done by British explorers in the past, and of honouring the heroic spirit of these unnamed thousands which drove them forth to face untold dangers, and thus to help to build that Empire of which we are so proud.

ORGANISATION AND PROGRESS IN ECONOMIC BIOLOGY.

DURING the past decade economic biology has slowly but surely taken a definite place in our system of sciences in this country, and although at present but a sturdy infant, it would seem that it is destined to play no mean part in stimulating research and experimentation in the near future.

We have, fortunately, outgrown the prejudice that has for many years clung to practical science, and on all sides we can see investigations taking place of deep and far-reaching scientific interest, but at the same time fraught with great import to man and his multifarious activities.

Once men begin to think and work along certain definite lines, it is not unnatural that they should seek to associate together, in order to discuss their methods of work, and the latest results obtained by their investigations. Without such association much unnecessary duplication of work occurs, and the lack of organisation retards otherwise legitimate progress.

The foundation of the Association of Economic Biologists in November, 1904, was the outward expression of a feeling such as this that had long been simmering in the minds of economic biologists in the British Isles, and on the occasion of the tenth general meeting, which has recently been held at the University of Birmingham, where the first meeting took place, it seems not unnatural that we should pause and reflect upon the organisation and progress of this special branch of biological science.

During the life of the above association, meetings have been held at the universities of Birmingham, Liverpool, Cambridge, Edinburgh, Oxford, and Manchester, and one each at the Imperial Institute and University College, London. In looking at the list of papers read at these meetings, one cannot fail to be struck at the large amount of original work that has been carried out by the members, much of which has been published and adequately illustrated. The problems discussed relate to almost every subject wherein the economic biologist can aid or assist the physician, veterinarian, agriculturist, horticulturist, stock breeder, fruit grower, forester, fisherman, manufacturer, &c. Since 1904 the members of this association have contributed in no small degree to the general advance that has been made in this particular science.

With progress and increased interest the workers also increase, and it is significant that at the last two meetings questions relating to organisation have figured prominently in the programmes. Few will forget Prof. Hickson's admirable address delivered last year at Manchester, on the place of economic zoology in a modern university, or the discussion that followed, both clearly indicating how fully it was realised that a sound scientific training was the best preparation for future specialisation.

In a more restricted sense, Mr. H. Maxwell Lefroy dealt with the training of economic entomologists at the last meeting. Mr. Lefroy has had a long and unique experience of the kind of men that are required in our colonies, but so far he has failed in his efforts to obtain such from

this country. From his address we gather that he would dissociate entirely the training in entomology from the general zoological training, doing it as a post-graduate course. The trend of the course, he pointed out, must not be that of the comparative anatomist, the evolutionist, the systematist, or the histologist. The difficulty in making economic zoologists in England, he thought, would be the preponderance of the academic view and the total absence of the economic view based on experience. English universities have a very long way to go before they can turn out entomologists of the practical stamp that America does.

Referring to the lack of knowledge of entomology of the medical men who apply themselves to entomological problems, he described it as very painful, but in England there are so few places where medical men can obtain their training, and even then it seems to lack much. The kind of training in our universities is too academic for men who are required to solve problems requiring practical solutions.

We are on the threshold of greater things, and whatever problem comes one must put one's hand on. Only so is the practical entomologist going to convince an unlearned public and sceptical governments that there is anything at all in it, and we are, in England certainly, beginners who must look to the future. England should be the source at least of the entomologists of her Empire, but she is not, and unless radical changes take place in the atmosphere of her teachers, she will not be. The training will have to be that of practical field entomologists if the demand has to be met from England, and the last thing it wants is the academic zoological training of the average English university.

A perhaps more important subject to economic biologists generally was Mr. H. Maxwell Lefroy's address on the standardisation of economic nomenclature. The almost hopeless muddle that at present reigns in the nomenclature in the literature bearing on economic biology is little short of appalling.

Mr. Lefroy proposes to meet this difficulty by having a standard catalogue of the important species with the name most in use in biological literature definitely decided on, so that the further changes in nomenclature need not affect the economic biologist. The guiding principles would be that it should be independent or unaffected by the rules of priority. It should be based on the name used in important biological literature. Genera in which there is a close uniformity of habit and life-history, or which form a distinct class of pest, shall, for this purpose, be retained whole and not subdivided, *e.g.* Lecanium, Dactylopius, Agrotis, Gryllotalpa. To make existing and future biological literature accessible by adopting and making permanent the name under which it was written, and not to perpetuate inviolate the author of a name or description in the systematic literature. Writing recently on this subject, Mr. Lefroy stated, "In this matter, teachers and practical entomologists alone are concerned; to the systematic entomologist, the mazes of synonym and priority are (apparently) the breath of life, and the pastime might be a quite harmless one; . . . but to practical men who wish to check the growing spread of insects from country to country, who wish to cooperate to deal with big problems, who see in agricultural education the chief solution of these big problems, the question is one of vital importance. I think all economic entomologists will agree that we are immensely adding to the difficulties of our work, if it is to be anything more than parochial, either by modifying our nomenclature in accordance with the priority discoveries of systematists or by arbitrarily using the nomenclature we think most suitable. It is impossible for an isolated worker in a far country to do more than offer suggestions; I feel assured it will be for the permanent ultimate good of our science if we can overcome this growing monster, and I think the Association of Economic Biologists might fitly take up the subject."

As the outcome of Mr. Lefroy's suggestion it was decided to form a committee to consider and report upon the matter. The committee appointed were Richard S. Bagnall, Prof. Geo. H. Carpenter, H. Maxwell Lefroy, Dr. R. Stewart MacDougall, Robert Newstead, and Walter E. Collinge (hon. sec.).

Such a scheme will greatly facilitate investigation and the reference to work done, and this desire to place matters upon a sound basis is perhaps one of the best auguries for the future prosperity of the association.

A further very interesting discussion was initiated by Dr. J. H. Priestley on the systematic recording of diseases of economic plants. The Biological Committee of the Agricultural Education Association have for some time past given consideration to the question of establishing at a convenient centre a record, as complete as possible, of the various fungus, insect, and other diseases of economic importance, reported in the British Isles from time to time. The main object of such a record would be to aid the scientific investigator who wished to get into touch as quickly as possible with the scattered literature and notes dealing with the distribution of, and other questions relating to, some disease or pest of which he was making a particular study. It had been decided to approach other bodies likely to be interested with a view to cooperation. It was decided to give the scheme approval and support.

All these activities indicate the growing importance of the subject, the possibilities of which we have yet but dimly realised; the multifarious lines of research are vast and the field is an ever widening one, and the need for work and workers pressing. That the workers of this country will bear their share in elucidating some of the hidden mysteries, and directing their application on the problems of our everyday life, is greatly to be hoped.

W. E. C.

ECOLOGICAL STUDIES.

A NOTE by Dr. C. C. Hosseus on the flora of Wang Djao, a station on the Meping River in middle Siam, appears in Engler's *Botanische Jahrbücher* (vol. xlv., part iii.). Trees of *Dipterocarpus laevis* and other species clothed with epiphytes, especially orchids, are prominent along the river banks. On the savannah lands in the vicinity *Cassia siamea* is the dominant tree, while *Andropogon brevifolius*, species of Scitamineæ, and *Hibiscus Abelmoschus* are conspicuous amongst the ground vegetation.

In the Bulletin of the Illinois State Laboratory of Natural History (vol. ix., art. 3), Dr. H. A. Gleason presents an instructive ecological study of the vegetation of the inland sand deposits of Illinois. He distinguishes prairie, blowout, swamp, and forest formations. The prairie formation consists largely of bunch grass associations, in which *Koeleria argentea*, *Leptoloma cognatum*, *Panicum pseudopubescens*, and *Andropogon scoparius* are dominant species, either alone or in combination. On the patches between the grass clumps there grow various perennials of the type of *Aster linariifolius*, or *Callirhoe triangulata*, some annuals, and *Selaginella rupestris*, which spreads in circular rings. The formation and different aspects of the sand dune are described. The most efficient dune-formers are *Panicum virgatum*, which possesses long tough roots and tufted stems densely covered with persistent leaves, and a local variety of *Rhus canadensis*, which continually grows above the sand that collects around its dense tangle of stems.

A phytogeographical sketch of the Andes in the south-east of Bolivia, communicated by Mr. K. Fiebrig to Engler's *Botanische Jahrbücher* (vol. xlv., part i.), provides a good biological account of the remarkable modifications developed on the wind-swept high plateaux, the Punas, at an altitude of 12,000 feet. Cushion plants of a much branched, closely compacted character are displayed by *Azorella madreporica* and *Pycnophyllum Pilgerianum*, while a less extreme type is developed by many of the Compositæ, an Ephedra, and the globular cacti. Acaulescent long-rooted plants are exemplified by species of Astragalus, a new species of Alyssum, and *Dalea callianthes*. The numerous dwarf shrubs include many species of Compositæ, a Fabiana (Solanaceæ), and the thorny rosaceous plant, *Tetraglochin strictum*. Several bulbous plants occur, notably an Alstrœmeria and a grass-like Sisyrinchium, and an evil grass, *Festuca orthophylla*, covers extensive patches with porcupine-like leaves. Other formations described are the Alpine, the valleys, and the lowland forests.

SOME RECENT WORKS ON AQUATIC ANIMALS.[1]

(1) DR. PASCHER'S monograph contains the first instalment of observations in progress on the biology of this "Grossteich"—a lake situated about 100 km. north of Prague. The present memoir, on the Chrysomonads (except the purely planktonic forms), deals with their classification (two new genera and eight new species being described), structure, motion, division, and encystment. The occurrence of contractile vacuoles in Microglena and of siliceous needles, as long as the cell, projecting from the surface of Mallomonas, are among the more noteworthy features referred to.

(2) The genus Ceratium is so common a constituent of the fauna of many lakes and seas that an account of its species, and the help offered in their more accurate identification, will be welcome to workers on plankton. A short account is given of the morphology and fission of *C. tripos*. The genus is divided into four sub-genera, the armature and relationships of which are examined. It is concluded that the genus probably arose in temperate waters, and spread thence into warmer and colder regions. There are no known "bipolar" species. *C. cornutum*, one of the three widely distributed fresh-water species, seems to be the oldest living species and to stand nearest to the hypothetical ancestor of the genus. The structural plan of the fresh-water species suggests that they are primitive, and that by migrations into the sea the marine forms have arisen, and subsequently attained their great differentiation. The author regards the heteromorphic chains discovered by Lohmann, in which the individuals at the two

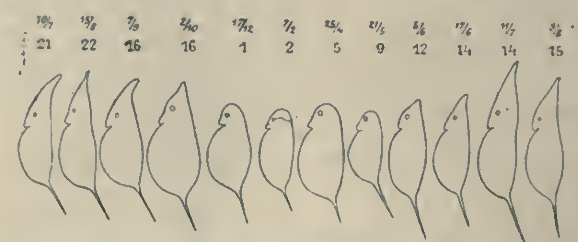

FIG. 1.—*Hyalodaphnia cucullata*, from Fursee, Denmark. Note the elongation of the cephalic shield in the individuals taken in the summer. The upper row of figures indicates the day and the month of capture of specimens, the lower row the temperature of the water (in degrees centigrade).

ends of the chain present more or less the characters of two distinct species, not as normal, but as due to retrogressive phenomena; possibly the reduced salinity of the Baltic, in which they were observed, is responsible for their formation.

(3) Dr. Wesenberg-Lund gives an account of some of the more recent work on fresh-water organisms, especially of his own observations on the planktonic fauna of the Danish lakes. He directs special attention to the variations in temperature, specific gravity, and viscosity of the waters of lakes at different periods of the year, and points out that, while the change in the specific gravity due to temperature variation is insignificant, the viscosity alters very considerably, being, in fact, only half as much at 25° C. as at 0° C. He concludes that, correlated with this latter factor, are certain morphological changes. For instance, examples of the Daphnid Hyalodaphnia, taken in summer, exhibit great elongation of the cephalic shield, which has the effect of so shifting the centre of gravity that, while the animal previously swam almost perpendicularly, it now moves almost horizontally, and its resistance to falling is thus very considerably increased. In the nearly related Bosmina the body is, in summer, higher than long, but in winter longer than high; the antennæ are twice as long in summer as in winter. It is pointed out that when the extent of these "temporal" variations is fully realised there will, no doubt, be a great reduction in the number of recognised species. A further example of modification is given—the rotifer *Asplanchna priodonta*, the body of which is in winter subspherical, but in summer is about five times as long as broad, and approximately cylindrical, so that if the horizontal position be assumed in swimming, the animal presents a greater resistance to sinking. Increase in the length and number of processes (*e.g.* Ceratium) or an increase in the surface of organisms is noticeable in summer, correlated with the increased flotation required.

(4) Dr. Weigold's account of the Lyncodaphnids and Chydorids of Saxony contains much information regarding the specific characters and biology of these Crustacea, details being given of the number of moults, the length of life observed, locomotion, relations of the sexes, variation

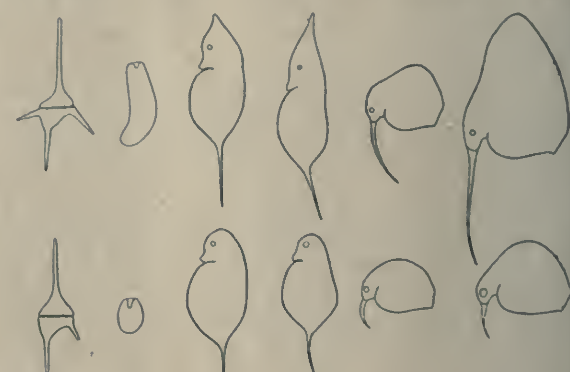

FIG. 2.—*Ceratium hirundinella, Asplanchna priodonta, Daphnia hyalina, Hyalodaphnia cucullata* and *Bosmina coregoni* (two races). Upper row; summer forms with increased power of floating; lower row, winter forms.

in form and numbers. The introduction of Chydorids to isolated waters is brought about almost exclusively by birds. The author has carefully worked out the breeding seasons, and shows that, in the plains of central Europe, the Chydorids have two sexual periods, sometimes almost confluent, but exhibiting maxima in July and October; in more northerly regions and in mountain waters the maxima approach one another, and finally blend into a single breeding period in August-September.

(5) The work described in the fifth memoir was undertaken in order to decide, by renewed observations and experiments, whether the conclusions reached by Weismann or those of some of his critics are to be accepted. The main results go to show that *Daphnia magna* passes, during the course of a year, through several phases, but the various generations and broods are not so sharply circumscribed, in regard to the mode of their egg-formation, as Weismann believed. The author states his views of the sequence of phases thus:—resting egg—strong tendency to parthenogenesis—waning of parthenogenesis and increased tendency to sexual reproduction—strong tendency to sexual reproduction—resting egg. The parthenogenetic and resting eggs, the genesis of which is traced, differ from one another, not only in number and in nature of yolk and shell, but also in mode of formation; each of the former arises from a group of four cells, one of which becomes the egg, while the other three are

nurse-cells; the resting egg arises from a modified group of four cells, which absorbs numerous other four-celled groups. The author confirms Weismann's statements that the origin of resting eggs is not connected with any influence of the male, that these eggs do not enter the brood pouch, but if not fertilised degenerate in the ovary, that the carapace of Daphnia changes into an ephippium only if the ovary is forming resting eggs, and that these eggs invariably give rise to females.

(6) The Donaciinæ, a sub-family of the Chrysomelidæ (leaf-beetles), are of special interest on account of certain peculiar features in the habitat and mode of life of the larvæ, which are fully described and illustrated in Dr. Böving's memoir, which also contains an exhaustive account of the larval anatomy. The author concludes that the features hitherto utilised to differentiate the larvæ of Hæmonia and Donacia are unserviceable; it has, in fact, not been possible to find real generic distinctions between the larvæ, although the adults present well-marked differences. Conversely, though the adults of Donacia and Plateumaris have been found to exhibit only small differences, from which it might have been expected that the larvæ would be difficult to distinguish, it is shown that the larvæ of Plateumaris, here described for the first time, are dissimilar from those of all other Donaciinæ. The larvæ gnaw the roots of certain aquatic plants (Potamogeton, Sparganum, Carex, &c.), and while doing so arrange the head and prothorax so that the latter forms with the plant a water-tight compartment in which the head can work undisturbed by, and the food be kept from admixture with, water and dirt. The mandibles of the larva have a cutting, and not a crushing, edge; they cannot be used for grinding, and, in fact, serve only to make an entry into the plant tissue, the sap of which then exudes and is received by the laciniæ of the maxillæ and passed backwards into the gut. The larvæ seem to feed exclusively on the sap; an examination of the gut contents, which consist of a homogeneous yellow fluid, shows that cell-fragments are not present. The external features of the head, the mouth parts, the muscles, and the mechanism of feeding are considered in great detail.

Aquatic insects have adopted various devices for obtaining a sufficient supply of air; the larvæ of the Donaciinæ have chosen a very remarkable one, namely, to tap the reservoirs of air in the intercellular spaces of the submerged parts of plants. At the posterior end of the abdomen is the "abdominal organ," which the author shows to be a bifore spiracle. The terminal hook of this organ is plunged into the vegetable tissue, air passes from the latter into the organ, and apparently through thin membranes into an atrium, which leads into the main trachea. The spiracular slit in the abdominal organ serves for expiration.

The making of the cocoon is described at length. The outer envelope is formed by a secretion of the whole body, and is lined with a substance produced in four large œsophageal glands; the larva gnaws one or two holes through the bottom of the finished cocoon so as to make connection with the air spaces of the root to which it is attached; air is thus secured for the pupal stage. The author gives a list of the food plants of the different species of larvæ of this family found in Denmark, and accounts of the gnawings, the sizes of the larvæ at different periods, the length of larval life, hibernation, the flying period of the adults, the eggs, and the post-embryonic development. The memoir forms a substantial addition to our knowledge of the anatomy, biology, and development of these interesting larvæ.

J. H. A.

PHYSICAL ANTHROPOLOGY OF AUSTRALASIAN RACES.

IN the Proceedings of the Royal Society of Edinburgh for the present session (1910–11) appears a series of four papers devoted to the physical anthropology of the races of Australasia. The papers are by three authors, two of them human anatomists, Prof. R. J. Berry and Dr. A. W. W. Robertson, the third a mathematician, Mr. K. Stuart Cross. The authors seek to fix the position of the Tasmanian and Australian natives amongst present and past races of mankind by applying biometrical methods to certain measurements of the skull.

The most valuable paper of the series is that by Dr. Robertson, where he gives the data obtained from measurements of 100 Australian crania. By applying Prof. Karl Pearson's test for purity of race, Dr. Robertson finds the native Australians are "pure" when the measurements of the width of the cranium is considered, but "impure" when the lengths are investigated. It will be seen that Dr. Robertson's results are somewhat equivocal, and may be quoted in support of either the unity or duality of the Australian race. Similar methods applied to the Tasmanian race show a much higher degree of homogeneity or purity. The difference in purity between the Australian and Tasmanian races may be explained by the fact that one is spread over a large continent, while the other is confined to a small island.

An attempt is also made by the authors to fix the position of the much-discussed Tasmanian race in the scale of human evolution. The result will somewhat surprise those who have sought to establish racial relationships on an analysis and comparison of mere anatomical characters, for by the methods here employed the Dschagga negro comes out as the advance guard of the human race, well in front of the European, while the native Tasmanian gains a good place, being sandwiched between two ancient Europeans—the man of Brünn and the Cro-magnon race.

From an anatomical point of view the results are surprising, for it would be hard to find greater cranial contrasts than those between the Tasmanian and Cro-magnon on one hand, and the Tasmanian and Brünn on the other. There can be no doubt, however, as to the high value of the new data with which these papers supply anthropologists.

THE PRODUCTION AND IDENTIFICATION OF ARTIFICIAL GEMS.[1]

I PROPOSE to limit the term "artificial" to such productions as possess the same chemical composition and physical constants as the natural stones, differing from them only in minute details consequent upon their being produced in the laboratory instead of being dug out of the earth, all other makeshifts being properly described as "imitations."

The scientific examination and identification of gems is a matter of the greatest interest, but it would take far too much time to discuss it in detail; and it is quite unnecessary to do so, because it has already been brought before the society most exhaustively by our chairman, Dr. Miers.[2] I propose, therefore, merely to remind you of the main points.

In order to bring this matter up to date, however, I must refer briefly to one or two particulars in which advance has been made since the time of these lectures.

The most important properties of a precious stone are those depending upon its refractive powers. Until recently, the accurate determination of the refractive index of a stone was a matter involving the use of complicated and expensive instruments, and a matter for the skilled mineralogist rather than the practical jeweller. It is true that at the time Dr. Miers published his lectures there existed an instrument known as the reflectometer, but the determination of the refractive index with this was a matter of some difficulty even in skilled hands, and its value for commercial purposes was very small. Since that time, however, thanks to the ingenuity of Dr. Herbert Smith, this instrument has been improved out of all recognition, and in its place we have the Herbert Smith refractometer (Fig. 1), by means of which anyone of normal common sense can determine the refractive index of a stone in a few seconds without even removing it from its setting, and which, with a little practice, will also enable one to determine with similar ease the amount and kind of double refraction and the degree of dispersion.

Taking the properties of precious stones as a whole, the great point about them is the remarkable combination of qualities; it is not so much that they have optical

[1] Abstract of a paper read before the Royal Society of Arts on April 26, 1911, by Noel Heaton.
[2] Cantor Lectures on Precious Stones, April, 1896.

properties which make them extraordinarily beautiful, or that they have remarkable hardness and durability, but they have *both*, and it is the impossibility of reproducing this combination in any other material that renders the detection of imitations a matter of ease in the hands of anyone familiar with the facts.

The most important point to remember about paste is its lack of durability; it is not only too soft to stand much wear, but its composition is so unstable that it rapidly deteriorates and loses its brilliancy on exposure. You will see, therefore, that although there is a certain legitimate scope for such paste imitations, they are very unsatisfactory substitutes for the genuine article. This being the case, as scientific knowledge has advanced, attention has been more and more concentrated on the problem of producing by artificial means the actual minerals found in nature, and thus obtaining what I have defined as artificial in contradistinction to imitation jewels, having both the beauty and durability of the natural article without the objectional concomitant of enormous cost.

The first point to be considered in attacking this problem is the composition of the stone, as it is obvious that, other things being equal, the possibilities of success are greater with a stone of simple than one of comparatively complicated composition. The economic aspect has also to be considered—it is not much use devoting time and ingenuity to the production of an artificial stone when the natural one is so common that the cost of the two would be practically identical.

Commercially, we are as far from being able to produce artificial diamonds as in the days of the alchemists. It is,

FIG. 1.—The Herbert Smith Refractometer.

perhaps, a bold thing to say that no such thing as an artificial diamond will ever be placed on the market, but one can safely assert that, so far as our knowledge stands at present, it is impracticable. In saying this, I am quite aware that statements as to the commercial production of synthetic diamonds being an accomplished fact have quite recently appeared broadcast in the public Press, but those who are responsible for such statements are (shall we say?) under a misapprehension as to the meaning generally conveyed by the term "synthetic," and are unable to follow the distinction I have drawn between an artificial gem and an imitation.

The chief problem to be faced is that of attaining the necessary temperature, and it is not surprising that crystalline alumina was produced as a scientific curiosity so far back as the commencement of the nineteenth century. It is at this time that we first begin to hear of the oxy-hydrogen blow-pipe (or the gas blow-pipe, as it was then called). The process of producing reconstructed rubies by means of the oxy-hydrogen blow-pipe is, roughly, as follows:—The residue from cutting rubies and small worthless stones is broken into coarse sand, a small quantity of which is placed on the centre of a disc of platinum; this is then carefully brought to the fusion point, care being taken at this stage not to raise the temperature to such an extent as to melt the platinum support. So soon as this mass is fused it serves to protect the platinum, and the reconstructed ruby can be built up on it by adding the fragments of ruby one at a time by means of small platinum forceps. These pieces have to be dropped on with great care in order to secure incorporation with the mass and prevent, so far as possible, the formation of air bubbles. It will be readily understood that this process is a tedious and laborious one, and, in fact, the formation of masses of sufficient size to yield large stones on cutting is a matter of such difficulty that the cost of production is very high.

Just about seven years ago, however, Verneuil[1] overcame this restriction when he hit on the extremely ingenious idea of introducing the raw material through the blow-pipe, and thus placing it on the support automatically. The blow-pipe is arranged vertically over a small insulated chamber containing the support on which the mass is to be built up. The oxygen tube communicates at its upper extremity with a funnel-shaped hopper, in which is suspended a small sieve filled with the raw material, which is rhythmically shaken by means of a small hammer actuated by an electromagnet or cam. Each time the hammer taps the support of the sieve, causing it to vibrate, a small quantity of the powder falls through into the tube below, and, carried along by the gas, passes out at its lower extremity into the zone of flame, where it is immediately raised to the fusion point, and falls as a melted globule on to the support below.

This support is arranged with a screw adjustment, so that as the mass of corundum is gradually built up by the constant addition of fresh globules the surface can be kept at a constant level, and the portion already formed removed from the zone of heating so as to allow it to stiffen. When the apparatus is first started the blow-pipe is adjusted so as to give a comparatively cool flame, and the powder is admitted slowly. By this means a small "stalk" is formed, which insulates the mass from the support and prevents the fusion of the latter. When this has been formed, the full pressure of the blow-pipe is put on, and the rate of admission increased, with the consequent formation of a "boule," as it is termed, having the shape of a pear, as illustrated in Fig. 2.

FIG. 2.—"Boules" of Artificial Corundum.

With this apparatus a boule weighing some twenty to thirty carats, and capable of yielding two cut stones of about six carats each, can be prepared in about half an hour almost automatically, a single operator being able to control several machines.

The "synthetic" corundum produced in this way, if pure ammonium alum is used, is, of course, colourless, and can be used as artificial white sapphire. If a small proportion of chrome alum is added, the resulting stones are rubies, and other colours may be produced in the same way. For a long time all attempts to reproduce the fine blue of the sapphire failed. A year or so ago, however, the problem of producing synthetic sapphire was finally solved by the use of titanium oxide, a very unexpected result considering the chemical position of this element. The artificial production of the corundum gem-stone may be considered to be completely solved, and cut stones can now be obtained in every variety of colour, from pure

[1] "Mémoire sur la reproduction artificielle du rubis par fusion," M. A. Verneuil, *Annales de Chimie et de Physique*, September, 1904.

white to ruby and sapphire, at prices ranging from four to ten shillings a carat, according to colour, quality, and size.

Whatever may be their economic importance, a very much debated question, there can be no doubt as to the scientific interest of this group of artificial gems. In the first place, it is a matter of some interest that a mass of fused material formed in this way should not only be crystalline, but possess all the characteristics of a single crystal. Crystallographers are agreed that each boule is a single crystalline individual, with the axis roughly perpendicular to the plane of formation—that is to say, running from the point of attachment of the pedestal to the top of the mass.

Then there is the matter of coloration. One would like very much to know what is the state of combination of the chromium in a ruby, and whether the colour is produced by chromium aluminate in solution or metallic chromium in molecular suspension.

A point of more practical interest is the fact that although the artificial corundum is a true crystal, it possesses the shape and formation of a congealed liquid or glass. The practical interest of this lies in the fact that it affords the only means of distinction between this artificial corundum and the naturally formed gem-stone. Being of exactly the same composition and crystalline structure as the natural mineral, it cannot be identified by any of the physical tests I briefly referred to above. For all practical purposes, the artificial ruby *is a ruby*, and one can only deny that it is a "genuine ruby" if this word is held to connote essentially a product found in the earth and not made by man.

FIG. 3.—Section of Natural Ruby, ×100.

And yet, owing to the curious anomaly of its structure, the artificial product can almost invariably be distinguished from the natural with the greatest ease. In the naturally formed stone any foreign matter which may be present is coerced into following the lines of growth of the crystal, and more particularly bubbles of gas which may be present in the liquid are distorted from their natural shape so as to accord with this symmetrical growth. It is the great exception to find a natural ruby entirely free from such inclusions, which generally form irregular cavities with a decided tendency to geometrical shape.

In the great majority of cases examination of the cut stone with a lens is sufficient to decide the artificial process of formation, but in doubtful cases a more minute examination may be made by placing the stone in a little cell filled with highly refracting liquid, in order to secure regular illumination, and examining it under the microscope by transmitted light, when the minutest trace of structure can be detected. In the case of an absolutely flawless stone it would be impossible to decide whether it were natural or artificial, but such stones are so rare that this case is almost theoretical.

Reconstructed emeralds have been made by the Verneuil process, but these are, of course, amorphous, and do not possess the double refraction and other properties consequent upon the crystalline structure of the natural stone. The problem of producing this stone artificially has not as yet been solved.

The opal ranks with the diamond in resisting attempts at artificial production, and is even superior to it in that it cannot be really successfully imitated.

The peculiar lustre of the pearl, like the colour of the opal, is due rather to its structure than its composition. It is formed in the oyster by the deposition of successive layers of calcium carbonate round some central object, and consists of an innumerable number of thin overlapping laminæ of the crystalline variety of this substance known as aragonite. These layers being semi-transparent, the light falling on the surface is partially reflected from the surface and partially transmitted into the stone, where it suffers reflection from the surface of lower layers.

Perhaps the well-known Japanese pearl may be correctly described as artificial pearl, although the oyster has a great deal to do with it.

Such pearls are formed by introducing a mother-of-pearl shape between the shell and mantle of the oyster, and then leaving the oyster alone for a time to allow it to convert this into a pearl by the deposition of several layers of nacre. The mass is then removed from the shell and converted into the semblance of a true pearl by supplying a back of mother-of-pearl. Such pearls, however, never have the fine orient of those produced under normal conditions, and they can readily be detected by examining the back, when the lustreless mother-of-pearl and the line of junction can be detected.

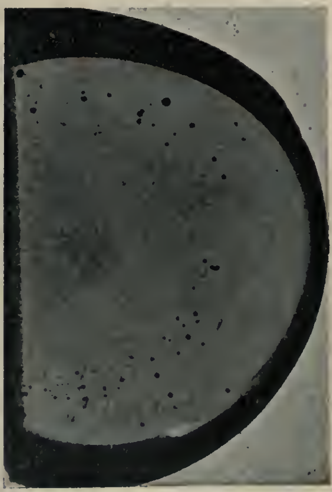

FIG. 4.—Section of Artificial Ruby, ×10.

Nobody has any right to supply anyone with paste under the name of artificial (or synthetic, or scientific, if these names are preferred) gem. I think that the distinction between the two should be clearly recognised, and that it should not be permitted to use the term artificial indiscriminately. At present this is being widely practised; every day one sees offered for sale "rubies, emeralds, sapphires, and pearls artificially produced, and having all the properties of the natural stone." Now, as I have indicated, such a thing as an artificial emerald answering this description is unknown, and, as a matter of fact, the stones supplied under this title are, as a rule, nothing more or less than paste imitations, the public being deliberately led to believe otherwise. There is in this case, as I have indicated, a real practical difference between the two articles, not merely a question of opinion.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—In the faculty of medicine an important change in the organisation of clinical teaching is being made. Hitherto this branch of teaching has been quite outside the control of the University. A clinical board appointed by the staffs of the Queen's and General Hospitals has directed the teaching and collected and administered the fees of students. In future the clinical board is to consist of nine members, of whom five will be appointed by the University and four by the two hospitals. The board will arrange all details of clinical teaching, and will nominate to the council of the University persons in the hospitals to act as clinical teachers, who will become members of the University staff. The fees for this teaching will be paid to and administered by the University. In consequence of the new arrangement, medical studies will be recognised by the Board of Education as a "technical" subject, in

aid of which a grant of money may be made—a privilege which could not be allowed so long as a part of the medical curriculum lay outside the control of the University.

CAMBRIDGE.—Mr. A. E. Shipley, F.R.S., Master of Christ's College, and Mr. P. V. Bevan, of Trinity College, have been approved by the general board of studies for the degree of Doctor in Science.

The Rede lecture will be delivered on Thursday, June 8, at 10.30 a.m., in the lecture room of the Botany School by the Hon. C. A. Parsons, C.B., F.R.S.

It is proposed that Dr. Haddon, F.R.S., and Dr. W. H. R. Rivers be appointed to represent the University at the Universal Races Congress to be held in London in July.

LONDON.—Mr. Andrew Carnegie has given a donation of 5,000*l*. towards the building and equipment of the Institute of Medical Sciences of University College.

Sir Felix Semon has offered to the University for the foundation of a lectureship in laryngology the sum of 1,040*l*., being the amount presented to him by British laryngologists on his retirement from practice. The benefaction has been accepted by the Senate.

The degree of D.Sc. (engineering) has been conferred upon Mr. F. C. Lea, an external student, for a thesis on "Influence Diagrams as concerned with Stresses in Structures" and other papers, and the degree of D.Sc. in geology has been conferred on Mr. R. L. Sherlock, an external student, for a thesis entitled "Relationship of the Permian to the Trias in Nottinghamshire" and other papers.

It has been decided to invite the committee of the fifth International Philosophical Congress to hold the meetings of the congress in the University buildings in the spring of 1915. The following appointments have been made:—The principal (Dr. H. A. Miers, F.R.S.), representative of the University at the celebration of the centenary of the Royal Frederick University of Christiania in September, 1911; Prof. J. D. Cormack, governor of the Imperial College of Science and Technology (in place of Sir Arthur Rücker, F.R.S., resigned); Dr. Thomas Buzzard, governor of Westminster Hospital Medical School.

MANCHESTER.—To enable those taking up farming, estate management, or the teaching of agriculture to obtain a thorough scientific and practical training in agriculture, an arrangement has been made between the University of Manchester and the College of Agriculture and Horticulture, carried on by the Cheshire County Council at Holmes Chapel, by which a scheme for complete courses of instruction in agriculture has been established. A course of study leading to the degree of B.Sc. in agriculture or to the diploma of the Agricultural College may be pursued. The students take lectures and laboratory work in chemistry, physics, and biology, as well as special courses in agriculture, estate management, agricultural chemistry, agricultural botany, agricultural zoology (including entomology). The courses in agriculture and estate management and part of the course in agricultural chemistry and in botany are taken at the Agricultural College. A special prospectus has been prepared giving full particulars of the courses.

Prof. T. W. Richards, of Harvard University, who is to deliver the Faraday Lecture of the Chemical Society, is to receive the honorary degree of D.Sc. on July 8.

OXFORD.—Dr. H. L. Bowman, Waynflete professor of mineralogy, has been appointed secretary to the delegates of the University Museum, in place of Mr. H. Balfour, curator of the Pitt-Rivers Museum, who resigns the office next month.

Dr. W. T. Brooks, Christ Church, has been appointed Litchfield lecturer in medicine as from October next.

Mr. William Bateson, F.R.S., has been appointed Herbert Spencer lecturer for 1911.

THE Edward Kempton Adams research fellowship has been awarded by Columbia University to Prof. R. W. Wood, of Johns Hopkins University.

PROF. R. PATRICK WRIGHT, principal of the West of Scotland Agricultural College, has been appointed agricultural adviser to the Scotch Education Department.

WE learn from *Science* that Dr. E. B. Wilson has been designated Da Costa professor of zoology in Columbia University in succession to Prof. H. F. Osborn, who becomes research professor of zoology.

DR. H. WENHAM, of the Union Medical College, Peking, announces that for the first time in history the Chinese Government has granted a medical degree. Sixteen out of twenty-one candidates have passed the required examinations.

THE University Society of Nottingham and the East Midlands was formed on Saturday last at a meeting held at the Nottingham University College, the object of which is the furtherance of university education in the East Midland counties.

THE West Riding Education Committee has appointed Miss Helen M. Wodehouse to the principalship of the Bingley Training College, which is to be opened in September next. Miss Wodehouse is at present lecturer on philosophy in the University of Birmingham.

IT has been decided that Dr. Roberts, the secretary of the forthcoming Congress of the Universities of the Empire, shall visit Montreal in order to be present at the preliminary Conference of Canadian Universities, which is to be held in the first week of June, to ascertain the views of the Canadian universities as to the most suitable questions for discussion at the congress and to give any information respecting the steps that are being taken in the United Kingdom.

IN the April issue of *The Technical Journal*, which has now been received, a new series of articles on "Famous Technical Schools" is initiated with an illustrated description of the Glasgow and West of Scotland Technical College, by Drs. G. S. Cruikshanks and F. J. Wilson. It is proposed that the series shall not be confined to schools in the United Kingdom, but shall deal, so far as possible, also with the leading Continental and American schools.

THE fifth annual conference of the Association of Teachers in Technical Institutions will be held at Southport on June 5 and 6. Mr. Barker North, of the Bradford Technical College, will deliver the presidential address, and among the questions arranged for discussion are "The Organisation of Higher Technical Instruction," "The Representation of Teachers on Educational Bodies," "The National Organisation of Technical Education," and "The Salaries and Pensions of Technical Teachers." Further particulars of the conference may be obtained from the hon. secretary of the association, Mr. P. Abbott, The Polytechnic, Regent Street, W.

THE record of a notable achievement was contained in the final report of the building committee of the Glasgow and West of Scotland Technical College presented to a recent meeting of the governors. The committee reported the completion of the buildings, the foundation stone of which was laid in May, 1903. The buildings contain about seven acres of floor space, and the cubic contents amount to 7,292,382 cubic feet. Their cost, including professional fees and electric lighting and ventilating installations, was 272,329*l*, or less than 9*d*. per cubic foot, although they are of the most substantial fireproof construction. The portions of the site not previously in the possession of the college were purchased for the sum of 46,153*l*., and the equipment of the laboratories cost 34,746*l*., making a total expenditure of 353,228*l*. The whole expenditure involved in this large undertaking has been met without the incurrence of any debt. The college received grants from the Scotch Education Department of 88,660*l*., and voluntary subscriptions and donations amounting to 278,603*l*.; a balance of 14,000*l*. is therefore available to meet additions to the laboratory equipment now in course of construction or about to be ordered. These additions include an experimental steam turbine of the multi-stage impulse type and

of 200–250 horse-power; also a larger turbine of the reaction type. A high-speed paraffin engine of 40 horse-power and a four-cylinder petrol motor have been presented recently to the laboratory. The development of the college has kept pace with the increased accommodation. Last year a school of navigation was established, and its success has justified the governors in contemplating the purchase of a sea-going training vessel. A lectureship in sugar manufacture has also been instituted. Mr. Alfred Campion, who was appointed lecturer in metallurgy two years ago, has been raised to the rank of professor.

A MEETING of the Association of Teachers in Technical Institutions was held on May 20 at the Cardiff Technical School to consider the formation of a South Wales branch of the association. There was a representative attendance of technical teachers from Cardiff, Swansea, Newport, and the county of Glamorgan. An address was delivered by Mr. P. Abbott, the honorary secretary of the association, on "The Aims and Work of the Association." Mr. Abbott said technical education was the last branch of education to be organised, and consequently technical teachers were the last to band themselves together for the purposes of joint action. The organisation of technical education has not yet gone far, and it is probably safe to say that in this respect we are ten years behind Scotland and twenty years behind Germany. It must be recognised that conditions are changing, and that the extent of the prosperity of a country in the future will be determined more and more by the number of skilled and highly trained industrial experts that it possesses. If this work of organising technical education is to be efficient there must be cooperation. On one hand are those whose business it is to organise, administer, and finance technical education; on the other there are the teachers with an acquaintance with the calibre and the economic conditions of the students. The two classes are complementary, and for true progress the teachers must make their contributions to the solution of the problems involved. Facilities must be provided for the interchange of views and the formulation of opinions. Hence the association has the highest of all claims for the support of technical teachers. Mr. Abbott dealt at some length with the work done by the association, and especially in connection with examinations and curricula. In many respects, he said, the technical teacher is to-day in a relatively worse position than any other section of the teaching profession. Returns showed that the full-time technical teacher is usually paid worse than the secondary-school teacher. In conclusion, Mr. Abbott emphasised the national character of the association. A resolution was passed unanimously in favour of the formation of a South Wales branch.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society May 18.—Sir Archibald Geikie, K.C.B., president, in the chair.—Prof. W. M. **Bayliss**: The properties of colloidal systems. II.—On adsorption as preliminary to chemical reaction. The existence of an "adsorption compound" containing acid and base uncombined chemically, and which can be isolated, is described, together with the manner of its conversion into the true chemical compound or salt. It is shown that a similar kind of compound is formed between an enzyme and its substrate, preliminary to the particular chemical change brought about by the enzyme in question. Adsorption between enzyme and substrate as affected by the presence of neutral salts is investigated, and found to follow the laws of "electrical" adsorption. The relation between the concentration of an enzyme and its activity is shown to be expressed by an exponential formula, the value of the exponent varying considerably according to circumstances. In certain conditions it may be unity, and in others the square root, but is usually between the two. Accordingly, the view that the rate of an enzyme action at any given moment is a function of the amount of the adsorption compound of enzyme and substrate in existence at that time is to be regarded as fairly well established.—S. M. **Jacob**: Inbreeding in a stable simple Mendelian population, with special reference to cousin marriage. The paper investigates, on the basis of Mendel's conception of the segregation of unit-characters, the proportions of different types among the offspring resulting from alliances of various degrees of inbreeding. A detailed examination is made of the consequences of first-cousin marriages, the form of inbreeding most frequently met with in actual human populations, while unions of other degrees of affinity, both those closer and those more remote, are also considered. The important point is brought out that for an evil which is a Mendelian recessive and is of common occurrence, a first-cousin marriage will not be much more likely to produce defective offspring than any other kind of marriage, but that a very rare recessive evil is relatively far more readily developed by such a consanguineous marriage. Now it is probable that there are very many of these rare defects latent in man. As the chance of a *particular* one of these appearing is increased by cousin marriage, the appearance of any random one of the large number is rendered much more probable by such a union. The same is true, on the Mendelian hypothesis, for any desirable qualities when such can be shown to be recessive. It is also established that the relative frequency of the appearance of the allogenic constituent in the offspring of related pairs diminishes by about one half for each grade of cousinship, so that the efficacy of cousin marriages in developing the recessive character diminishes with the grade of the marriage. In general, inbreeding accentuates both the pure dominant and the pure recessive strain to the same extent and at the expense of the hybrid element.—Miss M. **Wheldale**: The direct guaiacum reaction given by plant extracts. Previous work on oxidising enzymes has led to the interpretation of the direct blueing action in terms of the activity of a system consisting of an organic peroxide in conjunction with a peroxidase. The author finds that the power to give the direct action possessed by water-extracts of tissues is accompanied by another phenomenon, *i.e.* the formation of brown or reddish-brown pigments in the tissues on exposure to chloroform vapour. Both phenomena are characteristic of certain natural orders, but are absent from others or are characteristic of certain genera only in an order. When the direct action is not given, the plant extract will blue guaiacum on addition of hydrogen peroxide (indirect action), and the tissues do not show change of colour in chloroform vapour in the same period of time. The phenomenon of direct blueing of guaiacum is considered by the author to be the outcome of the presence of the dihydric phenol-pyrocatechin in the plants examined. Pyrocatechin is oxidised on the death of the tissues, and then acts as a peroxide, enabling the peroxidase, which is almost universally present, to transfer oxygen to the guaiacum. These conclusions are based on the following evidence:—(1) that pyrocatechin can be detected in plants (such as have been examined) which give the direct action and show change of colour in chloroform, whereas it cannot be detected in plants lacking these characteristics; (2) that solutions of both chemically prepared pyrocatechin and the actual plant product, after oxidation in air, will give a direct action with guaiacum and peroxidase only. The same result is not obtained with phenols having the hydroxyl groups in other positions. Hence the *direct* guaiacum reaction has, in all probability, no real significance as such in plant metabolism, but is merely the outcome of the presence of a certain metabolic product.—Dr. A. **Theiler**: Transmission of amakebe by means of *Rhipicephalus appendiculatus*, the brown tick. This is an account of experiments carried out at Pretoria, confirming the result arrived at by the Sleeping Sickness Commission during 1909, that the disease of calves in Uganda, known as amakebe, is in reality East Coast fever. It was arranged with the Government veterinary surgeon in Uganda, Mr. Hutchins, to send to Dr. Theiler nymphæ of *Rhipicephalus appendiculatus*, the brown tick, collected from calves in Uganda suffering from amakebe. On several occasions Mr. Hutchins forwarded ticks, which arrived at Pretoria alive and in good condition. The nymphs in transit moulted into the adult stage. Two experiments were performed to ascertain whether brown ticks, collected as nymphæ in Uganda from a calf suffering from amakebe, will transmit the disease when placed on susceptible calves in the

Transvaal. The first experiment, a bull calf, born and reared in Onderstepoort, was infested on January 23 with ten adult brown ticks, forwarded from Entebbe, Uganda, and received in the Transvaal on January 4. The ten ticks were found attached to the calf the following day. The animal died on the twenty-third day after tick infestation, and from the course of the disease and the *post-mortem* examination, a diagnosis of East Coast fever was concluded. Koch's bodies were found *post mortem* on microscopical examination of preparations of the lymphatic glands and spleen. The second experiment was carried out in a similar manner. On February 14 a calf was infested with ten adult brown ticks of the same batch, obtained from Uganda. On February 15 seven of the ticks were found attached. After an incubation period of thirteen days, a typical fever curve ensued. The animal died on the twenty-fourth day. During the course of the disease, Koch's bodies were found in the glands, and *Theileria parva* in the red cells of the blood. A diagnosis of East Coast fever was also concluded from the *post-mortem* examination in this case. Koch's granules were frequently found *post mortem* in the lymphatic glands and spleen.—S. J. **Meltzer**: Distribution and action of soluble substances in frogs deprived of their circulatory apparatus.—Dr. F. W. **Edridge-Green**: The discrimination of colour. If a definite portion of spectrum be isolated it will appear monochromatic, the size of the monochromatic region varying with the luminosity and wave-length of the light and the colour perception of the observer. Lord Rayleigh has expressed the opinion that he can discriminate between the colours in a monochromatic region even to the extent of distinguishing between the colours of the two D lines. The author does not find this possible when special precautions are taken to have a pure spectrum and to avoid the physiological effect of contrast through varying intensities of the areas to be compared. The monochromatic area may be magnified without altering its monochromatic appearance, the intensity of the light source being increased to compensate for the diminished luminosity. The monochromatic area may also be examined through a double-image prism, or be projected by means of a double-image prism upon a screen, so that the violet side of one area is adjacent to and just touches the red side of the other area. In this way the monochromatic area may be made as large as desired, the intensity of the source of light being increased as required. An arc light gives two very bright areas of colour. This method is the most favourable for the detection of any difference; the monochromatic areas, however, still remain monochromatic.

Royal Meteorological Society, May 17.—Dr. H. N. Dickson, president, in the chair.—Dr. H. R. **Mill** and C. **Salter**: The frequency and grouping of wet days in London. The purpose of this paper is to place on record certain facts, derived from the long homogenous records of rainfall kept at Camden Square, bearing on a recent scheme for insurance against rain risks. Days with a rainfall exceeding ·20 in. only are dealt with, as this is the limit adopted in several of the policies of insurance. The discussion is, of course, strictly applicable to London only, but it will probably apply fairly well to other inland stations in the south-east of England. The authors have examined a number of instances in which an insurance under one or two of the forms of policy offered would have resulted in a claim had a person in London insured every day for the week commencing that day during the whole period of fifty-two years. The actual compensation yielded by each 1*l*. invested during each seven-day period from 1859–1910 would have been as follows:—

Policy	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Year
A ...	8/8	6/5	6/10	4/1	4/9	11/3	10/7	11/1	10/1	18/10	15/9	11/1	10/-
B ...	9/1	8/6	7/10	7/7	9/1	11/3	11/4	10/10	10/-	13/10	12/8	10/8	10/9

E. **Mawley**: Report on the phenological observations for 1910. The most noteworthy features of the phenological year ending November, 1910, as affecting vegetation were the continuous and heavy rainfall in February, a sudden change from cold to warm weather in the middle of May, the great dryness of September, and the heavy rains and low night temperatures in November. During the greater part of the year wild plants came into blossom behind their usual time, the departures from the average being greatest at the end of April and the beginning of May. Such early spring migrants as the swallow, cuckoo, and nightingale made their appearance at about their usual dates. The only deficient farm crops were wheat, barley, and peas. On the other hand, the yield of oats, beans, potatoes, turnips, mangolds, and hay were above the average, and more especially beans, turnips, and hay. The crop of apples, pears, and plums was much under average, while all the small fruits, except strawberries, which yielded well, were also rather under average.

EDINBURGH.

Royal Society, March 20.—Prof. T. Hudson Beare, vice-president, in the chair.—Dr. J. R. **Milne**: Measurements on the scattering of light by "ground" glass. Certain preliminary experiments on the scattering power of various kinds of ground glass were described, as well as the form of apparatus which had been designed for the purpose of the research.—Margaret B. **Moir**: The magnetic properties of certain steels at moderate and high temperatures. The experiments were made in the physical laboratory of Glasgow University. In every case the specimen was rendered neutral at the new temperature previous to carrying out the tests. It is essential that this point should be attended to, and much of the previous work on magnetisation at various temperatures left a good deal to be desired in this respect. One result of interest was the discovery of a transformation point for carbon steel in the neighbourhood of 200° C. The changes in susceptibility which accompany the transformation are very distinct in cast iron and high carbon steels, not so marked for medium carbon steel, and imperceptible for soft iron.—Dr. J. A. **Gunn**: The pharmacological action of harmine. In this paper the actions of harmine were shown to be qualitatively very similar to those of harmaline, previously described by the author.

PARIS.

Academy of Sciences, May 8.—M. Armand Gautier in the chair.—P. **Appell**: The linkages expressed by the non-linear relations between the velocities.—Ch. **Lallemand**: The survey of the levels of Alpine valleys, with especial reference to the water-courses.—A. Michel **Lévy** and A. **Lacroix**: The materials of the rhyolitic and trachytic eruptive explosions of the volcano of Mont Dore. Details and discussion of two complete analyses of the rhyolitic pumice and four of the trachytic pumice.—A. **Müntz** and A. **Lainé**: The phenomena of the purification of sewage by the soil and by bacterial beds. It has been shown in a recent paper by the authors that in bacterial beds the destruction of organic matter by direct combustion takes place, and that this effect is greater than the nitrification. A study has now been made of purification by soil under ordinary agricultural conditions, and it has been found that the conditions of purification are different; in the bacterial beds combustion preponderates and nitrification is a secondary phenomenon, in soil nitrification predominates. The conclusion is drawn that soil is much superior as a nitrifying medium to bacterial beds.—M. **de Forcrand**: The hydrates of rubidium and cæsium fluorides.—Paul **Sabatier** and A. **Mailhe**: The catalytic decomposition of formic acid. From the reactions already known, formic acid might be expected to split up under the action of catalytic agents in three ways, giving carbon dioxide and hydrogen, carbon monoxide and water, or formaldehyde, carbon dioxide, and water respectively. The change into carbon dioxide and hydrogen is produced by platinum sponge, reduced copper, nickel, cadmium, and the oxides of zinc and tin. The second reaction is furnished by titanium dioxide and by the blue oxide of tungsten. Many substances, including thorium oxide, give all three reactions simultaneously.—L. **Cailletet**: The origin of the carbon assimilated by plants. The plants used in these experiments, according to the conditions of illumination, could take their carbon either from atmospheric carbon dioxide or from the organic material contained in the soil, or from both at once.—C. **Juel**: Simple cubic surfaces.—H. **Larose**: Trigonometrical developments with non-orthogonal components.—Georges **Rémoundos**:

The minimum modulus of integral functions.—M. **Riquier**: The existence of integrals satisfying given conditions along a contour.—Michel **Plancherel**: The application of Laplace's series to the method of summation of M. de la Vallée-Poussin.—Louis **Roy**: Viscosity in the motion of flexible wires.—H. **Vergne**: A development in series and its application to the problem of liquid waves by emersion.—L. **Hartmann**: The mechanism of the permanent deformation in metals submitted to extension. A description of the application of the method previously published to aluminium, nickel, two ferro-nickel alloys, copper-nickel, and other alloys.—J. **Olive**: Experiments made with the installation for aërodynamical measurements of the aviation establishment of Vincennes. The installation has for its object aërodynamical measurements on apparatus of full size displaced in calm air. Results are given for a Wright aëroplane.—M. **Rabut**: Partial tunnelling under the Rue de Rome and Boulevard des Batignolles. In the extension of the width of the line it was necessary to cut under these streets, portions of which were then supported on brackets of reinforced concrete.—L. **Houllevigue**: A radiation emitted in the interior of incandescent lamps.—A. **Leduc**: The work of magnetisation.—H. **Woltereck**: The production of ammonia and the economy of nitrogen in peat. It is shown that the treatment of peat by steam alone produces only one-third the quantity of ammonia obtained under similar conditions by the use of a mixture of steam and air.—G. **Charpy** and S. **Bonnerot**: The gases contained in steels. A source of error noted in these experiments was the slow evolution of gas due to a reaction between the heated metal and minute traces of water given off in the mercury pump. Extra precautions against this water vapour gradually diminished the continuous evolution of gas, but it could not be completely stopped.—Ed. **Chauvenet**: The action of carbon oxychloride on artificial and natural sulphides. The action of carbon oxychloride upon nine sulphides of different metals has been studied. The temperature of the reaction was in no case higher than 450° C., and in each case the normal chloride was the sole product. Examples are given of the application of the reaction in quantitative analysis.—F. **Bodroux** and F. **Taboury**: The bromination of some hydroaromatic compounds. Cyclohexane, prepared by the Sabatier and Senderens method, is not sensibly attacked by bromine in the dark at the temperature of the boiling point of the hydrocarbon. In sunlight the action is regular, hydrobromic acid being evolved and a good yield of cyclohexyl bromide being produced. Ultra-violet light cannot replace sunlight in this reaction. Higher bromine derivatives were also prepared.—M. **Lanfry**: A dinaphthothiophene.—P. **Freundler**: Researches on the oxyindazoles.—G. **Gauthier**: The synthesis of tertiary α-ketonic alcohols. Cyanhydrins are first prepared by the interaction of hydrocyanic acid and ketones, and these treated with an alkyl magnesium iodide. Three examples of the application of this general method are given.—A. **de Schulten**: The crystallographic examination of some fluorides obtained by M. Henri Moissan and his pupils.—V. **Vermorel** and E. **Dantony**: An anticryptogamic colloidal copper solution. Full details are given for the preparation of the new solution, which possesses certain advantages over those in current use.—M. **Marage**: Contribution to the study of consonants.—N. A. **Barbieri**: The mobility of neuroplasma.—Pierre **Lesne**: The battle against the caterpillar *Zeuzera pyrina*.—E. **Bataillon**: Embryogenesis provoked in the virgin egg of Amphibia by inoculation with the blood or sperm of a mammal. Traumatic parthenogenesis and impregnation without amphimixia.—MM. **Bordas** and **Touplain**: The original acidity of milk. The original acidity of milk, using phenolphthalein as indicator, is due exclusively to the free casein.—M. St. **Mostowski**: The glycogenic property of dioxyacetone.—E. **Kayser**: Beer yeast juice.

May 15.—M. Armand Gautier in the chair.—H. **Deslandres** and V. **Burson**: The laws relating to the movements of the solar protuberances. A study of the displacement of the K_3 line. The variations observed appear to correspond with the assumption that the velocity of rotation increases with the altitude, at least in the layers immediately above the chromosphere. No light has been thrown on the question as to whether the displacements east and west are equal or unequal.—J. **Carpentier**: The ophegraph, designed by M. Guillery. An account of an instrument for drawing tangents to a given curve by mechanical means. By means of this instrument, given a curve representing a function, the curve of the first differential of this function can be obtained graphically.—A. **Blondel**: Harmonic functions determined by certain conditions at the contour.—A. **Chatelet**: Abelian bodies of the third degree.—Ch. **Bertin**: A table of positions for purposes of navigation.—Captain **Duchène**: Good control of the aëroplane in air in motion. A description of two additions to an aëroplane, one designed for preserving longitudinal equilibrium, the other for transversal equilibrium.—M. **Yvon**: Cataphotography. Remarks on a recent publication of M. Guillaume de Fontenay.—Guillaume **de Fontenay**: Cataphotography. Acknowledging the priority of M. Yvon.—M. **de Broglie**: A particular case of distribution of ionisation in a gas. A very thin superficial layer containing ions of both signs. In the case of the ionisation of air by sulphate of quinine at the surface of the salt during the variations in hydration, there is an infinitely thin layer containing a high density of ions of both signs.—L. **Décombe**: A physical interpretation of non-compensated heat.—H. **Pélabon**: The resistivity of the selenides of antimony. From measurements of the specific resistances of various fused mixtures of antimony and selenium it was hoped to get some evidence as to the existence of definite compounds of these two elements. It was found, however, that the differences in resistance caused by tempering or annealing were so large that no definite conclusions could be deduced from the experimental figures.—A. **Rosenstiehl**: Some historical data relating to osmotic pressure.—Marc **Landau**: The action of the ultra-violet rays upon lactic acid. The gas evolved was mainly carbon dioxide, with some carbon monoxide. Ethyl alcohol, together with traces of pyruvic acid and an aldehyde, were detected.—Camille **Matignon**: The presence of zinc nitride in zinc dust and in commercial zinc. Zinc nitride appears to be present in all commercial samples of zinc dust. It is also met with, although in extremely small quantities, in certain solid zincs.—Pierre **Jolibois** and Eugène L. **Dupuy**: The definite compounds of arsenic and tin. From the metallographic study of a series of alloys of tin and arsenic only two compounds could be clearly defined. These had the composition of Sn_4As_3 and SnAs.—G. **Darzens**: A new method for the esterification of alcohols by the hydracids. The alcohol is treated with thionyl chloride and a tertiary base (B) such as diethylaniline, quinoline, or pyridine, when the reaction

$$R.OH + SOCl_2 + B = RCl + SO_2 + B.HCl$$

takes place quantitatively. A similar reaction with $SOBr_2$ gives good yields of bromides.—A. **Petit**: The fixing of phosphoric acid by the organic matter of the soil. Soils rich in organic matter do not fix any appreciable amounts of phosphoric acid.—Paul **Becquerel**: The supposed production of new plant forms by the method of traumatisms. The author concludes that neither in his own experiments with Zinnia nor those of M. Blaringhem with maize have new forms been really produced.—H. **Hallopeau**: The region of primary invasion of syphilis.—Albert **Berthelot**: Researches on di-iodotyrosine and its possible utilisation in therapeutics. Experiments made with 3 : 5-di-*l*-iodotyrosine showed that it is well tolerated by man and by animals, and promises to be a useful means of introducing relatively large quantities of iodine into the body without prejudicial after effects.—Jules **Amar**: Walking on an inclined plane.—P. **Achalme** and M. **Bresson**: The influence of the viscosity of the medium upon diastatic actions. An increase in the viscosity of the liquid, produced by the addition of glycerol, exerts a reducing influence on diastatic action which is very great compared with the variations introduced by other factors. The full discussion of the theoretical bearing of these experiments is reserved for a later paper.—Armand **Juillet**: Comparative observations on the relations between the lungs and the aërial sacs in birds.—J. **Wolff**: Some phenomena of reduction of oxyhæmoglobin. If the colouring matter is repeatedly reduced by ammonium sulphide and oxidised by shaking with air, after twenty-five or thirty times the

blood pigment is entirely destroyed. When, however, a biological reducing agent, such as the coccus obtained from a maceration of cheese, is employed, the alternate reduction and oxidation can be reproduced almost indefinitely.—Augustin **Wroblewski**: The soluble ferments of the brain. The presence of catalase, peroxydase, and lipase was proved.—Gabriel **Bertrand** and M. **Javillier**: The influence of zinc and manganese on the mineral composition of *Aspergillus niger*.—Jules **Stoklasa**: The physiological importance of manganese and aluminium in the plant cell.—R. **Lehmann** and C. **Vaney**: Percentages and qualities of the skins attacked by larvæ of Hypoderma in the Lyonnaise district.—Jules **Chalande**: Segmentary division in the myriopods.—E. **Roubaud**: The biological and morphological variations in *Stomoxe mutin* in tropical Africa.—A. **Gruvel**: Contribution to the systematic study of the Palinuridæ.—Pierre **Kennel**: The adipo-lymphatic bodies of some batrachians.—A. **Dehorne**: Nuclear permutation in the conjugation of *Colpidium colpoda*.—G. **Le Cadet**: The registration of a seismic shock by the large Richard barograph at the central Observatory of Indo-China.

DIARY OF SOCIETIES.

THURSDAY, MAY 25.

ROYAL SOCIETY, at 4.30.—Experiments on the Compression of Liquids at High Pressures: Hon. C. A. Parsons, F.R.S., and S. S. Cook.—Energy Transformations of X-rays: Prof. W. H. Bragg, F.R.S., and H. L. Porter.—Spectroscopic Investigations in connection with the Active Modification of Nitrogen. I. Spectrum of the Afterglow: Prof. A. Fowler, F.R.S., and the Hon. R. J. Strutt, F.R.S.—An Optical Method of Measuring Vapour Pressures; Vapour Pressure and Apparent Superheating of Solid Bromine: C. Cuthbertson and Mrs. M. Cuthbertson.—The Vacuum-tube Spectra of Mercury: Dr. F. Horton.—The Production of Characteristic Röntgen Radiations: R. Whiddington.

ROYAL INSTITUTION, at 3.—Air and the Flying Machine. II. Conditions of Safety for Floaters and Fliers: Dr. W. N. Shaw, F.R.S.

ROYAL SOCIETY OF ARTS, at 4.30.—N.W.F. Province of India: W. R. H. Merk.

AFRICAN VEGETATION.

Die Vegetation der Erde. Sammlung pflanzengeographischer Monographien. By Prof. A. Engler and Prof. O. Drude. ix., Die Pflanzenwelt Afrikas, insbesondere seiner tropischen Gebiete. Grundzüge der Pflanzenverbreitung in Afrika und die Charakterpflanzen Afrikas. By A. Engler. Band i., Allgemeiner Überblick über die Pflanzenwelt Afrikas und ihre Existenzbedingungen. 1 Hälfte (Heft i.), pp. xxviii+478. 2 Hälfte (Heft ii., und iii.), pp. xii+479–1029. (Leipzig: W. Engelmann, 1910.)

THE botany of Africa, especially of tropical Africa, has for the last twenty years attracted much attention among systematists, both in this country and on the Continent of Europe. The important and exhaustive "Floras" of South and Tropical Africa organised at Kew have, after a period of abeyance, progressed steadily towards completion. Many books and papers dealing with more restricted areas have been published, such as the enumeration of Dr. Welwitsch's Angolan collections, the important work on the vegetation of German East Africa, edited by Dr. Engler, of Berlin, and Dr. Wildemann's finely illustrated volumes on the botany of the Congo region. The results of various expeditions, many of which have been largely due to individual effort, have also added much to the botanical literature of this great continent. Towards the achieving of these results no one has worked harder or displayed greater zest than Dr. Engler. Not only has he made good use of the members of his staff at the Berlin Botanical Museum in working up the great mass of material which has been collected chiefly from the German colonies, but has also himself made botanical expeditions in various parts of the continent. Dr. Engler was therefore eminently fitted to prepare a general account of the vegetation of Africa, and the two substantial volumes in which this account is embodied form a valuable addition to the important series of monographs on plant geography issued under his own and Prof. Oscar Drude's editorship.

The greater part of the book, to be precise 870 out of a total of 1019 pages, is occupied with the introduction, a general review of the vegetation of the continent. This takes the form of a series of chapters descriptive of the vegetation of as many areas differing largely in size and importance. Chapter i. (pp. 1–50) deals with Mediterranean Africa, from Morocco to Egypt, and the Sahara. Chapter ii. (pp. 51–478), "Tropical East Africa to Eastern Capeland," deals with the vast area extending from Nubia and Somaliland to the Karroo district of Cape Colony, and includes among its principal subdivisions the Abyssinian flora, the floras of the Somali peninsula, of the Masai highlands, of German East Africa, Nyasaland, Portuguese East Africa, Rhodesia, the east Kalahari district, and the Karroo. The rich and characteristic flora of south-west Cape Colony forms the subject of the third chapter, while the fourth—"the extra-tropical and tropical summer-rain district of West Africa"—is concerned with the enormous area stretching from Namaqualand and Hereroland to Senegambia, and including the Huilla highlands, Angola, the Congo basin, the area of central tropical Africa from the Upper Congo to Uganda and the Great Lakes, the Ruwenzori district, the Cameroons (treated in some detail), Central Guinea or Togoland, Upper Guinea, and Senegambia. The fifth and last chapter deals with the vegetation of the Cape Verdes, the Canary Islands, and Madeira.

A perfect uniformity of treatment of these numerous and widely different areas, some only of which have been indicated above, could not be expected, and Dr. Engler is naturally most exhaustive in dealing with provinces the botany of which he has had most opportunity of knowing, namely, those under German government in East and West Africa. But his review as a whole forms a valuable *résumé* of the work which has been done on the botany of the various parts of the African continent, and gives, so far as is possible from the data to hand, a useful account of the chief characteristics of their vegetation. It shows not only what has been done, but, a matter of equal importance, what still remains to be done. Perhaps the most striking feature of this portion of the work is the wealth of illustration; the pictures occupy almost if not quite as much space as the text. There are more than fifty whole-page plates, beautiful photographic reproductions of vegetation, plant associations, or landscape. In addition there are more than 700 text figures, many of which occupy a full page; these illustrate habit or form of individual plants, or are botanical analyses of one or more species. The illustrations alone give a good idea of the characters of the vegetation of the district under discussion. Mention should also be made of the carefully elaborated list of botanical collectors classified according to districts, which precedes the text proper. Associated with this is a map indicating the routes and collecting stations of the more important collectors. Three other maps illustrate the vegetation of German South-West Africa, the Cameroons, and Togoland respectively.

The comparatively small portion of the book which remains after the introduction, is divided into four parts. Part i. deals mainly with climate—temperature and rainfall—of the tropical and north and south extra-tropical areas; it also includes a chapter on the nature of the soil. Part ii. gives a brief general account of the vegetation of a series of altitudinal regions—tropical rain forest, tropical steppe region, subtropical bush and grass region, subtropical high forest region, and subalpine and alpine regions. Part iii. deals similarly with the various formations—halophilous, including littoral and interior (such as occur in the Sahara in the north, and the Kalahari in the south); hydrophilous, including alluvial forest, marshland, lake, and river vegetation; hygrophilous megatherm, the evergreen rain-forest vegetation; hygrophilous mesotherm—the bamboo forest, high mountain bush, and damp meadow vegetation of the higher regions of the tropical mountains or the slopes

of the subtropical; subxerophilous, such as occur in districts with a short rain season of three to four months or a limited mist formation—a very extensive and diverse series, including the grass steppes at different altitudes, the dry wood- and bush-formations, and subalpine and alpine areas; and, finally, the true xerophilous formations. The fourth and last part contains an elaborate series of lists of orders and genera displaying the various component elements of the African flora, such as a general tropical element, palæotropic, African - Asiatic, African - Malagasy, American-African, Mediterranean-African, endemic tropical, and others. There is also a short sketch of the development of the African flora.

The difficult problem of indexing so extensive and elaborate a sytematic work has been solved by supplying an exhaustive table of contents and by confining the index to names of plants which are figured in the text.

A. B. R.

THE ALTERNATE-CURRENT TRANSFORMER.

Transformers: a Treatise on the Theory, Construction, Design, and Uses of Transformers, Autotransformers, and Choking Coils. By Prof. H. Bohle and Prof. D. Robertson. Pp. xiv+356+Tables A and B+18 plates. (London: C. Griffin and Co., Ltd., 1911.) Price 21*s.* net.

THIS very complete treatise on the alternate current or static transformer will no doubt be found of considerable value in the drawing office of practical transformer builders, and also by teachers and advanced students. Whoever uses it, however, will have to possess time and patience as well as very good eyesight to master the symbolical notation the authors have seen fit to employ, which to most ordinary readers will prove in certain respects exasperating. In dealing with simple periodic or variable quantities, such as alternating currents, electromotive forces, and fluxes, a widely used custom has been adopted of employing small letters for instantaneous values and corresponding large ones for the maximum values, and either brackets or bars over a letter to denote R.M.S. values. The authors of this book have adopted the plan of printing a little ᵗ inside the capital letter to denote the instantaneous value, and a little ᴹ to denote the maximum value. These special symbols are for most eyes quite illegible without the aid of a magnifying glass, and can only be described as producing the maximum amount of eye and mind strain to read them.

Again, most mathematical writers now employ block letters or clarendon type to signify vectors, but the authors of this book have turned their backs on this useful practice, and used block letters such as **T** and **N** to signify scalar quantities such as time, or mere numerics such as number of turns. This may seem to the non-mathematician to be a small matter, but at a time when an International Committee is endeavouring to obtain something like order and uniformity in technical symbolisation, it is a great pity for any authors to display an exuberance of ingenuity in devising symbols which have never been used before, and are not likely to be used again.

Apart, however, from the difficulties of perusal introduced by this deviation from beaten paths, the authors have produced a book which has many valuable qualities. It is characterised by admirable illustrations prepared from photographs of actual transformers, parts, and appliances, and also by excellent plates giving working drawings of transformers in use, which are rendered all the more useful by appended millimetre and inch scales.

There are also a large number of curves delineating the co-variation of pairs of important quantities.

The book is divided into twelve chapters covering general principles, magnetising and no-load currents, losses in transformers, temperature rise, magnetic leakage, transformer vector diagrams, systematic testing, insulating materials, examples of construction, design of transformers, applications of transformers, and polycyclic systems. Having regard to the fact that so much has been written on the subject of transformers, there is a remarkable absence of all references, either in footnote or text, to the work and writings of previous authors.

The subject of the alternate-current transformer has been treated from the point of view of theory and of the student with such completeness in the works of Blakesley, Fleming, Kapp, Bedell, Bedell and Pierce, Rhodes, and many others that the chief room for addition seemed to be in a practical treatise on the design of transformers, giving rules for the systematic predetermination of all dimensions and quantities to a prescribed specification.

This the authors have done in their chapter x., and have added also complete worked out specifications for transformers and choking coils of various sizes and types. These, however, would have been rendered more valuable if the actual results of tests of these transformers had been given to show how far the predetermined values agree with measured ones.

The chapter on testing of transformers seems deficient in not laying sufficient stress upon the measurement of secondary drop or giving good methods for determining it at all loads. When transformers have to be banked to work in parallel, the identity in their drop curves is most important, as otherwise one or more transformers may be overloaded or may overheat. Bragstad's and Kapp's diagrams for transformer regulation are, however, given and explained in the chapter on transformer diagrams.

It would require much time and, in addition, considerable expense to check or test the formulæ given by the authors for dimensions of transformers to comply with certain specified requirements, but the results are for the most part embodied or condensed into tables, which the practical transformer manufacturer can speedily bring into comparison with practice. The book, however, in many respects fills a distinct gap in transformer literature, and will no doubt be of great use to draughtsmen who are responsible for overhauling or improving a line of stock transformers to reduce cost or improve their working. It only remains to add that the book is excellently printed, and in this respect a model of what technical publications should be.

THE FEEDING OF CROPS AND STOCK.

The Feeding of Crops and Stock. An Introduction to the Science of the Nutrition of Plants and Animals. By A. D. Hall, F.R.S. Pp. xvi+298. (London: John Murray, 1911.) Price 5s. net.

THIS volume is the third of a series by Mr. Hall dealing with some of the scientific aspects of farming, and, like the preceding treatises, on "The Soil" and "Manures and Fertilisers," gives an exceedingly clear and able exposition of the principles of crop and stock feeding, valuable alike to student, teacher, and practical farmer. It might be well if Mr. Hall would at a convenient time consider the rearrangement of the series, as at present there is some overlapping of subjects which is particularly noticeable in the present volume.

The first four chapters are devoted to the study of the growth of and the chemical changes occurring during the growth of plants. The important points in this process are illustrated by simple experiments which can be performed without the aid of complicated apparatus, and which we particularly commend to teachers of "nature-study" in our elementary and secondary schools. Chapters v. to viii. deal with matter which is more fully elaborated in Mr. Hall's work on "The Soil." Chapters ix. to xi. break fresh ground in dealing with the animal and its food requirements, whilst chapters xii. and xiii. are digests of Mr. Hall's treatise on "Fertilisers and Manures," the last chapter, xiv., containing a short account of the composition of milk and other dairy products.

The subject of the feeding of animals is one to which we could wish the author had devoted more space. Rothamsted has a wealth of results of its researches on the feeding of plants, but the subject of animal feeding has not received the same attention, though by this it must not be understood that extremely valuable work in that direction has not been accomplished, but it is a sad fact, appreciated by all workers in agricultural science, that in England we have no well-equipped station for the carrying on of necessary research in animal nutrition. The United States and Continental nations have seen the importance of such work, and the experimental work of these countries is rich in results, of which Mr. Hall has made excellent use, and we feel confident that had Rothamsted the equipment for such work which its reputation and the *personnel* of its present staff deserve, our knowledge of the feeding of animals would be greatly increased, to the benefit of the stock feeders of the country. Will not some friend of agriculture come forward and establish at Rothamsted a digestion calorimeter and endow its efficient service?

Mr. Hall has, in the work under review, disposed of many fallacies with regard to plant and animal nutrition, and we would commend to all practical men the pages dealing with the valuation of foods and the use of the various constituents of foods in the stages of fattening. (An omission in proof correction of the first few lines of p. 181 in speaking of the cottoncakes may give rise to some misunderstanding.) To the stock farmer it will be obvious that there is much in the book to interest, and if not to instruct him, at least to explain the principles on which his good practice depends, and to the arable farmer there is also much which, from the purely practical point of view, may show the way to economics in manuring by a well-reasoned explanation of the influence of manurial constituents on plants having differing range of root action, differing periods and durations of growth, and differing final products to build up. Such an important point as the quality of wheat is elaborated, with a due consideration of all the factors, and one-time accepted theory that the order of the evaluation of the protein and starch is the cause of the wide variations in quality between strong Canadian and weak English wheats is regarded as untenable.

As has been already stated, many formerly accepted theories are rejected, and sound reasons brought forward for their rejection, the reasons for crop rotations, the acid excretion by roots, the changes induced by ensiling, the use of preservatives for farmyard manure, effect of food on milk, are among many changes of opinion which have been brought about by accurate researches into cause and effect, and although the practical man is apt to be bewildered by these changes of opinion and to be somewhat sceptical as to the accuracy of present theories, the fault lies with those who have in the past hastily enunciated reasons without due consideration of all the factors, not to those who, like the author of this book, demand that a theory shall be not merely a plausible explanation of phenomena, but something which will rigorously satisfy all requirements, and the truth of which can be demonstrated by an appeal to accurate experiment.

M. J. R. D.

PATHOGENIC INSECTS.

Insects and Disease: a Popular Account of the Way in which Insects may Spread or Cause some of our Common Diseases. By Prof. R. W. Doane. Pp. xiv+227. (New York: H. Holt and Co.; London: Constable and Co., Ltd., 1910.) Price 1.50 dollars net.

IN this volume, which gives evidence of considerable research, Prof. Doane has presented the first collective narrative, in popular form, of the principal results which have been achieved in relation to insect-borne diseases, both in man and his domesticated animals. And in order that the layman may the more readily understand the biological relations of the various pathogenic organisms and their intermediary hosts, the author has briefly reviewed some of the more salient points in relation to their structure and life-history; in this way it is believed that the most complex inter-relations may be followed clearly.

Prof. Doane has met a great want in producing this unpretentious volume, in which he has successfully collated the overwhelming evidence of the maleficent agency of certain insects and other allied animals in the dissemination of disease. We feel, however, that he has been a little too credulous in some few instances in accepting evidence which is

not of a thoroughly convincing nature, all the more so, seeing that the work is primarily intended for the layman, who has not the means of sifting out such matter and putting the correct interpretation upon it. Thus in dealing with Malta fever, in a few short sentences he would lead the reader to infer that mosquitoes often serve as the "inoculating" agents, and unfortunately leaves one entirely in the dark as to the true cause of the spread of this disease.

Many of the photographic illustrations which accompany this work are very good; indeed, more especially so are those representative of the various developmental stages of the mosquitoes; we do not agree with the author's statement, however, that all his pictures show "the insects, not as we think they should be, but as they actually are," because both colour values and general morphological characters are in many instances entirely wanting, and the resulting print is nothing more than a silhouette. Moreover, the photographs of both museum and microscopical preparations show a marked absence of care and neatness in the display of the various organs, and such figures as these stand out in marked contrast to those of Manson, Kellog, Nuttall, and others. We would point out also that Figs. 76 and 77 represent a female and male mosquito respectively, and not the reverse order, as stated by the author. *Ochromyia anthropophaga* (p. 49) should read *Auchmeromyia luteola*. The latter, not the former, is the parent of the congo-floor maggot.

This work is furnished with an extensive and useful bibliography occupying forty-seven pages, to which annotations are appended.

SYSTEMATICS.

Die taxonomischen Grenzen der Art und ihrer Unterabteilungen. Versuche einer genauen Definition der untersten systematischen Kategorien. By Andreas Semenov-Tian-Shansky. Pp. 24. (Berlin: R. Friedlaender and Son, 1910.) Price 2*s*.

THIS is the German translation of a pamphlet which appeared first in Russian. It deals on a wide basis with the definition of the term species and the lower categories in classification. The author —whose title, "Tian-Shansky," reminds us of his exploration of the Tian-shan or Celestial Mountains in Central Asia—pleads for uniformity of terminology in the various branches of botany and zoology, and then proceeds to examine critically the opinions of various botanists and zoologists on the criteria of species and its several component varieties. The large experience gained by Semenov from his many years' study of insects, especially Coleoptera, and his acquaintance with at least an essential portion of the literature bearing on the subject, enable him to substantiate his criticisms by illustrations drawn from his own knowledge and to adduce corroborative evidence from the writings of other authors. The co-existent species are defined by the author as units which are morphologically and psycho-physiologically separated from each other. The units thus isolated do not fuse, although very occasional intercrossing may occur. The individuals belonging to a species may all be practically alike, or they may form various kinds of varieties. Semenov defines four principal categories of modifications within a species:—

1. Subspecies or geographical race (*subspecies*) is the most important subdivision of a species, inasmuch as it represents a phylogenetic stage one degree below the complete separation from the parent stock.

2. Nation (*natio*) is a term proposed by Semenov for local varieties which are subdivisions of a subspecies, each *natio* occupying only a comparatively small definite portion of the whole area of the subspecies.

3. Morph (*morpha*) is adopted for the non-geographical varieties which are produced by the action of the seasons, the soil or the food.

4. Aberration (*aberratio*) is employed for purely individual deviations from the normal type.

It appears to us so very difficult and often impossible to draw in nature a distinction between subspecies and nation (=sub-subspecies) that in many cases the employment of one or the other term will entirely depend on the personal opinion of an author. The Greek term *morpha* does not appeal to us as a happy choice, and will hardly recommend itself to systematists generally, who are used to the Latin term *forma*, often employed with a convenient qualifying addition, such as *f. temp.*, for the seasonal form.

The pamphlet is a lucid interpretation of the distinguished author's view, and will be read with great profit by all who are interested in the philosophical aspect of systematics.

K. J.

COORDINATE GEOMETRY.

An Elementary Treatise on Coordinate Geometry of Three Dimensions. By R. J. T. Bell. Pp. xvi+355. (London: Macmillan and Co., Ltd., 1910.) Price 10*s*. net.

THE substance of this volume has formed the material of a course of lectures delivered for some years past to undergraduates in Glasgow. Its object is to provide the student, whose bent is towards applied mathematics, with as complete an exposition of the subject as he will require, and at the same time to act as an introduction to those who intend to proceed to a more exhaustive study of differential geometry and the theory of surfaces. Its scope is best indicated by a brief enumeration of the headings of the chapters:—coordinates, direction ratios, the plane and straight line, change of axes, the sphere, the cone, the conicoids, axes of sections, generating lines, confocals, the general equation of the second degree, systems of conicoids, conoids and general surfaces, curves in space, ruled surfaces, curvature, geodesics. It will be noted that there is no mention of homogeneous and tangential coordinates. The author has excluded these on the ground that the student has already acquired a knowledge of the general principles involved from his work in plane geometry. The same consideration has led him to exclude any section on duality or reciprocation. Some teachers will regret this omission, as the student is

always interested in the extension of general processes from two to three dimensions.

For those who are studying the subject with little or no external assistance, this is certainly an admirable text-book. The writer is evidently fully conscious of the kinds of difficulties that beset the inexperienced student. The expository work is excellent throughout, but in particular we may direct attention to the section on the discriminating cubic, the chapter on the intersection of conicoids, and the treatment of tortuous curves, which is always a serious stumbling-block at a first reading. Easy numerical examples are freely provided throughout the text to illustrate the working of each new idea. We are particularly glad to see that a fairly complete set of answers has also been supplied. At the end of each chapter there are sets of harder examples, which include some of considerable difficulty, and the book closes with a useful index.

Within the limits which the author has chosen the volume will be found comprehensive, thoroughly trustworthy, and eminently lucid. Those who have had much to do with higher school work or the junior students at the universities have felt for some time the need of a new text-book on solid geometry. We have no doubt that lecturers and tutors will find this volume most useful for their pupils, and we shall not be surprised if a welcome is extended to it from abroad.

PHYSICAL CHEMISTRY.

Traité de Chimie générale. By Prof. W. Nernst. Ouvrage traduit sur la 6e édition allemande. By Prof. A. Corvisy. Première Partie. Propriétés générales des Corps. Atome et Molécule. Pp. iv+510. (Paris: A. Hermann et Fils, 1911.) Price 12 francs.

IN the movement associated with the rapid development of general chemistry during the last twenty-five years, the apathy displayed by a considerable section of French chemists affords a striking contrast to the activity and enthusiasm which has marked the progress of physical chemistry in other countries. For this state of affairs there can be little doubt that the chief factor responsible is to be found in the influence of the older generation of chemists, whose attitude towards the problem involved in the operation of chemical forces has been determined largely by a patriotic adherence to the doctrines of Berthelot. Signs are not wanting, however, that the resistance, which has been offered to the spread of more rational and modern views, is rapidly decreasing.

The translation of the sixth edition of Nernst's well-known work cannot fail to accelerate the acceptance of these views, and the service rendered by the translator in bringing this classical treatise within reach of the average French student of chemistry is no mean one. Since the appearance of the first edition of the work, published in 1893, the book has undergone many alterations, and by appropriate additions the author has contrived to maintain its character as a thoroughly modern treatise of general chemistry.

Amongst such changes may be noted a more detailed treatment of the molecular theory in its application to the liquid and gaseous states of aggregation on the basis of the van der Waals's and the reduced equations of condition. Considerable modifications have also been made in dealing with the subject of electric conduction, and more particularly with the phenomenon of conduction in gases. The recent rapid progress of knowledge in the domain of colloidal chemistry has also necessitated an extension of the chapter dealing with the colloidal state, and a short section is devoted to the consideration of radioactivity. In this, the author's aim is not so much that of recording the epoch-making discoveries which have been made in recent years, as to show the general bearing of the ideas, which have resulted from these investigations, on the atomic and molecular theories.

As an exposition of the general properties of matter the book occupies a unique position, and the rapid sequence of new editions in the original language is a fitting testimony to the widespread recognition of its intrinsic merits in the country of its origin.

As in the case of many other German publications, exception must be taken, however, to the comparative neglect of the work of physical chemists in other countries. This is doubtless more or less accidental, but it is a matter to which attention might be given by the author in the event of the issue of further editions or translations. The present translation claims to be a faithful reproduction of the German, and, as such, the translator's task appears to have been carried out in a highly commendable manner.

OUR BOOK SHELF.

Elements of Analytical Geometry. By Prof. G. A. Gibson and Dr. P. Pinkerton. Pp. xxi+475. (London: Macmillan and Co., Ltd., 1911.) Price 7s. 6d.

IT is too often the custom to regard analytical geometry and analytical conics as synonymous terms. Most introductory treatises on Cartesian methods limit their scope to the investigation of properties of curves of the second degree, and it is left to writers on the calculus to supplement this course with a brief mention of the nature and functions of a few higher plane curves. A preliminary course in the use of fundamental formulæ is clearly essential, but so soon as facility in expression and interpretation has been acquired, it is both instructive and interesting for the student to realise their application, not merely to the conic, but to curves of a more general character. We therefore welcome the insertion of a chapter, following immediately after a thorough treatment of the straight line and circle, which introduces the student to the conchoid and cissoid simultaneously with the conic. The next sixty pages are devoted to the investigation of the shapes of curves which have simple algebraic equations of the type $y=f(x)$, with special reference to turning values and asymptotic forms. In some respects, simplicity would be secured by a more direct appeal to the methods of the calculus than the authors care to adopt. Such a treatment as is indicated in Mr. Mercer's recent text-book, entitled

"The Calculus for Beginners," will present little difficulty to those who are sufficiently mature to be able to appreciate the comprehensive work of the present volume, and the consequent abbreviation of analysis will render more prominent the principles which are being illustrated.

Owing to the general character of the structure of this book, it is not until page 318 that we first meet the systematic discussion of the equations of the three species of conics, reduced to their standard forms. These are taken together, and the importance of parametric notation is shown here as in the earlier parts of the book. We are glad to see that Joachimsthal's section-equation is employed for tangent and polar properties, not only because the method is intrinsically instructive, but also on account of its application to homogeneous coordinates. The final chapter gives a brief sketch of the theory of the general equation of the second degree, and a few properties of confocal conics and curvature. The authors have excluded line coordinates, homogeneous coordinates and invariants as being beyond the scope of their work. We have no hesitation in describing this text-book as an excellent introduction to Cartesian methods.

Bathy-Orographical Map of the World on Gall's Projection. (Edinburgh and London: W. and A. K. Johnston, Ltd., n.d.) Prices: Varnished, 12*s.*; unvarnished, 10*s.*

IN showing elevation on a map of the world generalisations are essential, but detail and accuracy must not be sacrificed for the sake of graphic effect if such a map is to have any practical value in teaching. On this map three areas are distinguished in colour on the land, above 5000 feet, 1000 to 5000 feet, sea level to 1000 feet, and below sea level. The 5000 feet line has been inserted with considerable care, and gives a fairly true representation of the main regions of high land, but some further distinction is needed between regions of great elevation, such as Tibet, and moderate heights, such as the Drakensbergen. It must be remembered that the principal use of a world map of this kind will be in connection with the study of climate. The absence of any higher elevations is against its use for, to take two examples, the study of the influence of elevation on temperature and that of high marginal ranges, such as the Himalayas, on wind movements and rainfall. That the map is intended to be used in the study of climate may be judged from the fact that inset maps are given of mean annual temperature and of rainfall. An exception must be made to the statement of the general accuracy of the map with regard to the higher elevations in Canada and Alaska. The result of recent observations has not been incorporated in the case of N.E. Canada, N. and S. of Hudson Strait, in which region are situated the highest mountains of the eastern part of N. America, and the accuracy of the Rockies and coast ranges of the N.W. leaves much to be desired when contrasted with that of the W. of the United States.

The next contour is at 1000 feet, which, in the case of countries such as Africa, largely above that elevation, is at too distant an interval to give an adequate representation of the land surface. A curious error has been made in the case of Great Salt Lake, which is shown as below sea-level. The sea depths are indicated at 100, 2000 and 3000 fathoms, but it is doubtful if these lines, which do not correspond to those shown on the land, will be of much use for the general study of land forms. On the whole it must be said that the map is of little use for advanced geographical work, and is too crowded with unnecessary names for elementary teaching.

Plant-Animals: a Study in Symbiosis. By Prof. F. Keeble. Pp. ix+163. (Cambridge: University Press, 1910.) Price 1*s.* net.

ALTHOUGH notices of two of the small volumes in this series have already appeared in NATURE, it has not been precisely indicated that they are early volumes of a new series of short works, dealing with scientific and literary subjects, and intended for the lay as well as for the professional reader, that was initiated last year by the enterprising University Press of Cambridge. The contribution by Mr. Keeble is particularly appropriate to the series as it represents a complete story, replete with instructive problems and a definite piece of research that has entailed persistent observation, ingenious experiment, and cautious interpretation of results.

The research covers the peculiar life-history of two lowly worms, *Convoluta roscoffensis* and *Convoluta paradoxa*, that inhabit the foreshores of Brittany, where they were studied in the sea and in a small laboratory. The first section of the book relates to their structure, rhythmic movements, and periodic seasons of reproduction, and contains an excellent discussion of their sense attributes as influenced by light, gravity, and memory (mneme). The plant element, in the shape of enclosed green or yellow-brown cells, is considered in the second part of the book, with regard to action, origin, nature, and significance, leading to the conclusion that they are reduced algal cells of the family Chlamydomonadineæ Instructive as are the facts, quite as much so are the observations, experiments, and arguments from which the conclusions are derived. In fact, it is difficult to say whether one admires more the patience and ingenuity displayed, the careful sifting of evidence, or the logical yet popular exposition. The booklet should be quite understandable to and interest non-scientific readers, yet few botanists will fail to glean information and ideas from its pages.

An Elementary Treatise on Conic Sections by the Methods of Coordinate Geometry. By C. Smith. New edition, revised and enlarged. Pp. x+449. (London: Macmillan and Co., Ltd., 1910.) Price 7*s.* 6*d.*

THE merits of this book are so well known that comment is almost needless. Nearly thirty years have passed since it was first published, and since then a few additions have been made from time to time, as experience has suggested. The latest edition is considerably enlarged. The number of illustrative examples has been increased; a section on envelopes has been inserted at the end of the chapter on the parabola; and a concise sketch of the theory of invariants of two conics is given in the concluding chapter. There are many other minor additions which will be found useful, such as occasional paragraphs on points of book-work, which have been hitherto regarded as problems, and three sets of miscellaneous examples.

For scholarship purposes in our opinion, this book is without a rival. The earlier portions are scarcely full enough for the novice, who probably requires a more extensive numerical introduction to the subject. But as soon as this initial stage is completed, it is quite certain that he cannot do better than turn to this text-book and read it from cover to cover.

There are, of course, some features which are open to criticism. The chapter on tangential coordinates is so compressed that a student may fail to appreciate the power of line coordinates and the analytical interpretation they offer of the principle of duality. Again, many teachers would prefer a direct appeal to the methods of the calculus in tangent properties;

and, lastly, we believe that considerations of simplicity render it desirable to replace trilinear by areal coordinates. To avoid overburdening the memory it is advisable to restrict the student at first to one or other of these systems, and in this case we have little doubt that areals should be regarded as the primary system. These are, however, scarcely more than mere matters of detail, and it is not difficult for the teacher to supply the remedy, if he feels it is needed.

The Forest of Auchnacarry.

BOTANISTS and many others will be very sorry to hear that a large part of what remains of the old forest of Scots firs at Auchnacarry has been sold to the timber merchant, and that the whole of it is likely to be felled ere long. The forest lies in the west of Inverness-shire, near Loch Askaig, on the first, or one of the first, of the glens that run westward from the Caledonian Canal, just north of Fort William. It is on the great estate, and near to the mansion house, of Cameron of Lochiel. While not so old as, for instance, the historic trees of the New Forest, or as that strange grove of oaks at Wistman's Wood, the Scots firs at Auchnacarry are of deep interest and value as perhaps the largest and finest fragment that is left to us of "primæval forest," neither planted nor tended by the hand of man. Its area is about 1500 acres, and the trees are of immense size, being mostly from 200 to 300 years old; the largest have a circumference of about 18 feet at 5 feet from the ground, and the dimensions of a very large number are said to be little less. The scenery of the forest is of great beauty, marking the difference that exists between the natural look of self-grown timber and the stiff, unvaried lines of an artificial plantation. In England we think of the Scots fir as an uninteresting, and even unsightly, tree, unpleasing in colour and often cumbering the ground (as in parts of the New Forest) to the exclusion of more picturesque trees. It is usually planted, as Gilpin said in his "Forest Scenery," "in thick array, which suffocates or cramps them, and if they ever get loose from their bondage they are already ruined." Very different from this description are the beautiful glades at Auchnacarry, where (to borrow words from Sir T. Dick Lauder), "We have seen it towering at full majesty in the midst of some appropriate Highland scene, and sending its limbs abroad with all the unconstrained freedom of a hardy mountaineer, as if it claimed dominion over the savage regions around it." And, to quote Gilpin once again:—"When I speak of the Scots fir as a beautiful individual, I conceive it when it has outgrown all the improprieties of its youth; when it has completed its full age, and when, like Ezekiel's cedar, it has formed its head among the thick branches."

The forest of Auchnacarry is, save for a few isolated trees or small surviving clumps, all that we know to remain of the great forest of Scots fir that once spread over all suitable ground in central Scotland from Ben Nevis to the Spey. There was immense and wholesale destruction of these forests in the latter years of the eighteenth and earlier years of the nineteenth century, owing to the needs of the shipbuilder and to the high price of Baltic timber during the Napoleonic Wars. It was then, for instance, that the great forest of Rannoch was cut down, which, from the borders of Argyll, Perth, and Inverness, stretched far and wide across the country to link with the forests of the Spey, the Findhorn, and the Beauly, as well as with those of the "Great Caledonian Glen." The forest of Glenmore on the Spey was purchased of the Duke of Gordon by a Hull timber merchant in 1783, and out of it he built and launched at the mouth of the Spey "forty-seven sail of ships, of upwards of 19,000 tons burden, the largest of them of 1050 tons." A plank from this great felling is, or was, preserved at Gordon Castle, 6 feet long by 5 feet 5 inches broad. In the early part of last century there still remained large portions of the forest of Rothiemurchus, where for many years together a great income was yielded by the timber, sometimes, it is said, more than 20,000*l*. a year. There were also great stretches left of Lord Seafield's forests of Abernethy and Duthel, though a great part of the former had been destroyed by fire just after the rebellion of 1745. But in these and others the axe was already busy, and nowadays, though here and there a few ancient trees remain, the present writer knows of nothing that is left to us so noble and so extensive, so

Scots Firs at Auchnacarry.[1]

worthy of preservation as a relic of an older Scotland, as this doomed forest of Lochiel's at Auchnacarry. There is much ado when a great picture leaves the country; but to the naturalist and to all tree-lovers the destruction of this ancient forest will seem a greater loss, greater because the object is unique and the loss irreparable.

D. W. T.

The End of the *Beagle*.

DR. WATASE, professor of zoology in the College of Science of this University, has directed my attention to a letter on this subject in your issue of December 9, 1909. In view of the Darwin centenary celebrations of the year before last, and wishing to be fully assured of whatever facts were known regarding Darwin's *Beagle*, Dr. Watase got me to write to my old friend Mr. N. E. Smith, C.B., of the Comptroller's Department, Admiralty, Whitehall. The reputed tonnage (B.O.M.) of the vessel bought by Japan was known to be 523; her length and breadth were variously stated as 150 feet by 25 feet 6 inches and 160 feet by 26 feet. Mr. Smith very kindly traced the following notes with regard to Darwin's *Beagle* and to a subsequent vessel of the same name. His conclusion is that the *Beagle* bought by Japan was not Darwin's, but the later vessel. His letter is as follows:—

"The *Beagle* in which Darwin made the voyage round the world was a 10-gun brig-sloop built at Woolwich in

[1] For this photograph we are indebted to the proprietors of the *North British Agriculturist*.

1820. This *Beagle* was sold, by public auction, to Messrs. Murray and Trainer, for 540*l*., in May, 1870, having for some years previously served as watch vessel at Southend.

"The next vessel of the name was a first-class gun vessel (screw), built at Blackwall in 1854 and carrying 4 guns. This vessel was serving on the East Indies and China Station in 1862, and in the Navy List of that year is shown as 'ordered home'; but in the following year she disappears from the list, and in Parliamentary Paper No. 560 of Session 1867 ('Navy—Ships sold') she is entered as 'sold abroad' in 1863, for 5500*l*. Inquiry has been made of the Contract and the Accountant-General's Department as to whether she was bought by the Japanese, but no information on this point is available, all such records of the period having been destroyed. Doubtless, however, this is the *Beagle* to which the inquiry refers.

"The following are the dimensions of the respective ships:—

	Beagle built in 1820.	*Beagle* built in 1854.
Tons	235	477
Length—		
Gun deck	90	160
Keel for tonnage ...	$73\cdot7\frac{5}{8}$	$143\cdot4\frac{3}{4}$
Breadth, extreme ..	24·8	25·4
Breadth for tonnage ...	24·6	25
Depth in hold	11	13·3
Light draught—		
Afore	7·7	5·10
Abaft	9·5	8·1

Distant Orientation in the Amphibia.

ROMANES, in his book on "Animal Intelligence," suggests that frogs have a distinct idea of locality, and he also expresses the opinion that frogs are able to perceive moisture from a great distance. One of his correspondents found that frogs removed from their habitual haunts for 200 or 300 yards returned to them again and again. Romanes quotes Warden, who, in his "Account of the United States," says that when a pond containing a number of frogs dried up, the animals "made straight for" the next water, though it was 8 kilometres away. During the spring of 1910 I made a series of experiments, which have been continued this year, with the view of settling how newts are able to find their way back to water when they have once left it or have been removed from it. Working with the Palmate newt (*Molge palmata*, Schneid.), I got no evidence of a faculty for the perception of moisture at a distance, and in order to explain the spring migrations of the newt it is unnecessary to presuppose its presence, because I certainly think there is a small homing faculty. My results directly point to this. Romanes gives no details, and more information on this question would be welcomed before I draw up a full account of the experiments. The subject has an important bearing on the psychology of the Amphibia, and must form when elucidated an interesting chapter in their natural history; yet the reference in Romanes is the only one I can find.

BRUCE F. CUMMINGS.

Cross Street, Barnstaple, N. Devonshire, May 14.

A Zenith Halo.

WITH reference to Mr. Gold's letter in your issue of May 11 concerning the halo observed by Mr. Kreyer, I should like to make the following remarks. I think Mr. Gold is quite right in assuming that the phenomenon observed was the so-called arc of contact of the halo of 46° radius, which for this altitude of the sun is really almost in contact with that halo, whereas, according to Bravais's theory, supported by numerous observations by Ekama and Besson, for lower altitudes these arcs may be separated by as much as 7° (with the sun at the horizon even 12°). But I think Mr. Gold is mistaken in assuming that the centre was at 80°, or 85° altitude.

Mr. Kreyer's observation that the arc formed part of a circle with the zenith as apparent centre is quite in harmony with Bravais's theory and the numerous observations in our country. Even Pernter, who accepts Galle's theory, besides that of Bravais, does not bring conclusive evidence of the existence of arcs in the same altitude with their centre outside the zenith. It is much more probable that Mr. Kreyer's estimate of 10° or 15° has been too low, as is usually the case with the estimates of arcs near the zenith, and that the real radius was about 20°.

These circumzenithal arcs are not of so little frequent occurrence as one might think from Mr. Gold's letter. Messrs. Besson and Dutheil have observed them at Montsouris 111 times in the course of ten years, and the Dutch staff of voluntary observers sixty-seven times in the same period.

In recent years the observations have been even more numerous in our country. The period 1904–8 gives fifty-five days with observations of circumzenithal arcs; 1904, even thirteen observations by one and the same observer. Perhaps the high altitude of the halo is the reason why it is rarely seen by unskilled observers.

E. VAN EVERDINGEN.

Meteorological Institute, De Bilt (Holland).

THE object of my remarks on Mr. Kreyer's observation was to make it clear that the phenomenon belonged to the class due to refraction through ice-crystals. For that purpose the exact position of the centre of curvature of the arc was immaterial, and in the absence of accurate measurements an altitude of 80° to 85° was sufficiently near the observer's estimate of 90°. Dr. van Everdingen suggests that the radius of the arc may have been 20° instead of 10° to 15° as estimated by the observer. I agree with him, and indeed I thought of suggesting this in my notes, but it seemed just as likely that Mr. Kreyer had made a slight error in estimating the altitude of the centre, and I did not regard the matter of sufficient importance to call for a discussion of the alternatives.

The interest of observations such as those of Mr. Kreyer, where the positions and distances are estimated only, does not rest on the support which they may give to the theory of Bravais or to that of Galle, but now that Dr. van Everdingen has reopened this question, I am sure meteorologists would welcome from him a discussion of the two theories in the light of the more extensive observations to which he refers, which no doubt contain the measurements necessary to prove or disprove the horizontality of the arc.

E. GOLD.

Meteorological Office, South Kensington, London, S.W., May 20.

The Yale.

THE animal upon which Prof. Hughes has based the sketches published in NATURE of May 25 (p. 415) is evidently the typical, or white-tailed, gnu. But this is a South African species, the northern limit of which is formed approximately by the Vaal River. How, then, can it represent an animal the home of which was supposed to be Ethiopia? The brindled gnu of East and North-east Africa has horns of an entirely different type. I may add that if Prof. Hughes can definitely identify "the antelope" he will perhaps kindly communicate his information to those who are less fortunately situated in this respect than himself.

R. L.

Apple Blossoms.

THERE is a theory that the retardation of the flow of sap tends to the production of fruit as against wood buds, and this retardation for apple and pear trees is effected in various ways—by root-pruning, cutting of the bark, for example.

Now last year the want of sunlight, I think, tended to weaken the vitality of trees, and so tended to retard the flow of sap. Should we not, then, expect this year to find an *excess* of fruit buds? The "show" of apple blossom round us, in Gloucestershire, is exceptionally profuse.

F. C. CONSTABLE.

THE RECENT CENSUS OF ENGLAND AND WALES.

IN reply to a question put by Dr. Addison, the President of the Local Government Board gave on May 24 a preliminary statement as to the results of the recent census. The figures, which are based on summaries furnished by the local registration officers, are, of course, of a provisional character, but it is not probable that any serious errors are involved.

The total population of England and Wales is returned at 36,075,269, as compared with 32,527,843 in 1901, a gain of 10·91 per cent. This compares with increases of 12·17 and 11·65 per cent. in the two preceding decades, and is the lowest percentage increase recorded in any decade since the commencement of the nineteenth century. It would seem to imply a loss of nearly half a million by excess of emigration over immigration.

The population of the administrative county of London shows an actual decrease, from 4,536,267 to 4,522,961, illustrating the almost universal outward trend of urban populations as the facilities for locomotion increase. The population of the "outer ring"—*i.e.* that portion of London which lies within the Metropolitan Police District, though outside the administrative county—has grown from 2,045,135 to 2,730,002, and the populations of the counties of Essex, Middlesex, and Surrey have increased by 30, 42, and 30 per cent. respectively.

The same tendency is clearly exhibited by many of the returns for the County Boroughs. Few show an actual loss of inhabitants; Canterbury, Halifax, Hastings, and Burton-on-Trent are the only towns coming under this category. Many, however, show only a very slight growth, notably Birmingham, with an increase from 523,000 to 526,000 only during the ten years. Coventry forms the most striking exception to the general rule of slackening growth, with its increase from 70,000 to 106,000, largely due, no doubt, to the motor industry. To realise the general nature of the changes, the figures given in the present return should be compared with the populations estimated by the Registrar-General for last year; these estimates are based on the rate of growth exhibited by each district during the preceding decade, and in the case of the great majority of the boroughs are in excess, often seriously in excess, of the true population even at the present time. The population of Bristol was estimated last year, for example, at 383,000; the census figures show only 357,000. That of Leeds was estimated at 491,000; the census enumerators could only find 446,000. That of Leicester was estimated at 248,000, against a census return of 227,000, and of Sheffield at 479,000, against 455,000.

The present return reinforces, in fact, the lesson that has been so often drawn by statisticians as to the necessity, both for a more frequent census, and for the use of better methods of estimating populations during the intercensal intervals. Many of the County Boroughs, and many of the Metropolitan Boroughs, have been credited during the last ten years with a fall in the death-rate far more rapid than they could lay claim to, owing to the consistent over-estimation of their populations; and this rapid fall has been used not only as the basis for natural self-congratulation by the local medical officers of health, but also as a foundation for party posters in county council elections. Quinquennial censuses would largely reduce the margin of error; the use of methods of estimation based on local information, *e.g.* those recently suggested by Mr. E. C. Snow, (referred to in a Note on p. 459), would narrow it still further. So many improvements in the form of the returns have been introduced during the new *régime* at the Registrar-General's office, that we feel some confidence in expecting a change in this respect. At present the figures given for birth- and death-rates in the annual summaries and reports are often, towards the end of an intercensal decade, very gravely misleading.

INDUSTRIAL BURSARIES.

THE Royal Commission for the Exhibition of 1851 propose to establish industrial bursaries for young men who, after a course of training in a university or approved technical college, desire to enter engineering, chemical, or other manufacturing works. The bursaries are intended to enable suitable applicants to tide over the period between their leaving college and obtaining remunerative employment in industry. The value of the bursary will depend on the circumstances of the candidate, but will as a rule not exceed £100 a year. A bursar will be elected in the first instance for one year, but the tenure of his bursary will ordinarily be prolonged for a second year provided that the Commissioners are satisfied with the work done by the bursar during his first year. In special circumstances a bursary may be renewed for a third year.

The appointments to the bursaries will be made by the Commissioners from among candidates recommended by the authorities of certain selected universities and technical schools, and in dealing with these recommendations great weight will be given to evidence that a candidate has the practical abilities likely to lead to his advancement in manufacturing work, academic success alone being an insufficient recommendation.

The candidate must be a British subject, under the age of twenty-five, and must have been a *bonâ-fide* student of science for a term of three years.

The candidate must further satisfy the Commissioners:—

(*a*) That he has obtained, or can, within one month of election, obtain a post in some engineering or other manufacturing works approved by them.

(*b*) That he is in need of pecuniary assistance to enable him to accept such a post.

A bursar may, if the Commissioners approve, spend part of the tenure of his bursary in studying a special industrial process or processes in works either at home or abroad.

No bursar shall enter a firm as a premium pupil without the special consent of the Commissioners.

A bursar must submit a report of his work to the Commissioners on the expiration of each year of his bursary.

The institutions invited to nominate in 1911 are as under:—University of Edinburgh; Heriot Watt College, Edinburgh; University of Glasgow; Glasgow and West of Scotland Technical College; University of St. Andrews; University of Aberdeen; University of Birmingham; University of Bristol; University of Leeds; University of Liverpool; University of Manchester; Armstrong College, Newcastle-upon-Tyne; University College, Nottingham; University of Sheffield; University of Oxford; University of Cambridge; University of London; Imperial College of Science and Technology; University College of Wales, Aberystwyth; University College of North Wales, Bangor; University College of South Wales and Monmouthshire, Cardiff; Royal College of Science for Ireland; Queen's University of Belfast; University College, Cork; University College, Galway.

THE NATURALIST'S PICTURE GALLERY.[1]

MR. KEARTON'S bird pictures are so well known that it is unnecessary to say much about his latest work, beyond indicating its scope and object, except that the pictures are larger than usual, and, if possible, more beautifully reproduced. This work has been prepared at the request of friends who have expressed a wish for Kearton pictures from nature on a larger scale of reproduction, and in order to give the man or woman, boy or girl, who knows but little of the countryside a bright and stimulating glimpse of the wild creatures dwelling therein. But it will not be to these alone that this sumptuous volume will appeal. Those who know our birds and beasts best will probably appreciate it more than anyone else, for to them these beautiful pictures of their old friends will be an unfailing joy and delight.

Upwards of fifty birds and beasts and reptiles are portrayed, and to each is devoted a pleasant descriptive article. First and foremost this is a picture book (wherein birds, beasts, and reptiles jostle together without system, as they jostle in nature's own domain), as its title implies; but the text, although of secondary importance, is as accurate, informatory, and interesting as care and experience can make it. Familiar wild birds and beasts find a place here side by side with the very rarest birds that visit our islands to breed. Mist-wreathed mountains and quiet hedgerows, the restless sea and peaceful meadow, the deep woods and the towering sea cliffs, have all been visited to find these pictures. Altogether the author is fully justified in his belief that the work will form the finest gallery of sun pictures of wild birds and beasts, taken amidst their natural surroundings, ever published in this or any other country.

FIG. 1.—Nest of the Dotterel in a slight natural hollow. From "Kearton's Nature Pictures."

Amid so much excellence we cannot help directing particular attention to the beauty and interest of the plates showing young thrushes, the peewit, trout, oyster-catcher, tree pipit finding a young cuckoo, and the great black-backed gull. A finer picture of a grand-looking bird in its native haunts than this last we never saw. Mr. Kearton has secured some excellent and characteristic photographs of that little-known reptile, the natterjack toad. This, we imagine, was no easy task. For we remember trying to help a famous photographer to secure some picture of the natterjack on a hot morning among the sand-dunes on the coast of Holland, and how often our efforts were frustrated by the extreme activity of the toads, one of the points in which it differs from the more familiar squat toad of our gardens. By permission of the publishers we reproduce two of the illustrations.

FIG. 2.—Oyster Catcher. From "Kearton's Nature Pictures."

[1] "Kearton's Nature Pictures," beautifully reproduced in Photogravure, Colour, and Black and White from photographs by Richard and Cherry Kearton. With descriptive text by Richard Kearton. Vol. i., pp. viii+96. (London, New York, Toronto and Melbourne: Cassell and Co., Ltd., 1910. Price 15s. net.

WILD PARAGUAY.[1]

EL GRAN CHACO is the name of that great, low-lying alluvial plain, which is situated where the Republics of Paraguay, Argentina, and Bolivia meet. Extending over 200,000 square miles, it is populated, but for a mere fringe of white settlements, entirely by Indians, the total population of whom is estimated at not more than 135,000. Many futile attempts have been made by the Spaniards to explore this vast district, or to "reduce" the fierce native tribes to the white man's ways; they ended mostly in massacres of the exploring parties, and the Chaco was therefore left severely alone until within quite recent times. Even the Jesuit missions in the middle of the eighteenth century had fared badly; futile also was the attempt made by Captain Allen Gardiner, founder of the South American Missionary Society, to settle among the Tobas in the year 1870, and it was not until the year 1889 that the same society succeeded in establishing a mission among the Chaco Indians.

W. Barbrooke Grubb, then quite a young man, was sent out and entrusted with the seemingly hopeless task. For twenty years this pioneer and marvel of devotion has lived amongst the savages, at first quite alone, later on joined by helpmates. The present book deals mainly with the events and experiences of the early five lonely years amongst the Lengua tribe, a little to the west of the Paraguayan town of Concepcion. Now there is a flourishing mission, called Waikthlatingmangyalwa, the place where Prof. J. G. Kerr and the late J. Budgett got their material for the mudfish Lepidosiren. It is safe for the white man to traverse some 200 miles west of the river Paraguay, over roads cut by the missionaries; thousands of cattle are now tended by Indians, where but a few years ago men, who had acquired lands, scarcely dared to inspect them for fear of these same Indians. In these parts Grubb's is a name to conjure with, and the Paraguayan Government fully acknowledge what they owe to this man by having made him Commissary-General of the Chaco, with the additional title of "Pacificador de los Indios."

FIG. 1.—Procuring Fire by Friction. From "An Unknown People in an Unknown Land."

How has he achieved it? By living alone with these savages and almost like one of them, learning their language and customs, without worrying them, but all the time trying to understand what is really at the back of the Indian's mind. Gradually they in turn came to look upon him not as a harmless lunatic, but to respect him. It was uphill work, and not without danger; as for that matter, one of his trusted and most intelligent friends shot an arrow into him, and left him for dead, several days' journey from the nearest native village. This foul deed enraged the native community so much that they ultimately caught the would-be murderer, killed him, and burnt his body to ashes. There is no other record of a Chaco-Indian being slain by his own tribesmen for the murder of a white man.

The greatest difficulty in gaining the confidence of the natives was the opposition of the medicine-men, or witch-doctors, utterly ignorant but shrewd humbugs, who, of course, saw at once that their power would wane as much as the white man's reasoning influence ascended.

The many long years spent with these hitherto almost unknown people have enabled the author to give us a narrative from the point of view of seasoned experience, instead of first impressions, and thus it has come to pass that chapter after chapter, as they deal with the mode of life, rites, and beliefs, are so many essays of ripened authority. It may, however, be regretted that many of the revolting features, and most of their rites are inclined that way, are scarcely hinted at, and that the question of sex is but lightly

[1] "An Unknown People in an Unknown Land": an Account of the Life and Customs of the Lengua Indians of the Paraguayan Chaco, with Adventures and Experiences met with during Twenty Years' Pioneering and Exploration amongst them. By W. Barbrooke Grubb. Edited by H. T. Morrey Jones. Pp. 330. (London: Seeley and Co., Ltd., 1911.) Price 16s. net.

touched. The Lenguas, being strong believers in reincarnation, are convinced that the soul of a deceased person hovers about his old haunts, watching for the opportunity of slipping into some living person. Such a chance is provided when a man dreams, because then his soul is wandering, and these people suffer terribly from dreams, so much, indeed, that it may be questioned whether a more rational diet, or medical relief from indigestion, would not have at least accelerated the painfully slow process of religious conversion. This reincarnation doctrine leads to such ludicrous mental conditions that a man in full vigour may be in doubt whether he is himself or not, asserting gravely that his own real soul is at a distance, being kept away by devils, and that some other, departed, soul has crept into him!

Owing to the custom of infanticide, especially of girls, the men are in the great majority, with the result that every girl has a wide selection of partners.

FIG. 2.—Blanket Weaving. From "An Unknown People in an Unknown Land."

Further, native law requires that the man must leave his own people and join those of his wife. Her main object in life being to feed well and to have as little drudgery as possible, she seeks a mate of a mild disposition, who will be subservient to her rule, besides being a good hunter and gardener. There is a delightful chapter on the baneful result of communalism, socialist principles being carried to such perfection that the lazy bodies will neither hunt nor fish as long as there is something to eat elsewhere, because it is a strict law that all shall share in everybody else's spoil.

The author's profits of this remarkable and well-illustrated book will be devoted to the support of the Church of England South American Missionary Society.

PROF. M. H. N. STORY MASKELYNE, F.R.S.

PROF. MERVYN HERBERT NEVIL STORY MASKELYNE, whose death on May 20 was announced in last week's NATURE, was born on September 3, 1823, and was the son of Anthony Mervyn Story, F.R.S., who married the only daughter of Nevil Maskelyne, the famous Astronomer Royal. The family is thus one of scientific distinction through three generations, and it is not surprising that Maskelyne was early in life attracted to the study of science. He went to Wadham College, Oxford, where he took his degree in 1845, and even in those early days all his spare time, energy, and resources were devoted to the pursuit of chemistry, at a time when there were very limited facilities for the study of science at the university.

In 1856 Maskelyne succeeded Buckland, and became professor of mineralogy, and held that office until the year 1895. He had a laboratory and residence under the Old Ashmolean Buildings, and was one of the chief workers in experimental chemistry in Oxford. He was indeed urged by many persons to be a candidate for the chair of chemistry, which became vacant in 1855, but was not willing to stand in opposition to his friend, Benjamin Brodie. He played a prominent part in the establishment of science teaching in Oxford, and was secretary of the first committee formed to promote the scheme for building a university museum. Some of his reminiscences of that period are related in Dr. Vernon's "History of the Oxford Museum," where it is stated that his classes in analytical chemistry were attended, amongst others, by Thomson, afterwards Archbishop of York, and Henry Smith.

In 1857 he became keeper of the department of minerals in the British Museum, and for twenty-three years combined this office with his Oxford professorship. The keepership of the mineral department he resigned in 1880, when he became Liberal member of Parliament for Cricklade, and afterwards for North Wilts, until the year 1892, when he retired from active political life. Referring to his father's death, he wrote, "it was like a whirlwind that bore me from the museum, where my life would have been impossible, to this country life and into the House of Commons."

Maskelyne's scientific activity was for the greater part of his life in the field of mineralogy, and especially crystallography, and his interests were largely centred in the development of the great collection of minerals at the British Museum. In particular, he brought together the wonderful collection of meteorites which for years has maintained its position as the best, or one of the two best, collections in the world. Much of his time was devoted to the scientific study of these remarkable objects. In 1850 Mr. Sorby had laid the foundation of the modern study of rocks by showing that it was possible to grind sections of them so thin as to be transparent, and Maskelyne was the first to apply the new method to the study of meteorites, and was able by the microscope to identify in them many terrestrial minerals and to discover some which are unknown on earth.

Although in the study of higher physics and mathematics he must have been mainly self-taught, it was towards the physical and crystallographical sides of mineralogy that he was particularly attracted. Mineralogy had become an exact science in the hands of Haüy at the close of the eighteenth century, and Whewell and his eminent successor Miller kept alive in Cambridge the mathematical treatment of crystallography.

It was Maskelyne's work to develop in particular the subject of the symmetry of crystals, upon which he gave a course of lectures before the Chemical Society in the year 1875. Victor von Lang, who subsequently became professor of physics at Vienna, had

been his assistant in the British Museum for a short period (1862–4), and his suggestive book, published in 1866, was one of the first dealing with this subject; much that appeared in the books of both authors was doubtless the result of their discussions during this period.

Maskelyne's own "Treatise on the Morphology of Crystals" did not appear until 1895, the year in which he resigned his professorship in Oxford, but much of it had been written thirty years before, and, if it had been published at that time, the book would have been regarded as a highly original treatise. The proof sheets were familiar to many of his students, and introduced them to a very attractive treatment of what was then a new subject. Owing to the late appearance of this book, his methods were chiefly made known to the world in an indirect way through his pupils, and it is possible that he may not have received the credit that is due to him. For example, it is mentioned in Lewis's "Crystallography" that the mathematical establishment of the angles possible between planes of symmetry in a crystal was first given by Maskelyne in his lectures in 1869, but no publication of such a result was made until that by Prof. Gadolin in 1871.

Among those who worked with him at the British Museum, in addition to his old friend von Lang, were Thomas Davies (1862–80), who was responsible under him for the arrangement of the "Collections"; Dr. Walter Flight, F.R.S. (1867–80); W. J. Lewis (1875–7), now professor at Cambridge; and his successor, Lazarus Fletcher (1878–80), now director of the Natural History Museum. He always spoke with particular admiration of Grailich, of Vienna, who was an early and intimate acquaintance. One of his dearest friends was that remarkable man, Henry Smith, of Oxford, with whom he frequently discussed mathematical problems. It was the good fortune of the present writer, when an undergraduate, to receive instruction from Maskelyne in an informal way in Henry Smith's house; on these occasions the lecture was delivered from an armchair in the drawing-room, Smith himself playing the part of a second student, and illuminating the discourse by questions and comments of profound significance. An example of the stimulus which Maskelyne's active mind gave to those with whom he came in contact is the investigation by Smith of the conditions under which lines in a crystal can be perpendicular to each other.

It is not necessary here to give a detailed account of Maskelyne's scientific papers. They range over a wide field, and are characterised by a charm of literary style which is well known to all who received letters from him. His activities date from so early a period that it is difficult now to ascertain what personal part he played in some of the scientific discoveries of the middle of the nineteenth century, but he worked for a time in Faraday's laboratory at the Royal Institution, was one of the earliest to take a practical interest in the newly invented process of photography, and, indeed, throughout his long life interested himself in almost every branch of scientific inquiry.

Faraday stayed with him during the British Association meeting at Oxford in 1847, when, he writes:—"I showed Faraday for the first time the making and developing of a photo of the College Quad from the window. His joy was that of a boy."

Maskelyne's interests outside science were also very wide, and he was the owner of one of the best and most carefully selected private collections of antique engraved gems; his catalogue of the Marlborough gems, which was privately printed, is well known.

He possessed a remarkable elasticity and alertness of mind, as of body, even in advanced years, and his enthusiasm for all that was new in science, literature, and art was maintained to the end. Only four years before his death he was occupied on a scientific handbook for the use of the dairy farmers of Wiltshire, and was well known throughout the county as a man whose intellectual activities were always available for a good cause. Everything that he did was evidence of his taste, and was marked by a conspicuous refinement and distinction of style and manner.

In a letter written only three years ago he said:—"I think there must be some cement in the smaller sciences like mineralogy and crystallography that links their students by a bond unlike the relations that exist between the advocates of the larger sciences; jealousies and rivalries seem to hold aloof, and certainly from the days of Grailich and Lang to those of my old age some of my dearest and most honoured friends have come to me through the sciences that you and I have professed at Oxford since 1856."

It was in reality his own warm, impulsive, quick-tempered, and sympathetic nature which united him by the closest ties of affection to so many of his pupils and scientific friends. The charm of his manner and the astonishing versatility of his mind were the qualities that most impressed those who met him in the later years of his life.

He received the honorary degree of Doctor of Science at Oxford in 1903, and the Wollaston Gold Medal from the Geological Society in 1893. He was an honorary fellow of Wadham College, and a corresponding member of several foreign societies. In 1858 he married a daughter of Mr. J. D. Llewelyn, F.R.S.; she survives him, together with three daughters, one of whom married the late Mr. H. O. Arnold-Forster, and another Sir Arthur Rücker. H. A. M.

MRS. W. P. FLEMING.

BY the death of Mrs. Williamina Paton Fleming, astronomy has suffered an almost irreparable loss. Concerning the general spectral classification of stars Mrs. Fleming had accumulated a store of knowledge which was second to none.

Born at Dundee, Scotland, in 1857, she became an assistant at the Harvard College Observatory, Cambridge, Mass., in 1879, and in 1898 was officially appointed as the curator of astronomical photographs, a department wherein Harvard holds a unique position. Here Mrs. Fleming was charged with the supervision of a number of ladies whose duty it is to examine minutely, and to classify, the ever-growing library of plates taken at the Cambridge and Arequipa stations. Her special personal labours were chiefly devoted to the study of the enormous number of stellar-spectra plates which form the Draper Memorial. This collection was commenced in 1886 as a memorial to the late Dr. Henry Draper, and consists of an immense number of photographs of stellar spectra taken with the 8-inch and 11-inch Draper telescopes. Each plate covers a comparatively large area, and contains the spectra of a large number of stars, and when we learn, from Prof. Pickering's latest report, that there are now 18,182 plates taken with the 11-inch, and 36,852 taken with the 8-inch telescope, it is easy to understand that Mrs. Fleming's task was no light one.

The chief result of these studies was, perhaps, the production, in 1890, of the "Draper Catalogue of Stellar Spectra," in which Mrs. Fleming classified the spectra of 10,351 stars down to about the eighth magnitude. This Durchmusterung, with its revision,

will probably long remain unexcelled as a comprehensive, comparative study of the broad features of stellar spectra. Its magnitude prevents it, of course, from dealing with the individual spectra in detail, but it stands not only a memorial to Dr. Draper, but also to the patient and specialised studies of Mrs. Fleming.

The minute examination of such a wonderful collection of photographs afforded great opportunities for discovery, and right well did Mrs. Fleming and her staff avail themselves of them. Of the eighteen novæ discovered since 1885, fourteen first stood revealed on the Harvard photographs, by reason of their characteristic spectra; of these, ten were found by Mrs. Fleming.

The first nova thus found was Nova Normæ, on a plate taken at Arequipa on July 10, 1893, and examined by Mrs. Fleming on October 26 of the same year. Some of these discoveries were rather more belated; for example, Nova Persei (No. 1) "appeared" in 1887, but was not "discovered" until the plate was examined at Harvard in 1895.

Then, again, Mrs. Fleming's researches led her to the discovery of a great number of new variable stars, stars having peculiar spectra—such as those of the Wolf-Rayet type—and nebulæ. In a list of 108 nebulæ discovered at Harvard, and published in No. VI., vol. lx., of the "Annals," Mrs. Fleming was credited with fifty-two, discovered during the period 1888 to 1907. It was also her examination of the Harvard plates, in 1891, that revealed the duplicity of β Lyræ, which, up to that time, had remained an enigma, from the changes in its spectrum, to astronomers. Such discoveries as these, by Mrs. Fleming, have been a consistent feature of the Harvard "Circulars" for many years, and from Prof. Pickering's report for the year ending September 30, 1910, we learn that, during that year, Mrs. Fleming's keen examination revealed twenty-one new variable stars, one star of the fourth type, two of the fifth, four of the sixth, four gaseous nebulæ, and one star the spectrum of which appears to be unique. Not a bad haul of discoveries for one year!

Those who had the good fortune to come into personal contact with the deceased astronomer found her most unassuming in her manner, although fitted and ever-ready to give, from her wonderful store of knowledge, every assistance possible to anyone who desired information concerning the remarkable variations of stellar spectra. At Harvard, in America, in fact, throughout the whole astronomical world, her death will be felt as a great loss.

WILLIAM E. ROLSTON.

THE SCIENCE MUSEUM.

IN NATURE for May 4 we announced the publication of the report of the Departmental Committee on the Science Museum and the Geological Museum, and we gave some extracts from it. Since then "Further Correspondence and Memoranda" have been published (Cd. 5673), and besides this there have been many letters in *The Times* on the subject. These have come mainly from biologists, urging that any building erected as a science museum at South Kensington would ultimately interfere with the possibilities of the expansion of the Natural History Museum. As a counterblast to the memorial from representatives of the physical and mechanical sciences published in the report, there has been issued another from representatives of the biological science. As usual, the men of science are working against each other, a sorry spectacle which must greatly gratify those who are asked for money to help its progress.

It would appear also from an "Historical Memorandum," printed in the white paper referred to, and from a letter from Sir Norman Lockyer, which was printed in Tuesday's *Times*, that the authors of the correspondence to which reference has been made have not been too careful about their facts; the main facts are shortly stated in Sir Norman Lockyer's letter, which we reproduce, but even he does not tell us the whole story. When land was to be allocated to the Natural History Museum, 1863, two proposals were before the Government, according to Lord Palmerston, its spokesman (*Hansard*, June 15, 1863), schemes demanding three acres and eight acres respectively. Lord Palmerston compromised with five acres, about the same area on which it is now proposed to build the Science Museum.

To the Editor of THE TIMES.

SIR,

Some four years ago I considered it my duty to call the attention of the Royal Commission of the Exhibition of 1851 to the fact that practically the whole of the land belonging to them had been allocated, and that, so far, no proper provision had been made for a Museum doing for the Physical, Chemical, and Mechanical Sciences what the British Museum Library does for books, the Galleries for Antiquities, the National Gallery does for pictures, and the Natural History Museum does for the Biological Sciences.

As the action of the Royal Commission on my Memorandum has produced a situation which has given rise to some correspondence in *The Times*, I ask your permission to deal with the main question, which is being lost in the various side issues and details now being discussed.

In the original idea of the Prince Consort, by whom the purposes to be served by the Estate were laid down, a Science Museum was contemplated. The Commission sold their first plot of land west of Exhibition Road to the Government in 1863. Lord Palmerston, in introducing the Vote for this purchase, said in the House of Commons (*Hansard*, June 15, 1863):—

"Now, the question is, what do we want? What are the requirements that press on the Government? In the first place we want a Patent Museum." . . . "Then we want an addition to the British Museum." . . . Thereafter he referred to the need for a Portrait Gallery, now provided elsewhere.

The White Paper Cd. 5673 giving, at the instance of Lord Cromer, "Further Correspondence" on this subject, includes an historical memorandum which refers to leading points in the development of the ground. Some of these, however, may well be noted here.

In 1880 the building of the Natural History Museum was completed, and the land on which it was built was fenced off on the north side. The area then fenced in contained very nearly 11¾ acres, more than twice the land assigned to the Natural History Museum by Lord Palmerston. The building itself covered very nearly 3¾ acres, leaving 8 acres unoccupied. From that day to this, *i.e.* a period of thirty-one years, there has been very little reduction of this unused ground, sacred for all this time to nursemaids.

In 1874 the Duke of Devonshire's Royal Commission on Science urged the importance to the nation of the development of the Science Museum and of the organisation of a Solar Physics Observatory—both institutions in direct furtherance of Science and the Arts, the aim of the Commissioners in selling the land to the Government in 1863. The Government acted on both these recommendations. In 1876 a Loan Collection of Scientific Apparatus was organised, and the Office of Works gave permission for an Observatory to be erected on the ground.

In 1876 the success of the Loan Collection was so marked that the Royal Commission offered 100,000*l.* to commence the building of an adequate Science Museum. In 1888 the Government came into possession (with the regrettable exception of the N.W. corner) of the whole area of land between the Cromwell Road and Imperial Institute Road, nearly 21 acres (20·9).

This is now allocated as follows:—

	Acres
Natural History Museum and grounds, including private roadway between E. and W. boundaries, up to the original fence	11·64
Imperial College, Post Office, and Meteorological Office, and necessary open spaces	3·3
	14·94

Say 15 acres.

These 15 acres deducted from the 21 acres leaves 6 acres for the purposes of the Science Museum, roughly only 2 acres more than the area actually occupied by the Natural History Museum building.

Now to use even a part of this area for a Science Museum, which must eventually stretch right across the strip, the Spirit Museum, not necessarily the building, but its inflammable contents, must go. If there is any opprobrium attached to this suggestion, I am content that it should fall on my shoulders, for I was careful to point out this necessity in my Memorandum of 1907 written for the information of the Royal Commission, and I do not know that anyone had considered the question before that year. If there is any difficulty about placing the enlarged Spirit Museum along Queen's Gate, it can be built in two portions east and west of the entrance in Cromwell Road. The future extensions of the Museum might then be erected on the frontages to Queen's Gate and Exhibition Road.

It will be noticed that my figures give a little larger area for the Science Museum than those shown in the "Further Correspondence" (Cd. 5673); this arises from the fact that I not only take the original line of fence, but consider the already existing road to the north of the Natural History Museum is sufficient to serve the purposes of both Museums. If the two organisations work together, not only would space be thus saved, but the amenities of the gardens, until they are built over, would be made common to both Museums.

I now come to the real question at issue in which the Nation is chiefly interested. Now that we have an Imperial College responsible for the highest teaching, both in the Physical and Biological Sciences, represented by the two Museums, it is clear that the highest efficiency of the teaching, if Museums are worth anything, will be secured by all three institutions being as close together as possible.

There would then be a grave objection to one of the courses recommended by one of your biological correspondents, namely, that the whole of the remaining 6 acres should be added to the Natural History domain, making in all nearly 17 acres, of which at present they use about 4, while the Museum dealing with all the other branches of Science should go elsewhere.

It must not be forgotten, too, that the munificent offer of the Royal Commission of 100,000*l.*, now made for the third time, towards the building of the Science Museum has been made on the understanding that the Museum was to be built on land conveyed to the Government by them in accordance with the Prince Consort's views that the National Collections of all kinds should be housed on it.

The Science Museum must then take its place by the side of the Natural History Museum on the South Kensington site. What is it to include? What is likely to be its rate of expansion? It should include all the products of men's ingenuity in science, both pure and applied; it should form the base of the discoveries and the applications of the future in all scientific directions. It should be to the worker in science what the British Museum Library is to the student in literature—a stepping-stone to higher things.

As we have in it to deal with the works of man, and over an enormous field, the new Science Museum should from the start increase rapidly year by year, while the Natural History Museum, dealing with the works of nature, is already an old institution, and has largely completed its general collections. Nature's new species, representing animal advance, are not produced at the rate at which, at this moment, man's new species, representing intellectual and material advance, come into being.

An area, therefore, for the Science Museum about the same as that thought necessary for the Natural History Museum by Lord Palmerston when the land was purchased, an area, indeed, not yet occupied by the buildings for that Museum, should not be considered excessive for the Science Museum. Moreover, it is certain, when space is available, to increase more rapidly than the Natural History Museum, and it will be pinched for space before two generations are out unless the design for the Museum building is prepared on a scheme that will take full advantage of modern methods of construction with the possibility of several superimposed stories of Exhibition Galleries readily accessible by lifts. The frontage Galleries of the adjoining Art Museum show how much can be done in this way.

This being so, is it just and decorous for representatives of the biological societies to claim more space when they already have more than they will require during the next century, judging by the rate of expansion during the last thirty years?

At the same time, it is not to be denied that recent investigations have opened out new inquiries of a most important and far-reaching character. And what has happened in the past may occur again in the future. Ample space must be forthcoming to provide for all such contingencies.

This does not necessarily suppose great expansion of exhibition space; but it may do so, and it will assuredly require the provision of adequate accommodation for investigation of the collections now existing or to be formed.

With regard to extensions of the two Museums in the distant future there is no difficulty. There is a block of houses and mews covering roughly 6 acres to the west of Queen's Gate, and opposite the 21 acres of Government ground. The ultimate purchase of this would allow of the two frontages being continued. It is fair to leave to a future generation the question of such an extension, for we cannot forecast the nature of the demands which may then be made for further Museum accommodation.

Has not the moment at last come when all those interested in science in its various aspects should co-operate to find the solution of a question which has been debated for a generation? There should be no contention between these persons—their aims are the same; they desire to afford the best facilities for the increase and coordination of knowledge in all its branches. In my opinion it can be shown that all this can be accomplished at South Kensington, and a really splendid monument can be provided. Is this the moment for contention as to whether this or that branch has a big enough show? Ought we not rather to come together and see how best to utilise what we have got?

(*Signed*) NORMAN LOCKYER.

NOTES.

THE Faraday lecture of the Chemical Society will be delivered by Prof. T. W. Richards, of Harvard University, on Wednesday, June 14, in the theatre of the Royal Institution.

THERE will be a display of calculating machines on Tuesday, June 13, at the Royal Statistical Society's house, 9 Adelphi Terrace, W.C., from 4 to 5.30, during an at home, for which invitations have been issued.

THE second Biennial Congress of the Far Eastern Association of Tropical Medicine is to be held in Hong Kong from January 20 to 27, 1912. The association is international, and, as the title denotes, was formed to promote the study of tropical medicine in the Far East.

THE death is announced of Prof. Samuel Calvan, professor of geology in the State University of Iowa, and State geologist of Iowa. Prof. Calvan was seventy-one years of age, and had been connected with the University of Iowa for thirty-seven years.

At the annual general meeting of the Institution of Electrical Engineers, held on Friday last, Mr. S. Z. de Ferranti was elected president, and Mr. W. Duddell, F.R.S., Major W. A. J. O'Meara, C.M.G., Mr. W. H. Patchell, and Mr. J. F. C. Snell vice-presidents, for the session 1911–12.

A festival in memory of Richard Jefferies is to be held at Swindon on Saturday, June 10. Jefferies was born at Coate, near Swindon, and spent his early life in the latter place. It is proposed to pay a visit to Coate Farm, the naturalist's birthplace, and an open-air concert, morris dancing, speeches, and a short service in Chiseldon Church have been arranged for.

The sum of 1000*l.* has been placed at the disposal of the Home Secretary by a colliery proprietor to form a prize for the best and safest electric lamp for use in mines, and Messrs. C. Rhodes and C. H. Merz have consented to act as judges upon the lamps submitted. The competing lamps must be addressed: care of Mr. C. Rhodes at the Home Office Testing Station, Rotherham, and must be delivered by, at latest, December 31 next.

An appeal is being made to all who are interested in photography, or in the history, archæology, and science of Kent, to become members and correspondents of the Photographic Record and Survey of the county, and to contribute, if possible, half-a-dozen prints each year to the collection in the County Museum of Maidstone. At the recent annual general meeting Sir David Salmons, Bart., was re-elected president, and the secretary reported that 553 prints had been added to the survey collection during the year. Prospectuses of the survey and any information relating to it will be gladly supplied by the secretary, Mr. H. E. Turner, 14 Queen's Road, Tunbridge Wells.

At the anniversary meeting of the Linnean Society, held on May 24, the following officers and council were elected for the ensuing year:—*President,* Dr. D. H. Scott, F.R.S.; *treasurer,* Mr. H. W. Monckton; *secretaries,* Dr. B. Daydon Jackson, Prof. A. Dendy, F.R.S., and Dr. Otto Stapf, F.R.S.; *council,* Prof. V. H. Blackman, Mr. H. Bury, Sir Frank Crisp, Prof. A. Dendy, F.R.S., Prof. J. Stanley Gardiner, F.R.S., Mr. E. S. Goodrich, F.R.S., Mr. H. Groves, Prof. W. A. Herdman, F.R.S., Mr. A. W. Hill, Dr. B. Daydon Jackson, Mr. H. W. Monckton, Prof. F. W. Oliver, F.R.S., Prof. E. B. Poulton, F.R.S., Dr. A. B. Rendle, F.R.S., Dr. W. G. Ridewood, Miss Edith R. Saunders, Dr. D. H. Scott, F.R.S., Dr. Otto Stapf, F.R.S., Miss E. N. Thomas, and Dr. A. Smith Woodward, F.R.S.

At the anniversary meeting of the Royal Geographical Society, the Founder's medal was awarded to Colonel P. K. Kozloff for his explorations in Central Asia since 1883, and the Patron's medal to Dr. J. B. Charcot for his expeditions to the Antarctic continent. The Victoria research medal was awarded to Captain H. G. Lyons, F.R.S., for his work on the Nile Basin and the topographical, cadastral, and geological surveys in Egypt, which he directed when Director-General. Other awards were made to Dr. Wilfred Grenfell, of Labrador, Captain G. E. Leachman for work in Arabia, Dr. Arthur Neve for his investigations in the Himalayas, and to Mr. R. L. Reid for his surveys of the Aruwiari River.

The anniversary dinner of the Royal Geographical Society was held on May 26 at the Hotel Cecil, when Lord Curzon, the president of the society, reviewed the many striking events of geographical importance which had occurred during his predecessor's tenure of office. He alluded to the very inadequate accommodation which the society possessed at the present time, and urged that, in the interest of the scientific development of the subject in this country, better and more commodious premises were urgently needed. Twenty-two past and present medallists of the society were present, and Sir John Forrest, who was honoured by the society as early as 1870, and Dr. Charcot, one of the medallists of this year, responded on their behalf.

The *Terra Nova*, the vessel which conveyed Captain Scott and his expedition to their base of operations, has now been overhauled and chartered by the New Zealand Government for surveying work. Sailing from Christchurch in July, work will be carried out on the northern coast of North Island, and then between the northern coast and the small islands of Manawa Tawhi. The delimitation of the 100-fathom lines and shoal soundings are to be undertaken which should lead to results of much practical importance. The Central News further reports that Mr. D. G. Lillie, a biologist of the Antarctic expedition, has, in sorting and preserving specimens for transmission to Europe for study by specialists, recognised that the collection contains a number of species of invertebrates hitherto unknown.

Prof. W. L. Grant, professor of colonial history at Queen's University, Kingston, Canada, lectured before the Royal Geographical Society on Monday last on the geographical conditions affecting Canada. After alluding to the physical character of the country, the lecturer pointed out the immense resources, agricultural, mineral, and climatic, which must inevitably give Canada before many decades a dominant position in the Empire. Much remains to be done, but the large ideas of early pioneers have been fully justified, and bold schemes for the further development of the country are being confidently put forward. Still, there is great need of an adequate inventory of the Dominion's resources, which, though vast and imperfectly known, are of the greatest value, and any squandering of them needs carefully to be guarded against.

The Research Committee of the National Geographic Society of Washington, it is reported in *Science*, has made a grant of 1000*l.* for continuing the glacier studies of the two previous years in Alaska. The work, beginning in June next, will be done by Prof. R. S. Tarr, of Cornell University, and Prof. Lawrence Martin, of the University of Wisconsin, who have directed the National Geographic Society's Alaskan expeditions of 1909 and 1910 in the Yakutat Bay, Prince William Sound, and lower Copper River regions. This year's expedition will study briefly a number of regions of glaciers not previously investigated by the National Geographic Society, although partially mapped by the Alaska Division of the U.S. Geological Survey. Work will be done on the present ice tongues and the results of glaciation in the mountains and plateaus of parts of the interior and some of the fiords of south-eastern Alaska, the former having lighter rainfall and smaller ice tongues than the Yakutat Bay and Prince William Sound regions.

In a paper read at the Buxton meeting of the Association of Water Engineers on May 20, on the water supplies of the river basins of England and Wales, Mr. W. R. Baldwin-Wiseman, of Southampton, directed attention to the lack of proper coordination and control in the administration of the fresh-water resources of this country. He pointed out the pressing need for river boards, which,

while thoroughly representative of local interests, would subordinate their functions to the general direction of a national hydrographical department, and he considered that this body should be represented in Parliament by a Minister of Water Supply. It is certainly true that, compared with the highly efficient hydrological organisations existing in France, Italy, and the United States, the efforts of similar bodies in Great Britain are local and sporadic, and this lack of interdependence and control is conducive neither to a satisfactory conservation of our resources nor to their effective development. Mr. Baldwin-Wiseman has also dealt with the matter in a paper on the administrative aspect of water conservancy, read before the Society of Engineers in April last. Both papers are timely, for the problem is one which must inevitably be faced and solved at no distant date.

AT the last scientific meeting of the Zoological Society Dr. C. W. Andrews, F.R.S., gave an account of some fossil mammalian remains lately received at the British Museum (Natural History) from British Central Africa. The specimens, which were collected on the eastern side of Lake Victoria Nyanza, were sent to the museum by Mr. C. W. Hobley, C.M.G., Commissioner of Mines for the district. For the most part only fragments of bones are preserved, but in addition to these there is a portion of a mandible of a small species of Dinotherium with several well-preserved teeth, so that there is no doubt as to the genus. The species seems to be very closely similar to *Dinotherium cuvieri* from the Lower and Middle Miocene of France, and it may be that the beds from which the African species is derived are of the same age; but, on the other hand, it is also possible that Dinotherium survived in Central Africa long after it became extinct elsewhere, in which case the deposits may be of a later date. The interest of this discovery is that it is the first record of the existence of Tertiary mammals in Central Africa, and that when the age and relationship of the beds in which they occur are known, much light may be thrown on the geological history of the African lakes. In the same beds occur fragments of a small rhinoceros, a giant land-tortoise, Trionyx, and crocodile. The excellent condition in which the bones are preserved gives great hope that careful collections will lead to the discovery of new forms which will clear up many obscure points on the history of the Mammalia.

THE summer meeting of the Concrete Institute will be held in the Lecture Hall, Denison House, Vauxhall Bridge Road, on June 7 and 8, when the following papers will be read and discussed:—The æsthetic treatment of concrete, by Prof. Beresford Pite, after which an interim report of the Tests Standing Committee on the testing of concrete, reinforced concrete, and materials employed therein will be presented, and the Y.M.C.A. building, Manchester, by Mr. A. E. Corbett, to be followed by the presentation of a report of the Reinforced Concrete Practice Standing Committee on the standardisation of drawings of reinforced concrete work. The first annual dinner of the institute will take place in the evening of June 7, and in the evening of the following day there will be a conversazione in the galleries of the Royal Institute of British Architects.

THE programme of the jubilee meeting of the Institution of Naval Architects (which, as already announced, is to take place on July 5, 6, and 7) has just been issued. We learn from *Engineering* that among the papers to be presented are the following:—Warship building, by Sir P. Watts; naval engineering, by Engineer-Vice-Admiral Sir H. Oram; naval artillery, by Sir A. Noble; mercantile shipbuilding, by Dr. S. J. P. Thearle; steam turbines, by the Hon. C. A. Parsons; armour, by Mr. C. E. Ellis; fifty years' architectural expression of tactical ideas, by Admiral Sir C. Bridge; the history of the institution and the progress of scientific education in naval architecture, by Sir W. White; some further notes on cavitation, by Mr. S. Barnaby; naval construction, by Rear-Admiral Kondo; naval engineering, by Engineer-Rear-Admiral Fujii; mercantile shipbuilding, by Mr. Yukawa and Dr. Terano; and a paper on the service performance of two Japanese turbine-driven ships. A paper on passenger steamboat construction will be read by Mr. F. E. Kirby, and one on the results of tests on models of submarines by Mr. M. F. Chace. Prof. Rateau will deal with the rational application of the turbine to ship propulsion, and Prof. Marbec with the collapsing of beams and elastic curve slips. Dr. O. Schlick will treat of the present knowledge of the vibration phenomena of steamers, and Prof. O. Flamm will deal with the scientific study of naval architecture in Germany. Lieut.-Colonel G. Russo will review progress in shipbuilding in Italy, and Mr. J. Johnson that of recent developments in the transportation of ore.

MR. R. D. BANERJEA, of the Indian Archæological Department, announces the discovery at Dacca, on a temple image of the terrible goddess Chandi, consort of Siva, an inscription of the reign of Lakshmana Sena Deva, King of Bengal, dated 1122 A.D. This is the first inscription of the kind from eastern Bengal proper which gives the date of a king of Bengal. He is said to have reigned over a tract of country extending from Benares to the Garo Hills, and from the Himalayas to the sea. The result of this discovery is that, in the light of the fresh information which it supplies, the greater portion of the ancient history of the Province of Bengal must be re-written.

IT has repeatedly been stated that the effects of a tropical sun in inducing sunstroke, &c., are due more to the chemical than to the heat rays, and therefore clothing lined with or made of a fabric of material which does not transmit the chemical rays has been recommended for wear in tropical climates. An experiment with orange-red underwear has been tried in the Philippines, and is recorded by Captain Phalen, of the U.S. Army. No beneficial effect whatever was observed from the use of this clothing; on the contrary, it added to the burden of heat upon the system, and it is concluded that white or khaki clothing sufficiently excludes the chemical rays (*Philippine Journal of Science*, v., No. 6, 1910, p. 525).

IN the report of the Zoological Society of Philadelphia for the past year stress is laid on two factors in regard to the well-being of animals in captivity, namely, the importance of *post mortem* parasitical investigations and the success of the outdoor treatment. Even the loss of the tips of their tails through frost-bite by a pair of hamadryad baboons is considered no bar to the continuance of the "simple life" method.

MR. C. FORSTER-COOPER, who recently made an expedition to the Bugti Hills of Baluchistan for the purpose of collecting fossil mammals, has returned to this country. A considerable series of fossils are, we understand, on their way home, and will eventually be added to the collections of the British Museum. The first mammalian fossils from the Bugti Hills were collected by the late Dr. Blanford and described by Mr. Lydekker; they indicate a lower

horizon than the typical Siwalik fauna. A number of new types have recently been described by Mr. Guy Pilgrim.

FROM a report contributed by Dr. F. A. Jentink to Nos. 2 and 3 of vol. xxxiii. of Notes from the Leyden Museum, it appears that the recent Dutch expedition to the Snow Mountains of New Guinea did not obtain anything very striking in the way of mammals. In fact, the only novelties are three species of pouched mice of the genus Phasgologale, one of which is the largest, and a second the smallest, of the Papuan representatives of the group. A lower jaw of a peculiar rat, *Anisomys indicator*, hitherto known only by a couple of specimens and characterised by the extreme narrowness of the lower incisors, was, however, obtained from the natives.

WE have been favoured with a copy of a pamphlet, by Prof. Berthold Hatschek, of Vienna (published by W. Engelmann, of Leipzig), entitled "Das Neue Zoologische System." In this scheme, which is the last of several already prepared by the same author, the animal kingdom is divided into the two sections Protozoa and Metazoa, and the latter again subdivided into three main groups, namely, Cœlenterata (including sponges), Ecterocœlia, and Enterocœlia, the last comprising Chætognatha, Echinodermata, Brachiopoda, Enteropneusta, Tunicata, and Vertebrata, while the second group embraces all other metazoan invertebrates except cœlenterates. The Cœlenterata are regarded as the direct descendants of the Protozoa; but the chief novelty claimed for the scheme is the independent derivation of the two main groups of Cœlosomata, that is to say, the Ecterocœlia and Enterocœlia, from distinct groups of Cœlenterata.

THE May number of *The Zoologist* contains an account of a new earthworm or treeworm recently discovered by the Rev. Hilderic Friend. It is named *Dendrobaena merciensis*, Friend, because it was found near the old capital of Mercia. At first sight it resembles *D. beddardi* and *Bimastus eiseni*, but it differs from these in the fact that the girdle extends from the twenty-second to the thirty-first segment. It is destitute of tubercula pubertatis. In the same journal we have a continuation of the same author's studies in the distribution of British annelids, in which the county records are set forth alphabetically. There are no records known to the author for Bedford, Berkshire, or Cheshire, but we find Bucks credited with eleven species of earthworm, Cambridge sixteen, the Channel Islands and Cornwall twelve, Cumberland seventeen, and Derbyshire sixteen. The total number of known British species has now been raised by Mr. Friend to forty.

IN Heft 4 of the *Zeitschrift der Gesellschaft für Erdkunde* Dr. A. Grund describes the hydrographical results of the first cruise of the steamship *Najade*, which has been detailed by the Austrian Government for the oceanographic investigation of the Adriatic by Austrian and Italian specialists. Four sections were sounded from east to west, while others were at the same time being executed by the Italian surveying ship *Ciclope*. Temperature, density, and salinity of the water were also studied, though the "Bora" blowing down the gulf hindered the work at times.

IN Erganzungsheft No. 4 of the *Mitteilungen aus den Deutschen Schutzgebieten* Dr. F. Jaeger gives the result of a very thorough exploration carried out in 1906 and 1907 in the southern portion of the Eastern Rift Valley, to the south-west of Kilimanjaro, and to the south-east of Lake Victoria. As careful a survey was made of the region as time would allow, and accurate triangulation was utilised to control the topographical work. A large collection of geological specimens was made, and these are described in the present memoir, but no general account of the structure of the district is given. The form of the ground traversed is indicated by form-lines on two maps of large scale (1 : 150,000), but is not described in the text. A vast crater basin with many minor vents occupies the northern portion near Lake Njarasa (Eyassi), and many points rise to more than 3000 metres. The whole area is immature in its topography, the drainage lines being short and steep, leading to the floors of the fault valleys in which the lakes are situated. The southern portion shows more clearly a series of parallel fault-blocks striking N.E., with lakes or marshes occupying the low-lying ground between. The meteorological observations have not been printed, but have been autographed and deposited at various institutions in Germany. As a study of earth forms, the maps are highly instructive.

THE report of the Botanical Club of Canada for 1909, issued by the secretary, Dr. A. H. Mackay, contains the announcement that the club has been dissolved, and that the work of collecting and tabulating phenological observations in the Dominion, formerly undertaken by the club, has been transferred to the officials of the Meteorological Service.

A SHORT paper contributed by Dr. Wm. Trelease to the Transactions of the Academy of Science of St. Louis (vol. xviii., No. 3) deals with the species of Agave cultivated during recent years in Mexico under the name of "zapupe." Of the various forms for which numerous local popular names exist, five different species, all new to science, are delimited according to spine characters, and these fall into three groups. They may be distinguished as "azul," "Tepezintla," "ixtle," "cimarrón," and green zapupe, and are probably all referable to the section Euagave; as cultivated plants they rarely set capsules, and appear to be freely bulbiferous after flowering.

IN the absence of definite criteria, the phylogeny of the algæ provides scope for varying opinions and hypotheses. Thus in the *Biologisches Centralblatt* (April 15) Mr. J. Brunnthaler elaborates the view that the red algæ are the most primitive. A primary reason is supplied by the argument that in early times the earth was surrounded by a dense vapour through which the sun penetrated with difficulty, and therefore the conditions of diffused light which prevailed were similar to those under which most red algæ now live. The origin of the group is referred to primitive ancestors of the Flagellatæ. Next in sequence are placed the brown algæ, derived partly from red forms and partly from the Flagellatæ, while the youngest line of development is assigned to the green algæ.

THE cold days of May were rather late in their occurrence this year, but were experienced towards the close of the period shown by the average results for a series of years. This year, May 19, 20, and 21 were the only really cold days, the maximum temperature for the period at Greenwich being 56·5°, and on May 20 the highest temperature was 52·3°. Last year the cold days in May fell fully ten days earlier, and in 1909 a week earlier. A brisk northerly wind was blowing this year, and an anticyclone was situated in the Atlantic in close proximity to our coasts. A change to warmer weather set in on May 22, when at Greenwich the shade temperature ranged from 35° in the early morning to 70° at midday. The summary of the weather for the week ending May 20, issued by the Meteorological Office, shows that the mean temperature

for the week was above the average over the whole area of the British Islands, the greatest excess being 3·6° in the Midland counties, and the least 1·1° in the north of Scotland. The absolute temperature ranged from 73° in the east of England to 33° in the east of Scotland.

A NEW edition (the seventh) of the handy "Hints to Meteorological Observers," prepared under the direction of the Council of the Royal Meteorological Society by Mr. W. Marriott, has been received. The present edition has been revised and enlarged; the explanations and illustrations of ordinary and self-recording instruments are very satisfactory. We are glad to find a considerable addition to the very useful glossary of meteorological terms, including those most recently introduced. We think this might be still further improved by more additions, and occasionally by a little fuller explanation. We notice here and there a slight departure from the explanations usually given, *e.g.* the order of the colours of the corona. We can only repeat the opinion before expressed, that the work takes a high place among the best of such handbooks published in any country.

AN interesting article on the weather in the seventeenth century, by Mr. W. Sedgwick, is published in *Symons's Meteorological Magazine* for May, containing extracts relating to the spring (March–May) between 1658 and 1705 from the diaries of John Evelyn, F.R.S., and Samuel Pepys, F.R.S. The author proposes in this and subsequent numbers to give an opportunity of considering whether these extracts show that any marked change in the climate of London has occurred since that period. Statements are often made that our climate has undergone considerable changes in comparatively modern times. On the other hand, well-known investigators of the present day have shown that any apparent changes either in temperature or rainfall can be accounted for by the difference in the instruments and their exposure. Although these instruments were known before the close of the seventeenth century, there were but few in existence; they cannot have been used regularly, if at all, by Evelyn or Pepys, and the tendency in the case of non-instrumental observations would be to record abnormal rather than normal conditions. Another important consideration pointed out by the author is the change from the Julian to the Gregorian Calendar, which was made in England in 1752. With reference to the popular belief about the old-fashioned Christmas, in several years during the last decade there have been considerable falls of snow after Christmas which would have occurred before Christmas if the Julian Calendar had been still in force.

THE Journal of the Royal Statistical Society for May contains an important paper, by Mr. E. C. Snow, on a new method of estimating post-censal populations, *i.e.* the populations of different districts of a country in the years following a census. The estimation of such populations often offers considerable difficulties, especially in districts of a rapidly changing character in the neighbourhood of large towns, and the method at present in official use—based on the assumption of the approximate maintenance of the rate of change during the preceding intercensal decade—may lead to very serious errors. For example, the birth- and death-rates in Salford in 1890, based on the estimated population, were calculated at 28·8 and 22·4 respectively, but when the results of the census taken in the following year were made known, these figures were altered to 35·6 and 27·6. Mr. Snow suggests that definite indices of a change of population, such as changes in the number of births, deaths, marriages, or houses, should be used as the basis of the estimate, that regression equations should be formed by the method of correlation between the change in population of a district and the changes in these several indices during a completed intercensal decade, and that these regression equations should be applied to the following decade. Trial of the method on several groups of districts of diverse characters showed that it would lead to greatly increased accuracy.

INVESTIGATIONS of the hitherto almost unknown ultraviolet spectrum—the Schumann region—are of special interest, because the conditions attending the production of these extremely short wave-length radiations are obviously of a different character from those attending the production of the more familiar spectrum. In this research Mr. Theodore Lyman has taken a great part, and in the March number of *The Astrophysical Journal* (vol. xxxiii., No. 2, p. 98) he publishes results obtained from an investigation of the nature of the radiation from oxygen, hydrogen, nitrogen, helium, and argon in the region more refrangible than λ 1900. No lines of helium and oxygen have yet been discovered in this region; if they exist they are too faint to be disclosed by the present methods. By varying the conditions of discharge in the vacuum tube, two spectra of nitrogen were revealed, one of faint bands with heads on the more refrangible edges, the other consisting of two pairs of sharp lines at $\lambda\lambda$ 1492·8, 1494·8, 1742·7, and 1745·3. No lines were seen in the "red spectrum" of argon, but a considerable number, about forty between λ 1333·7 and λ 1886·1, exist in the "blue spectrum." Repeating the experiments made by Schumann, Mr. Lyman has, as yet, been unable to obtain the primary spectrum of hydrogen which Schumann suspected. An interesting spectrum, apparently intimately associated with hydrogen, appears in the region λ 1650–λ 1450, and consists of five groups, each group containing five lines. Argon containing a trace of hydrogen at a pressure of 2 or 3 mm. shows this spectrum well if aluminium electrodes and no capacity are employed. Nitrogen, oxygen, and helium containing a trace of hydrogen do not show the groups, and if other electrodes are used considerable enfeeblement occurs. With pure hydrogen these groups always appear—with the other lines—and they disappear if the last trace of hydrogen is removed from the argon mixture. If their origin is an impurity in the hydrogen, it must be of a fundamental character, for the groups appear in all the hydrogen used by Lyman and by Schumann for many years; they may be a new spectrum of hydrogen. For a description of the apparatus and methods employed in the research the reader is referred to the original paper.

THE April number of *Le Radium* contains a memoir by M. L. Dunoyer, of the laboratory of Madame Curie, on the production of a material radiation of purely thermal origin. A tube of hard glass about a centimetre in diameter and about 30 centimetres long is joined at its upper end to a wider tube, the length of which varies from 2 to 13 centimetres in different cases. A side tube leads from the enlarged head to a Gaede pump. The lower end of the tube is covered inside with a film of metallic sodium obtained by distillation *in vacuo* from a heated tube originally communicating with the experimental tube, but sealed off when the deposit has been formed. When the lower part of the tube is now heated, so as to vaporise the sodium and drive it into the upper part of the tube, it is found that if diaphragms with small openings of the order 2 or 3 millimetres diameter are placed in the tube above the sodium deposit, the molecules of vapour are driven through the openings with such velocity that they form a

deposit on the end of the enlarged part of the tube which reproduces the shape of the opening of the last diaphragm through which the vapour has passed. If a plate with holes of any form in it is interposed in the path of the molecules, the deposit on the end of the tube reproduces the openings sharply. M. Dunoyer is already engaged in experiments to determine the kinetic energy of the projected molecules or particles and to measure their electric charge, if any.

Red Book No. 155 of the British Fire Prevention Committee deals with the loss of life at the Asch Building fire in New York on March 25. It will be remembered that there were 145 deaths. The committee has procured a trustworthy report from Prof. Ira Woolson, of New York; this report was originally prepared by Mr. F. J. T. Stewart, superintendent of the New York Board of Underwriters. This great loss of life occurred where the structural damage was relatively small, and practically affected only the fitments and equipment of the three top stories of the building. Bad planning and exit facilities, neglect of the ordinary precautions to prevent an outbreak of fire, the absence of any prearranged system of utilising the existing appliances, together with neglect to have all routes of exits clear for easy and immediate use, are the primary causes of the catastrophe. The building comprised a sub-basement, basement, ground floor, and nine floor levels; its height may have some bearing on the total number of lives lost, but scarcely on the general extent and character of the calamity.

WE have received a pamphlet from Mr. Wm. Love, of 42 Claremont Square, London, N., giving particulars of his system of maintaining straight the rolls used for rolling flat sheets. The method appears to be novel, and consists in supporting the rolls by means of intermediate bearings. These bearings are in turn supported by means of beams, so arranged that the deflections of all the bearings under a uniform load on the roller are equal; hence the roller remains practically straight. There are no supports at the ends of the roller. Suppose, for example, that four intermediate bearings are fitted. The roller is divided into four imaginary equal segments, and each bearing is at the centre of a segment. The four bearings are supported on a beam, which we may imagine to be divided into two equal segments. This beam is supported at two points, one at the middle of each segment, and the supports are formed symmetrically on a longer beam, which is in turn supported at its ends. On the latter beam deflecting under the load, the two points at which the first beam is supported will suffer equal deflections, and by the arrangement of bearings on the first beam, all these bearings will deflect equally. In this system the roller may be much less in diameter than has been customary, as reliance on its stiffness is unnecessary. For example, a roller 2 inches diameter by 24 inches long, supported in the ordinary way, would deflect, say, 0·1 inch; supported on Love's system, the deflection for the same load is 1/2560 inch. Other applications of the principle are given in the pamphlet.

MESSRS. MACMILLAN AND CO., LTD., announce for early publication the third English edition of Prof. W. Nernst's "Theoretical Chemistry," corresponding to the sixth German edition, and translated by Mr. H. T. Tizard, Magdalen College, Oxford. The portion of the book dealing with thermodynamics has been largely rewritten and includes a detailed account of the author's new theorem of thermodynamics. A chapter on radio-activity has also been added. The text of the earlier English edition has been completely revised and partly rewritten. The translator has also made some additions to the text, at the suggestion of Prof. Nernst, in order to bring the book up to as late a date as possible. These include an account of Nernst's work on specific heats at low temperature, and a short summary of Perrin's recent researches on Brownian movements.

MESSRS. E. AND F. N. SPON, LTD., announce for early publication "Bibliographical History of Electricity and Magnetism Chronologically Arranged," by P. F. Mottelay.

OUR ASTRONOMICAL COLUMN.

METCALF'S COMET, 1910*b*.—An observation of Metcalf's comet was made by Dr. Schiller at the Bothkamp Observatory on April 18, and showed that the comet still has a sharply defined stellar nucleus of magnitude 13·5. The total brightness was about equivalent to that of a star of magnitude 12·8, and when thin clouds obscured the comet the nucleus could still be seen. Dr. Ebell continues his ephemeris up to the end of July, when the estimated magnitude will be 14·8. The present position of the comet is two or three degrees north of κ and ι Ursæ Majoris (*Astronomische Nachrichten*, No. 4495).

RECENT OBSERVATIONS OF HALLEY'S COMET.—Prof. Barnard secured good observations of Halley's comet on April 16, 23, and 25, but finds that the object is rapidly growing fainter. On April 23, in a very good sky, the magnitude was estimated to be 14·5 or 15·0, but on April 25, with the sky not quite so good, it was estimated to be 15 or 16. Prof. Barnard states that the brightness has been subject to considerable fluctuations, and at the time of the second observation was probably in one of its fainter phases (*Astronomische Nachrichten*, No. 4500).

EARLY VISIBILITY OF THE NEW MOON.—Mr. Horner's observation of the new moon is discussed by Mr. Whitmell in No. 435 of *The Observatory* (May, p. 203). It appears that the observation was made when the moon was but sixteen, not seventeen, hours' old, which, so far as is known, constitutes a record; the moon was "new" at 1h. 13m. on the morning of February 10, 1910, and was seen by Mr. Horner, whilst looking for comet 1910*a*, at 5h. 13m. the same evening. The difference in azimuth between the sun and moon was roughly 10°, and, according to a paper which Mr. Fotheringham published in the Monthly Notices (R.A.S.) for May, 1910, the moon should be unobservable if its altitude were lower than 11°; but when Mr. Horner saw it the moon had an altitude of only 4° or 5°.

LARGE PROPER MOTION OF A SMALL STAR.—The examination of plates taken in 1892 and 1906 led Prof. Max Wolf to the conclusion that a 9·7 mag. star in Leo had an extraordinary proper motion. This was confirmed by Prof. Burnham, who has since kept the star under observation, and, from measures made during the period 1907–11, together with the 1892 photograph, finds that the most probable value for the proper motion is 1·228″ in 190·4°. The star's position (1900) is R.A. = 11h. 23m. 20s., dec. = +8° 6′ 1″, and it is 70s. preceding, and 185″ north of, the 7·5 magnitude star B.D. +8°2512 (Monthly Notices (R.A.S.), vol. lxxi., No. 6, April).

PHOTOGRAPHIC DETERMINATIONS OF STELLAR PARALLAX.—Having described the methods of photographically determining stellar parallaxes with the Yerkes 40-inch refractor, Dr. Schlesinger is now discussing the results in his series of papers appearing in *The Astrophysical Journal*. In papers iii. and iv. of the series (*The Astrophysical Journal*, vol. xxxiii., Nos. 2 and 3) he gives the results for fourteen stars, and in four cases finds positive parallaxes exceeding 0·1″. These are Groombridge 34, $\pi = +0·266'' \pm 0·010''$; μ Cassiopeiæ, $\pi = 0·105'' \pm 0·010''$; Weisse I., 5h. 592, $\pi = +0·189'' \pm 0·010''$; and Fedorenko 1457–8, $\pi = +0·148'' \pm 0·015''$. The last-named is a well-known double star (Σ 1321), which has a proper motion of 1·7″ per annum, and Dr. Schlesinger gives an interesting discussion concerning the probable source of a systematic error which appears, including therein a discussion of the effect of atmospheric dispersion on the measured images of the stars.

The parallax of π^4 Orionis is found to be $+0.012'' \pm 0.007''$, and in the cases of ψ Orionis and S Monocerotis negative parallaxes result from the measures.

THE PARIS OBSERVATORY.—M. Baillaud's report for the year 1910 contains a record of a great deal of work successfully accomplished, and, besides, gives interesting accounts of several ingenious instrumental devices. The ordinary astronomical work was carried on as usual, but, together with the observations of Halley's comet and other special observations, was greatly interfered with by the unfavourable skies at Paris.

The distribution of time signals by radio-telegraphy took place regularly after May 23, 1910, and on November 23, and subsequently, a signal was sent at 11 a.m., as well as at midnight as previously. A brief account of the installation for this purpose is given.

THE LONGITUDE OF THE RED SPOT ON JUPITER.—In a communication to the *Astronomische Nachrichten* (No. 4498), the Rev. T. E. R. Phillips records his observations of the Red Spot on Jupiter during the present apparition. These show the remarkable fact that the longitude of this feature has diminished by approximately 30° in the unprecedentedly short time of ten months. While in June last year the zero meridian of system ii. practically bisected the hollow, the longitude on April 13 and 16 was but slightly more than 330°.

MEASURES OF DOUBLE STARS.—Lick Observatory Bulletin No. 190 contains the measures of 159 double stars made by Mr. C. P. Olivier. The paper is the fifth of a series on double stars lying south of the equator, and sixty-one of the present objects are south of −30° declination; twenty-four new pairs are included. The bulletin also contains a table displaying Mr. Olivier's personal equation with respect to Messrs. Aitken and Hussey.

THE BRITISH SOLAR ECLIPSE EXPEDITION.[1]

TO continue the hospitality which had been showered on us, Mr. Mills placed a large customs steam launch at our disposal, and the same afternoon took us for an impromptu cruise about the beautiful harbour, Mr. Hedley, the assistant curator of the Sydney Museum, accompanying us. Unfortunately, however, at about 4.30, while steaming up Middle Harbour, we piled up on a sandbank on a falling tide, and it was not until 7.30 that we were able to float off. As we did not arrive back to the hotel until 9 o'clock, our trip to the capital site had to be postponed until next morning. Mr. Hunt had already sent numerous telegrams and secured tickets and sleeping accommodation in the train, but these were generously replaced by others available for the following day. The next morning (March 21) Mr. Hunt showed me the screens on the wall of the Sydney Post Office, in which were exposed the meteorological forecasts. These seemed to be very popular, judging by the number of people I saw closely examining them whenever I passed by. Then he showed me the meteorological department at the observatory. The view from the tower of this observatory is magnificent, and as I had my panoramic camera with me I took views all round. From an astronomical point of view the observatory is very hampered, for on three sides it is surrounded by closely packed buildings, rendering the atmosphere very smoke-laden. The afternoon was spent in motoring in the vicinity of Sydney, and very fine views of the country were obtained. In the evening Mr. Hunt and I left for the capital site. To reach this region we had to make a night railway journey, arriving at Queanbeyan at 4.30 a.m. At the hotel there we turned in until 8 o'clock, and then started away in a two-horsed vehicle for the surveying camp, which is situated on the site of the future capital. This meant a drive of eight miles over a somewhat rough road, but this road is in progress of betterment every day. At this camp we were received by Mr. C. R. Scribner, the chief Commonwealth surveyor, who has the whole Commonwealth territory for surveying purposes in hand. In his offices we were shown contour maps of the whole region, the sites for the water supply, railway, &c. He had in process of making some model relief casts made accurately from the contour maps, and these were being coloured before dispatching them to the various world centres for competition. The competition consists of suggestions for the best arrangement for a "model city," and I believe a valuable prize will be awarded to the winner. Mr. Scribner has a nice little meteorological station in good working order near the camp site.

After lunch we drove a distance of about 6½ miles to the foot of a hill called Stromlow. This hill is 600 feet above the plain below, and its summit is 2600 feet above sea-level. It forms a kind of "Hog's Back" in a north and south direction, the land falling rapidly away on both sides. The eastern horizon is well open, so that solar observations can be made just after sunrise. The observatory site reminds one rather of that chosen for the Solar Physics Observatory at Fosterdown, Caterham, but, of course, on a very much larger scale. As the nearest town to the Stromlow hill will be the capital site, 6½ miles away, and as the latter will be on the leeward side of Stromlow in relation to the prevailing winds, the observatory cannot be rendered ineffective at any reasonably near date. Further, a very large reserve of land all round the hill has been set apart for protective purposes. Both on this and on the hill gum trees are in their thousands, but most of these have been ring-barked, and are therefore dead. The planting of other and quicker growing trees is now going to be undertaken, so that radiation from the ground will be reduced to a minimum. The result of my visit was that I was highly pleased with the site, and Mr. Hunt assured me that the weather conditions all the year round were of the best. The following is the brief report I sent to the Minister for Home Affairs with respect to the Stromlow site:—

AUSTRALIA HOTEL,
SYDNEY,
March 23, 1911.

SIR,

Accompanied by Mr. H. A. Hunt, escorted over the site by Mr. C. R. Scribner, I have now had the opportunity of inspecting the proposed location of the future Solar Physics Observatory. I carefully surveyed the situation with respect to those main requirements which could be judged on inspection, and I feel sure that Stromlow will admirably serve the purpose for the site of a National Observatory such as is proposed.

In selecting a site for a National Observatory for the study of Solar Physics, it is most important that one should look a long time ahead, and that any site selected now should be as good a site in, say, 100 years' time. The Stromlow site seems to be admirably suited in this particular. Again, it is fundamental that the observatory should be situated at a high elevation, because definition for solar observations is best in the very early morning just after sunrise, and an unobstructed eastern horizon is imperative. In fact, solar physics observatories are now situated or are now being removed to high localities to secure these observing conditions, and this result is the outcome of considerable experience.

In the present instance Stromlow is well adapted in this particular, for it is 2600 feet above sea-level and 600 feet above the neighbouring plain, and has an open eastern horizon. The highest points of this site should be utilised for the solar instruments.

Further, the site is good with respect to the western and northern horizons, rendering the location as an observing station one of the highest order.

Another important desideration in the choice of a good site is that the northern, eastern, and western slopes are such that there need be little fear from defects arising from the presence of future buildings on them. On the southern side of the site the plateau is very well adapted for the erection of the main business buildings of the observatory, apart from the observing instruments.

The observatory should be a sufficient distance away from any large town in order to render the sky as little illuminated as possible in the neighbourhood of the observatory from artificial town lights; in addition, it should be situated on that side of the nearest town from which the prevailing winds blow in order to free the

[1] Continued from p. 429.

observatory site from the presence of driving town smoke. These two conditions are, I find, allowed for in the site in question, the Capital site being at a sufficient distance of 6½ miles from the locality and on the eastern side, the prevailing wind being from the north-west.

Another important favourable point in the position of the site is that the area is of sufficient dimensions for the accommodation of the necessary buildings for the observation and study of other allied branches of work, such as meteorology, astronomy, seismology, &c. In the case of magnetism, I would suggest that the *observations* should be made at another site very far removed, while their work of *reduction* should be accomplished in special quarters at Stromlow.

It is very important, further, in the light of modern research, that there should be a rapid means of communication between the head workers in all the above subjects, since the latter are so intimately associated with one another. The bringing together of the various departments into one locality is therefore of considerable value, for instant intercourse and collaboration of the work between the heads of departments can be most efficiently accomplished in this way. For such a large country as Australia this centralisation of work is, I think, the most economical and effective course to take.

Trust that this brief summary of the results of the inspection of the site may serve a useful end,

I have the honour to be, Sir,
Your obedient servant,
WILLIAM J. S. LOCKYER.

The Hon. King O'Malley,
Minister for Home Affairs.

On the evening of March 22 Mr. Hunt and I left by train for Sydney, arriving there at 5 a.m. the next morning. After a short rest I went down to the wharf to see about the ten gallons of spirit which had arrived in the P. and O. steamship *Mongolia*, and had been forwarded by the British Museum authorities for use at Vavau for the preservation of the natural history specimens I proposed to have collected for them. A few days previously I had met Mr. A. W. MacIlwaine, of H.M.S. *Pegasus*, and he told me of the valuable fish collection he had made for the Sydney Museum on a previous cruise. He put me up to all the wrinkles of catching, and escorted me to the museum to introduce me to Mr. Maccullock, who looks after this branch there. Mr. Maccullock kindly supplied me with all the necessary materials for collecting and preserving, and promised to pack our catch properly for dispatch to London as soon as it arrived at Sydney after the eclipse.

Friday, March 24, was spent in packing and saying adieu to many kind friends preparatory to going on board H.M.S. *Encounter* in the evening after seeing Mr. Hunt off by train to Sydney, and I should like to take this opportunity of thanking him for his extreme kindness to me and all of us during the whole time we were in Australia. In Mr. Hunt the meteorology of Australia is in good hands; he and his staff are working at problems of extreme interest, which will be to the benefit of Australia in particular and the world in general.

H.M.S. "Encounter," April 2.

Saturday, March 25, saw us steaming majestically out of the beautiful harbour of Sydney away to far-off Vavau, the scene of our future labours. The ship, with her two tall masts carrying the network of Marconi wires between their tops, and the three funnels sending out the tailings of Newcastle coal, must have looked a pretty sight with the background of abnormal green grass and trees which studded the shores. On board were the two eclipse parties safe and sound, namely, Fathers Cortie and Pigot and Brother McKeon, and my party of Mr. McClean and Mr. Anderson, while safely stowed away below were the eclipse instruments and huts. On board also were some livestock, sheep, cocks and hens, and last, but not least, the ship's goat.

FIG. 1.—Evening Cloudscape in the Doldrums.

The first day out I erected the screen for the three self-recording instruments, which ought to have been used all the way out from Tilbury. Then I adjusted and started the instruments themselves, the screen being placed on the starboard side of the ship well forward of the funnels and against the conning tower. That evening I gave a lecture, having now lantern and slides, the object of which was to explain to the whole ship's company the kind of assistance they could render us both in the preparations and during the eclipse. The lecture seemed to have attained its end, for the captain asked all those who were willing to assist to give their names in by six o'clock on Sunday, *i.e.* the next day. Not only did all the officers come forward, but 168 men handed in their names.

Sunday was occupied in preparing lists of the requirements of assistance at each instrument and for several parties, such as corona drawing, star observations, &c. When this was completed the captain handed it to the commander to portion off the officers and men for the several lines of work. In addition to the eclipse work, there were numerous volunteers for the "'ologies," as the natural history branches were termed. Thus the captain, assisted by Staff-Surgeon Milln, volunteered to do the catching of the butterflies, moths, beetles, spiders, &c., and he stated that Mrs. Colomb (who is on her way to Vavau with other ladies, wives of the officers) was bringing him the killing bottle. Mr. Anderson has occupied himself with geological study preparatory to rock-specimen collecting. The collection of flowers, seeds, and especially fern seeds, will be undertaken by Lieut. Hunt Gruhl, while Mr. Lane, the purser's clerk, was posted by Mr. MacIlwaine, of the *Pegasus*, in the art of catching fish. Lieut. Clover will look after the birds and bats, &c., and will be assisted by Staff-Surgeon Milln in their prepara-

tion. The Rev. Peshall has also volunteered to make a collection of shells, sponges, &c. Thus even if we are clouded out and do not get our astronomical observations, we hope at least to bring back some new material which may advance science in other directions.

On Tuesday, March 28, Father Cortie delivered a lecture on "Eclipses in General," while the following evening Mr. McClean was persuaded to describe and give his experiences on aëroplanes. In fact, we have all been most busy, and the ship has been rolling and pitching nearly all the time, and a stiff head wind N.E. has been blowing.

On March 31 we were invited to a concert given by the ship's company, which proved very successful.

Early this morning (April 2) we passed on our starboard side the islands of Tofua and Kao; both are volcanoes, the former active, but there were no signs of activity. Tofua lies in the centre of the eclipse track, but has not been looked upon as a suitable place for an eclipse station. On our port side we are now nearly abeam of Late Island, a lonely peak in this landless ocean. In fact, except for a very few birds and a few flying-fish, the ocean and air have been lifeless. The barograph is daily marking out the diurnal double oscillation superimposed on long waves of rise and fall. The temperature has been steadily rising, and has now reached the eighties. The hydrograph persistently records more than 80 per cent. of saturation, but on the moving ship this humidity is not very much felt except when violent exercise is indulged in. We are now in very quiet trade winds, and the good ship *Encounter* is becoming more steady. To-night, or rather this afternoon, we expect to arrive at our destination, and then we shall feel the effects of the temperature and humidity.

At the present moment no decision has been arrived at as to whether we shall live on board or ashore. Most probably it will be the latter. Our present intention is to occupy the spot indicated on the large-scale map of Vavau portioned off as a naval coaling station, for the harbour is sufficiently deep for the ship to lie just off. This harbour has only a very narrow entrance, so that the ship will be well protected from strong winds and landing will be easy.

To-morrow morning (April 3) will be spent in looking for a suitable site, and then on the following day the Union Steamship Company's mail boat arrives from Auckland, bringing the Australian astronomers and the other members of my party, namely, Messrs. Brooks, Raymond, and Winkelmann.

I have arranged with Captain Colomb that, should we be successful on the day of the eclipse, the ship will not leave Vavau until about May 5. The object of this is to give us plenty of time quietly to develop and copy all negatives; as the climate is so hot and humid, particular care must be taken to produce the best results, and it is quite possible that development may only be successfully accomplished during the cool (!) of the night. In the case of our being clouded out, Vavau will be left on May 2. On her return journey to Sydney, H.M.S. *Encounter* will make for Suva, Fiji, to coal, and to land Mr. McClean and myself there.

It is now 11.30 a.m., and two small patches of land ahead give us the first imprint of Vavau, our future home for some time to come. At last we are there after this long journey.

W. J. S. LOCKYER.

THE PRIVATE SESSIONS OF THE IMPERIAL EDUCATION CONFERENCE.

IN our review of the public sessions of the conference (see NATURE, May 4), we hoped that the report of the private sessions would reveal a useful interchange of ideas between the delegates from various parts of the Empire, and that organised concerted action would result. The report (Cd. 5666, price 1*s*.) issued by the Board of Education is now before us, and we may state at once that it disposes of the fear—to which the character of the public meetings naturally gave rise—that the Colonial Governments had not been duly consulted with reference to the agenda of conference. Furthermore, we believe that the debates have been of a useful character, and that an important step has been taken to fulfil our aspirations by the organisation of an Imperial Education Bureau. The agenda of the meetings may be summarised as follows:—(1) action arising from the previous conference in 1907; (2) memoranda prepared by the Office of Special Inquiries and Reports on schools in the self-governing dominions; (3) training and qualifications of teachers; (4) cost of instruction and cost of living in connection with advanced technical colleges and universities; (5) the Board's examinations in the overseas dominions; (6) the formation of an Imperial Education Bureau.

Two mornings were devoted to problems of an educational, rather than administrative, character. English spelling and spelling reform formed the subject of papers by Dr. E. H. Edwards (H.M.I., England) and Dr. A. H. Mackay (Nova Scotia); also Dr. W. J. Viljoen (Union of South Africa) contributed interesting information with reference to the simplification of Dutch orthography and grammar. H.E. the Governor of Sierra Leone submitted a paper, written by R. F. Honter, on the psychology of the negro child and on the adaptation of primitive customs, manners, laws, and traditions in a system of education. Sir F. D. Lugard, Governor of Hong Kong, presented a memorandum on the best methods of training character and inculcating a high moral standard in universities founded primarily for non-Christian races, without the compulsory teaching of the Christian religion, and this subject is to be considered further at the next conference. Among the appendices is a report of the Conference on Bilingualism, convened by the President of the Board of Education. The discussion of this question by representatives of South Africa, Canada, the India Office, Scotland, Wales, and Malta, brought clearly into view the desirability of bringing into the common stock the varied knowledge and experience of administrators under diverse conditions.

But the success of the conference rests upon its treatment of the urgent administrative problems indicated in our six items of summarised agenda, especially in regard to the last. Much credit is due to Dr. Frank Heath, as director, and his staff at the Special Inquiries Office. Their activity has been even more productive than appeared from Mr. Runciman's address (*vide* NATURE, *loc. cit.*), as the interchange of officials, as well as of official memoranda, has been facilitated, and the difficulties of mutual recognition of teachers' certificates are approaching solution. The main outcome of the conference is the extension of the work of Dr. Heath's department. If the unanimous and weighty recommendations of the conference are carried into effect, the Office of Special Inquiries and Reports will perform the functions of an Imperial Education Bureau. The machinery by which these functions are to be performed, the provision for the continuity of the conference, modes of cooperation of the several education departments of the Empire, have all been made the subject of definite proposals of a practical character. From these, which will be found on pp. 12 to 18 of the report, we quote the penultimate recommendation:—

"That the several Education Departments of the Empire should publish, each for their own part of the Empire, the following monographs in the order named:—(*a*) the curricula of schools for general education; (*b*) the training of teachers for schools giving general education; (*c*) the laws of compulsory attendance and their working; (*d*) the general education of children in sparsely populated areas; and (*e*) the medical inspection of schools for general education."

G. F. DANIELL.

THE ENDOWMENT OF HOME SCIENCE.

IT was announced on Friday last (the Queen's birthday) that a sum of 50,000*l*. had been subscribed for the endowment of "home science" in connection with the Women's Department of King's College, and that her Majesty had graciously allowed her name to be associated with a new hostel to be erected at a cost of 20,000*l*. Another 20,000*l*. is to be used for building and equipping laboratories, and it is hoped to supplement the remaining 10,000*l*. so that the endowment for salaries and current expenses may be 60,000*l*.

A trust fund committee has been formed to receive moneys given for the foregoing purpose, composed of the following:—the Marquis of Anglesey (chairman), Sir William Anson, M.P., Mrs. Asquith, Mr. Balfour, Lord Justice Buckley (hon. treasurer), Viscountess Esher, Lady Meyer, Sir Arthur Rücker, F.R.S., Lady Rücker, and Dr. John Atkins (hon. secretary).

The funds will be administered in accordance with the terms of the trust deed by an executive committee composed of representatives of the donors and of King's College for Women, including the Rev. Dr. Headlam, Prof. Jackson, Dr. Miers (the principal of the University of London), Miss Oakeley, Lady Rücker, and Prof. Smithells.

Among those who have generously contributed to the fund raised for the purposes of the endowment of King's College for Women are:—the Marquis of Anglesey, Mrs. Asquith, the Duke of Devonshire, Sir Richard Garton, Sir Carl Meyer, Lady Mond, Mr. Almeric Paget, M.P., Mrs. Almeric Paget, the Earl of Plymouth, Messrs. Rothschild and Sons, the Marquis of Salisbury, the Earl of Scarbrough, Lady Wantage, and the Duke of Westminster.

The Times in a leading article on Saturday, May 27, warmly eulogises the new departure, which, it says, "will be received throughout the country with universal satisfaction and sympathy."

This sudden and remarkable development will be hailed with satisfaction by those who during the last two years have been engaged in carrying out in connection with King's College, under great difficulties, the first attempt made in a university institution in this country to establish a course of higher education for women, centring round home and institutional life. In spite of the unsuitable accommodation and lack of funds, a beginning has been made, and those who are in charge of the scheme are confident of its value and permanent success. Now that funds and influential support are forthcoming, the chief obstacle to progress will probably consist in the difficulty of winning the goodwill of the educational world.

It is a little unfortunate that there is no good term available for indicating the range of studies that are comprised in the King's College course. The expression "home science" is not very felicitous, and it is to be regretted that its classical equivalent, economy (Οἰκονομία) or economic science, has lost its original significance. The pleonasm, domestic economy, has, not without good reason, fallen into disrepute. But whatever be the term used, it can hardly be doubted that, as in agriculture and other crafts, long left in the empiric state, it should be possible to delimit and develop a tract of higher intellectual studies which will rationalise and inform the vastly important work of household administration.

ANNUAL TABLES OF CONSTANTS AND NUMERICAL DATA.

AT the International Congress of Applied Chemistry held in London in 1909, an International Commission was appointed for the purpose of compiling and publishing annual tables of constants and numerical data, and this commission was subsequently accorded the patronage of the International Association of Academies at the meeting of that body held in Rome in 1910 (NATURE, May 26, 1910, p. 371).

According to the programme drawn up by the commission, the tables published in any one year are intended to contain all the numerical data likely to be of interest in connection with chemistry, physics, and allied sciences, pure and applied, to be found in the literature published during the previous year. The data are to be accompanied by full bibliographic references. This programme has now (May) so far matured that portions of the volume for 1910 are already in the press, while the manuscript of the remaining portions is approaching completion.

Owing to the immense volume of scientific and technical literature which is continually being produced, the difficulties in the way of finding out whether any given measurement has been made or not are increasing year by year. Existing systems of indexing and abstracting offer only limited help, since a large number of measurements are made in the course of researches to which they are purely subsidiary, so that their existence cannot be inferred from the titles and subtitles of the papers in which they are recorded. Also tables which appear only at long intervals, such as those of Landolt and Börnstein, can of necessity cover only a small part of the ground, and, moreover, in most cases they are hampered by the limitations of private enterprise. The annual tables should therefore fill a serious gap which has hitherto existed in the systematic indexing of scientific and technical results.

It is hoped that ultimately the enterprise may become self-supporting; but obviously this cannot be the case for some time to come The commission has been greatly assisted by grants from various societies; for example, in this country, from the British Association, Chemical Society, Faraday Society, Royal Dublin Society, Royal Irish Academy, Royal Society of Edinburgh, and the Society of Chemical Industry. Donations have also been received from a few private persons, notably from the Earl of Berkeley, F.R.S. The financial position is, however, still far from satisfactory, and further help from societies and private donors is urgently needed. In this connection it may be mentioned that neither the general secretary nor the members of the commission receive payment for their services, except in so far as they may perform actual compiling or abstracting.

The organisation of the commission is sufficiently complete to deal effectively with the periodical literature, but it happens occasionally that data are published only in non-periodical publications, such as books or monographs, and such data may easily be overlooked. Accordingly, in order that the annual tables may be as complete as possible, the authors of such books, monographs, &c., are requested to communicate with one or other of the members of the commission. In cases where the data are numerous, specimen copies or corrected proofs of the tables containing the data would be very acceptable.

The members of the International Commission for the United Kingdom are:—Dr. Alex. Findlay, The University, Edgbaston, Birmingham; Dr. R. T. Glazebrook, C.B., F.R.S., The National Physical Laboratory, Teddington, Middlesex; and Dr. N. T. M. Wilsmore, University College, Gower Street, London, W.C. The general secretary is Dr. Charles Marie, 98 Rue du Cherches-Midi, Paris VI.

STANDARD TIME-KEEPING.

APPARENTLY the efforts of the British Science Guild to show the commercial need that exists for a more widespread observance of standard time than exists at present (see NATURE of February 16) have already attracted some attention, for last week we had an opportunity for inspecting a demonstration of yet another clock synchronisation system, to be made available by the Greenwich Time Co., which, we believe, is either a branch or offspring of the Normalzeitgesellschaft of Berlin, where there are about 30,000 clocks under the control of the company.

The company has offices in Albany Street, N.W., where a Time Bureau is to be established, and by means of the usual arrangements with the Post Office authorities, the Greenwich time signal is transmitted to the bureau over wires provided for the purpose. This signal controls a regulator clock, the function of which is to control electrically, half a dozen times during the day, other clocks in subscribers' premises. These clocks are arranged so as to report back their behaviour at certain times. If the synchronisation is reasonably efficient, the latter appears to us to be a rather unnecessary procedure. We gather that the company is prepared to let out, on hire, clocks suitable for this purpose for an annual rental of something under 2*l.* per clock. This seems rather expensive for subscribers who require a number of clocks, as must be so in the majority of cases, for the whole of the utility of a synchronisation scheme depends upon *every* clock showing the same time.

We observe that some of the reports in the daily Press hailed the inauguration of this company as something entirely novel, but, as readers of NATURE will remember, the scheme is not at all a new one; in fact, the Post Office authorities have for a long time been synchronising their old clocks, and it seems desirable to place on record

again that the Standard Time Co. has offered the public time service in London for many years. Then many of the electric clock firms, notably the Silent Clock Co., the Synchronome Co., and the Aron Time Distribution Co., have for a considerable time offered trustworthy synchronised Greenwich clocks to the public at rates which are, we believe, lower than those quoted by the new company. We wish every success, however, to a laudable endeavour to ensure accuracy in time-keeping.

ARCTIC TIDES.[1]

THE Coast and Geodetic Survey of the United States has just published the summarised account of the tides of the Arctic Ocean, based on the observations made by Peary's expedition and on those by Messrs. Mikkelsen and Leffingwell at Flaxman Island, to the north of Alaska. The recent Russian observations at Taimur Bay and on one of the New Siberian Islands are not yet available for inclusion. Peary's observations were made at Cape Sheridan, Port Aldrich (near Cape Columbia), Cape Bryant, Cape Morris Jesup, and Fort Conger for periods ranging from seven and a half months, November 12, 1908, to June 30, 1909, at Cape Sheridan, to fourteen days at Fort Conger; and hourly heights of the tide are given, as well as for Flaxman Island in 1906. These are followed by a table giving the principal harmonic constants for all stations north of the sixtieth parallel where such constants are at present available, and fifty-four of these have been collected. Besides this, however, the same region furnishes a long range of data from many points which have been obtained by successive explorers, and these have been brought together to show the intervals, ranges, tidal hours, &c., from all published sources, and to deduce from them the mean ranges of the semi-daily tide and the mean tidal hours.

A co-tidal chart from the Pole to latitude 65° shows the results arrived at by means of lines giving the Greenwich lunar time of mean high water, and on this chart a large area of about half a million square miles between Alaska and the Pole is represented as being land but slightly submerged. The following facts are quoted as showing the necessity for such land or shoals: at Point Barrow the flood stream comes from the west; the range of the semi-daily tide at Bennett Island is 2·5 feet, whereas it is but 0·4 foot at Point Barrow and 0·5 foot at Flaxman Island; the observed tidal hours and ranges of tide show that the semi-daily tide is not propagated to the Alaskan coast directly across a deep and uninterrupted polar basin. Not only the position of such a land area is indicated, but its approximate shape is given as roughly trapezoidal, for certain points are suggested by velocity and direction of currents, by Peary's Crocker's Land, and by some of his soundings.

This paper provides a useful and instructive summary of the tidal movements of the Arctic Ocean so far as they are known, and makes a very suggestive addition to our knowledge of the distribution of north polar lands.

[1] "Arctic Tides." By Rollin A. Harris. (Washington: Coast and Geodetic Survey, 1911.)

AVIATION NOTES.

MR. WINSTON CHURCHILL has wisely amended his "Aërial Navigation Bill," and transformed a measure which, in its original form, promised to kill aërial navigation into one of comparatively small importance. The Bill as it now stands provides that if any person navigates any kind of air vessel over any area prescribed by order of the Home Secretary, unless he can prove that he was compelled to do so by stress of weather or other uncontrollable circumstances, he shall be guilty of an offence, and be liable to six months' imprisonment or a fine of 200*l.*, or both.

The prime object of the Bill is to prevent any daring or reckless aviator from flying over the Coronation processions. It is, however, an open question whether it would succeed in its aim were it not that the Royal Aero Club has requested aviators not to do so, and has provided a penalty for disobedience—the suspension of the certificate of proficiency. It will be perfectly obvious that an aviator could pass high over the processions without incurring any penalty whatsoever. At a height of 1500 feet and upwards the identity of the pilot would be unrecognisable.

M. Jules Védrines has performed an extraordinarily fine feat in flying from Paris to Madrid, a distance of 660 miles, in 12h. 15m., thus winning the prize offered by the *Petit Parisien*. The flight was accomplished on a Morane monoplane fitted with a 50 horse-power Gnome motor and an "Integrale" propeller. M. Védrines started from Issy-les-Moulineaux on May 22, reaching Angoulême, 250 miles away, in 3h. 42m. 18s. The second stage, to San Sebastian (193 miles), took 3h. 43m. 19s., and the final stage, on May 26, to Madrid (220 miles), took 4h. 48m. 42s. The times given are those of actual flight; but it is satisfactory to note that the first two stages were flown without a stop, and only one halt made in the last stage, owing to the breaking of a valve spring in the motor.

The most notable advance recently made in the improvement of aëroplanes has just been successfully tested near Versailles. M. Henry Farman has fitted a silencer to the motor of his military-type biplane, which was already furnished with a wireless telegraphy transmitter. The motor—a Renault—worked without a hitch.

A meeting of the Aërial League of the British Empire was held at the Mansion House on Wednesday of last week to promote a special Coronation appeal for 250,000*l.* for the establishment of a National Institute and School of Aëronautics. The following motion (moved by Sir E. Shackleton) was put to the meeting and carried unanimously:—"That this meeting of the citizens of London and the Empire supports the principles laid down in the circular issued by the Aërial League of the British Empire, and pledges itself to do all in its power to assist the League in its efforts on behalf of the advancement of aëronautics," as was also the following (proposed by Mr. Joynson-Hicks, M.P.):—"That a Coronation fund be raised for the purpose of inaugurating a National Institute and School of Aëronautics."

NEW ORGANIC COMPOUNDS OF NITROGEN.[1]

IN the diversity of behaviour exhibited by its derivatives, nitrogen is unrivalled by any other element. This is illustrated not only by the contrasting properties of ammonia, hydrazine, and azoimide, substances composed solely of nitrogen and hydrogen in different proportions, but also by the chemical, physiological, and æsthetic variations displayed by organic compounds of nitrogen, such as nitrocellulose, indigo, azo-dyes, alkaloids, enzymes, and proteins.

Azoimide or hydrazoic acid, HN_3, discovered by Curtius in 1890, is the parent of a series comprising numerous highly reactive organic compounds, the first of which—phenylazoimide—was brought to light by Peter Griess in 1866, after which date the subject lay dormant for more than twenty years. Two methods are applied commercially to the production of sodium azide; the first, described by W. Wislicenus (1892), consisting in passing nitrous oxide over heated sodamide; the second, due to Stollé and Thiele working independently (1908), depending on the interaction of hydrazine, sodium ethoxide, and an ethereal nitrite. In consequence of these, the salt, originally a chemical curiosity, may now be purchased at 40*s.* per pound, largely owing to the simple and inexpensive preparation of hydrazine devised by Raschig (1908). The principal methods by which organic derivatives of azoimide may be obtained are:—

(1) Action of nitrous acid on a substituted hydrazine, applied by Curtius to the production of numerous acyl azoimides.

(2) Addition of hydrazoic acid to a diazonium sulphate, found by Noelting to yield aromatic azoimides quantitatively.

(3) Interaction of organic halides and sodium azide, as practised at the Royal College of Science in preparing aliphatic azoimides.

[1] Abstract of a discourse delivered at the Royal Institution on Friday May 5, by Prof. Martin O. Forster, F.R.S.

It commonly happens that the materials thus obtained are, like the parent compound, explosive, and they are, moreover, very sensitive to light. From a study of their refractive power, it appears that in the aliphatic series the increment of refraction for the triazo-group is 8·91 as compared with 8·93 for bromine; and whilst the atomic dispersion of this halogen is 0·35, that attributable to the triazo-group is 0·36. Moreover, the elevation of boiling point produced by this complex lies between those due to bromine and iodine, whilst the effect on the dissociation constant of an aliphatic acid exceeds that of iodine, but is less than that of bromine. Thus the physical evidence supports those chemical characteristics which classify the triazo-group as a complex radicle having a strong family resemblance to the halogens.

The changes undergone by triazo-compounds may be referred to one of three main types:—

(1) Liberation of two nitrogen atoms in elemental form, leaving the third attached to the carbon which originally carried all three. This is exemplified by triazoantipyrine, which passes spontaneously into a red azo-compound, whilst in triazoacetone, triazocamphor, and triazoacetic acid the change is accelerated by alkali. Sometimes this type of alteration is violently explosive, as in the case of triazoacetic azide.

(2) Unfolding of the three-atom nitrogen ring into a straight chain such as occurs in diazoaminobenzene or in the cycloid tetrazole. Allylazoimide, for instance, a colourless liquid, changes spontaneously into an isomeric solid which no longer contains the triazo-group, whilst hydrazoic acid converts prussic and fulminic acids into tetrazole and hydroxytetrazole respectively.

(3) Complete removal of the triazo-group in the form of hydrazoic acid. The simplest example of this change is found in the behaviour of triazomethylamine derivatives, which liberate hydrozoic acid when treated with cold water; this happens also when triazotised carbon is associated with a halogen, as in the case of triazoethylene dibromide, but more generally this type of decomposition requires the action of alkali.

Although the preparation of chloroazoimide by Raschig (1908) indicates the possibility of producing hexatomic nitrogen by the union of two triazo-groups, this new form of the element has not yet been realised.

A NEW METHOD OF CHEMICAL ANALYSIS.[1]

I HAVE had on several occasions the privilege of bringing before the members of the Royal Institution some of the results of the experiments on the positive rays on which I have been engaged for the last few years. I wish this evening to direct your attention to some applications of these to various chemical problems.

The first application I shall consider is the use of these rays to determine the nature of the gases present in a vacuum tube, to show how they can be used to make a chemical analysis of these gases—an analysis which, as we shall see, will enable us to determine, not merely whether an element, say, for example, oxygen, is present in the tube, but will tell us in what form it occurs, whether, for example, it is present in the atomic as well as the molecular condition, and whether there are allotropic modifications present, such as ozone, O_3, and other still more complex aggregations.

The method is as follows: the positive rays, after passing through a fine tube in the kathode, are exposed simultaneously to magnetic and electric forces, the magnetic field being arranged so as to produce a vertical deflection of the rays, while the electric field produces a horizontal deflection. Thus, if when neither electric nor magnetic fields are present, the rays strike a screen placed at right angles to their direction at a point O, they will, when both electric and magnetic forces are at work, strike it at a point P, where the length of the vertical line PN is equal to the deflection produced by the magnetic field, and the horizontal line ON to that produced by the electric field.

We know from the theory of the action of electric and magnetic fields on moving electrified particles that

$$PN = A\frac{e}{v} \qquad ON = B\frac{e}{mv^2}$$

where A and B are constants depending on the strength of the magnetic and electric fields and the geometrical data of the tube, e is the charge on the particle, m its mass, and v its velocity.

From these relations we see that

$$\frac{m}{e} = \frac{A^2}{B}\frac{ON}{PN^2}.$$

When these rays strike against a photographic plate, they affect the plate at the point against which they strike, and thus when the plate is developed we have a permanent record of the deflections of the rays. The methods of taking these photographs and the details of the experiment are described in my paper in *The Philosophical Magazine*, February. The values of A and B can be determined accurately by the methods I have given in previous papers, and hence if we measure on the photographs the values of ON and PN, we can determine the value of m/e. If we wish to compare the values of m/e for two different rays, it is not necessary to determine A and B; all we have to do is to measure the values of ON and PN, and thus the photograph alone gives us the means of comparing the value of m/e.

Since for the same type of carrier m/e is constant, so that whatever may be the velocity $\frac{PN^2}{NO}$ is constant, and therefore the locus of P, *i.e.* the curve traced on the photographic plate by this carrier, is a parabola. The reason we get a curve instead of a point is that the rays are not all moving with the same velocity, and the slower ones suffer greater deflection than the quicker ones. Each type of carrier produces its own line on the plate, and there are as many curves on the plates as there are kinds of carriers; from an inspection of the plates we can find, not merely the number of kinds of carriers, but from the dimensions of the curves we can at once determine the atomic weight of the carrier, and thus determine its nature. This is one of the great advantages of this method. To illustrate this advantage, let us compare the method with that of spectrum analysis. If the spectroscopist observes a line unknown to him in the spectrum of a discharge tube, the most he can deduce without further investigation is that there is some unknown substance present in the tube; and even this would be doubtful, as the new line might be due to some alteration in the conditions of the discharge. But if we observe a new curve in the positive-ray spectrum, all we have to do is to measure the curve, and then we know the atomic weight of the substance which produced it. To take an example, I have photographed the positive-ray spectrum for nitrogen prepared from the atmosphere and that for nitrogen prepared from some nitrogenous compounds, and have found that the former contains a line[1] which is not in the latter, and that the value of m/e for this line is 40 times that for the atom of hydrogen. We thus know that atmospheric nitrogen contains an element of atomic weight 40, which is not present in chemical nitrogen—this element is, of course, argon. We might by ordinary spectrum analysis have found lines in the spectrum of atmospheric nitrogen which are not in the spectrum of chemical nitrogen, and might thus have suspected the presence of another element; but spectrum analysis could not tell us anything about the nature of this element, whereas the positive-ray spectrum at once gives us its atomic weight.

The positive-ray method is even more delicate than that of spectrum analysis, for by it we can detect the presence of quantities of a foreign gas too minute to produce any indication in the spectroscope. I have, for example, often been able to detect the presence of helium by this method when no indication of its presence could be detected by a spectroscope.

Again, when a line in the positive-ray spectrum can be seen, the atomic weight of the carrier which produces it can be determined with great accuracy. Though the method is only a few months old, it is even now sufficiently developed to determine with an accuracy of 1 per

[1] Discourse delivered at the Royal Institution on Friday, April 7, by Sir J. J. Thomson, F.R.S.

[1] As a matter of fact, there is a second, very faint line for which m/e is about twenty times that for the atom of hydrogen. This is probably due to an atom of argon with two electric charges.

cent. the atomic weight of a gaseous substance, without requiring more than 1/100 milligram of the substance. Another very important advantage of this method is that it is not dependent upon the purity of the material; if the material is impure, the impurities merely appear as additional lines in the spectrum, and do not affect the parabola due to the substance under examination, and therefore produce no error in the determination of the atomic weight. The method would seem to be peculiarly suitable for the determination of the atomic weights, not

FIG. 1.

merely of the emanation from radio-active substances, but also those of the products into which they disintegrate.

The rays, too, are registered within less than a millionth of a second after their formation, so that when chemical combination or decomposition is occurring in the tube, the method may disclose the existence of intermediate forms which have only a transient existence, as well as of the final product, and may thus enable us to gain a clearer insight into the process of chemical combination.

I will now show a few slides prepared from the photographs we have taken of the positive-ray spectra. The first (Fig. 1) is that of nitrogen prepared from air; the measurements of the photograph showed that the atomic weights of the carrier producing these curves were as follows:—

Positive	Negative
1 H_+	1 H_-
1·99 H_{2+}	11·20 C_-
6·80 N_{++}	15·2 O_-
11·40 C_+	...
13·95 N_+	...
28·1 N_{2+}	...
39 A_+	...
100 Hg_{++}	...
198 Hg_+	...

The symbol H_+ denotes that the carrier is an atom of hydrogen with one charge; H_{2+} that it is a molecule of hydrogen with one charge; N_{++} that it is an atom of nitrogen with two charges; and so on.

FIG. 2.

With nitrogen from NH_4NO_2 the lines were as follows (the magnetic force was so large that some of the lines corresponding to the lighter particles were thrown off the plate):—

6·1 C_{++}	44·2 CO_{2+}
7·02 N_{++}	65·5 Hg_{+++}?
12·08 C_+	100 Hg_{++}
14·01 N_+	204 Hg_+
27·9 N_{2+}	

The next slide (Fig. 2) is the positive-ray spectrum for CO, and again the magnetic field is so great that the lighter carriers do not appear.

From the measurement of the lines we find that the atomic weight of the carrier is

Positive	Negative
6·00 C_{++}	12 C_-
6·95 N_{++}	16 O_+
7·95 O_{++}	...
12·02 C_+	...
13·9 N_+	...
15·95 O_+	...
28·05 CO_+	...
43 CO_{2+}	...
69·5 Hg_{+++}(?) very faint	...
100 Hg_{++}	...
202 Hg_+	...

The spectrum for CO_2 is represented in Fig. 3; the atomic weights are:—

5·98 C_{++}	43·9 CO_{2+}
8·00 O_{++}	62·5 Hg_{+++}(?) very faint
12·00 C_+	99·6 Hg_{++}
16·00 O_+	200·0 Hg_+
28·02 CO_+	

The spectrum of CH_4, of which a small region with five lines close together is shown in Fig. 4. This is interesting, because the measurement of these lines shows that their atomic weights are 12, 13, 14, and 15, 16, and thus that we have here C, CH, CH_2, CH_3, CH_4. If I am not mistaken, this is the first occasion when the atoms CH, CH_2, CH_3 have been observed in a free state.

FIG. 3.

The spectrum of the analogous compound chloroform, $CHCl_3$, is represented in Fig. 5. The atomic weights represented in this are:—

1 H_+	18·5 Cl_{++}
1·5 (?)	27·7 CO_+
2 H_{2+}	36 Cl_+
3 (?)	46·5 CCl_+
6 C_{++}	63 (?) faint
8 O_{++}	81 CCl_2
11·9 C_+	102 Hg_{++}
13·7 N_+	201 Hg_+
16 O_+	

The carriers with atomic weights 1·5 and 3 have not been identified. They are of frequent occurrence. I have here two slides, one of SiH_4 (Fig. 6) and the other of the residual gas in the tube, in which they are well marked, though at their best they are only faint lines. In Fig. 7 we have the positive ray spectrum of air, taken under conditions which produce very narrow lines, which can be accurately measured.

Let us now consider some of the results brought to light by these photographs. In the first place, they show that a gas through which an electric discharge is passing is a much more complex thing than a collection of molecules all equal to each other. Even an elementary gas becomes in these circumstances a mixture of a great many different substances. Thus, to take oxygen as an example, the photographs show that when a current of electricity passes through it, we may have present simultaneously oxygen in the following states:—

(1) Ordinary molecular oxygen, O_2.
(2) Neutral atoms of oxygen, O.
(3) Atoms of oxygen with 1 positive charge, O_+.
(4) Atoms of oxygen with 2 positive charges, O_{++}.
(5) Atoms of oxygen with 1 negative charge, O_-.
(6) Molecules of oxygen with 1 positive charge, O_{2+}.
(7) Ozone with a positive charge, O_{3+}.
(8) O_6 with a positive charge, O_6.

And, in addition, there are free negative corpuscles. Thus in the elementary gas there are at least nine (the list has no claim to be exhaustive) separate substances present when the discharge passes through it. Each of these substances has almost certainly different properties, possibly a characteristic spectrum. If we took any other gas we should find that the same thing would be true: thus in hydrogen we have H, H_2, H_+, H_-, H_{2+}, even if we do not ascribe to hydrogen the lines giving $m/e=1\cdot5$ or 3. In nitrogen we have N, N_2, N_+, N_{++}, N_{2+}, carbon occurs as C_+. C_{++}. C_-, chlorine as Cl, Cl_2 Cl_+, Cl_{++}, and Cl_-, mercury as Hg, Hg_+, Hg_{++}, and probably as Hg_{+++}, as there is a very persistent line for which m/e is about 66.

Thus, whenever the electric current passes through a gas, and probably whenever a gas is ionised, the gas becomes a mixture of many different substances. We can thus readily understand why in the spectra of many elements many of the lines may be grouped together so as to form different series—the principal series, the first coordinate series, and so on—and the spectrum of the discharge tube regarded as the superposition of a number of different spectra the relative intensities of which may be subject to very great variations. This, indeed, is just what would happen if some or all of the substances which are present when the gas is in the ionised state gave rise to different spectra.

FIG. 4.

Another feature which I think is of great interest from the point of view of the theory of chemical combination is the occurrence of particles with negative charges. Let us consider for a moment how these are formed. They are formed after the particles have passed through the kathode; the path between the kathode and the photographic plate contains abundance of corpuscles produced by the ionisation of the gas; a neutral particle, after passing through the kathode, picks up a negative corpuscle, and so becomes negatively charged. For this to occur, the attraction between the corpuscle and the neutral particle must be exceedingly strong, for it is not a question of a particle at rest attracting to itself a negatively electrified corpuscle sauntering about in its neighbourhood. In our case the neutral particle is rushing past the corpuscle with a velocity of the order of 10^8 cm. per sec. In order that the particle may in these circumstances be able to drag the corpuscle along with it, the attraction between the two must be so great that to move a corpuscle against this attraction from the surface of the particle away to an infinite distance must require an amount of work of the same order as that required to communicate to the corpuscle a velocity of 10^8 cm. per sec.; this is equal to the work required to move the atomic charge against a potential difference of about 3 volts, and is therefore comparable with the work required to dissociate some of the most stable chemical compounds.

The fact, then, that some particles get negatively charged shows that in the neutral state these particles have an exceedingly strong affinity for a negatively electrified particle, while the absence of a particular particle from the negative side shows that its affinity is much less, but does not imply that it vanishes altogether. From what we have said, it should follow that the more slowly the neutral particles are moving relatively to the corpuscles, the more easily will the negatively electrified systems be formed. This is confirmed in a very striking way by our experiments, for when the discharge is passing very easily through the tube, and the velocity of the neutral particles is relatively small, the number of negatively electrified particles is very much increased; indeed, in some cases the brightness of the part of the photograph corresponding to the negative particles is as great as that corresponding to the positive, whereas when the discharge is passing with great difficulty, and the velocity of the neutral particles is very high, the negative part is very faint compared with the positive.

The particles which have been observed on the negative side are the hydrogen atom, the carbon atom, the oxygen atom, and the chlorine atom. The presence of oxygen and chlorine atoms might, perhaps, have been expected, as these are universally regarded as strong electro-negative elements, *i.e.* as elements which have a strong affinity for negative electricity. The presence of the hydrogen atom is more remarkable, for hydrogen is generally considered to be a strongly electro-positive element, yet on these photographs we find it more persistently on the negative side than any other particle; often when no other line on the negative side is strong enough to be detected, the line corresponding to the hydrogen atom is distinctly visible. This is all the more remarkable, because the hydrogen atom, being the lightest of all the particles, is moving with the greatest velocity relatively to the corpuscles, and therefore would, other circumstances being the same, be the least likely to capture them. The heavier the particle, the slower is its velocity, and the greater chance it has of capturing the corpuscles; the fact that heavy complicated particles are conspicuous by their absence on the negative side shows that the attraction of these for the corpuscles must be exceedingly small compared with that exerted by a neutral atom of hydrogen. It will be seen that the atom of carbon, also regarded as an electro-positive element, is also conspicuous on the negative side.

FIG. 5.

On looking at the list of the particles which occur on the negative side, we are struck by the fact that they are all atoms: there is not a molecule among them. Thus, although the curve corresponding to the negatively electrified hydrogen atom occurs on every plate, there is not a single plate which shows a trace of a curve corresponding to a negatively electrified hydrogen molecule, although that corresponding to the positively electrified molecule is always present, and on some of the plates is stronger than that due to the positive hydrogen atom. Again, on some plates the positive oxygen molecule shows stronger than the oxygen atom, but on the negative side only the atom is visible.

Thus neutral atoms, but not neutral molecules, can exert on the negative corpuscles those enormous attractions which, under the conditions of these experiments, are required to bind the corpuscles to these rapidly moving particles. We may compare this result with the properties ascribed by chemists to bodies when in the nascent condition, *i.e.* when they have only recently been liberated from chemical combination, and when they are likely to be partly in the atomic state, for atoms, as we have seen.

exert forces on electric charges in their neighbourhood vastly greater than those exerted by molecules.

We may compare the forces exerted by a neutral atom on the corpuscles with those exerted by an unelectrified piece of metal on a charged body in its neighbourhood. In consequence of electrostatic induction, the charge and the metal will attract each other. This attraction is dependent on the electricity in the metal being able to move under the electric forces exerted by the charge, and to rearrange itself in such a way that if the charge is positive, the negative electricity in the metal moves to the part of the metal nearest to the charge, while the positive electricity moves to the part remote from the charge. The force between the metal and the charge depends on the freedom of the electricity to move about in the metal under the action of the electric field. If the metal is replaced by a substance of high specific inductive capacity, like sulphur, in which the electricity has an appreciable amount of freedom, though not so great as in a metal, the attraction, though still appreciable, is very much less than it was with the metal. A very simple experiment will illustrate this point. I have on this cardboard disc, which is suspended from a long string, a number of magnets such as are used for compasses; if I mount the magnets on pivots, so that they are free to turn round, the system of magnets is strongly attracted when another magnet is brought near it; if, however, I take the magnets off their pivots, so that they are no longer free to turn, the magnet exerts very little attraction upon them.

FIG. 6.

A view of chemical combination which I gave some time ago in *The Philosophical Magazine*, and also in my "Corpuscular Theory of Matter," suggests that there is a very close analogy between the causes at work in the experiment we have just made and those which produce the difference between the behaviour of atoms and molecules. On that theory the atom was supposed to consist of a large number of corpuscles arranged inside a sphere of positive electricity, the corpuscles arranging themselves so as to be in equilibrium under their mutual repulsion and the attraction of the positive electricity. The configuration depends on the number of corpuscles, and the stiffness and stability of the system also change as the number changes. For some particular numbers of corpuscles the system is very rigid, and any movement of the corpuscles would be strongly resisted; since the movement of electricity inside the atom is brought about by the movement of the corpuscles, the electricity could only move with great difficulty inside these atoms, and they would therefore not be able to exert more than feeble forces on electrical charges outside the atom: they would therefore not enter readily into combination with other atoms. We may ascribe such a constitution as this to the atoms of the inert gases, helium, argon, and neon. A system with one, two, or three more corpuscles than the system we have just described would not be nearly so stable, and there would be a tendency to discard the extra corpuscles from the atom so that it might return to the more stable form. We may roughly picture to ourselves the atom with one extra corpuscle as consisting of a number of fixed corpuscles plus one which is free to move about; the freedom of this corpuscle would enable the electricity in the atom to move about, and would endow the atom with the property of attracting any electrical charges which might be near it. If there were two corpuscles in the atom more than the number required for the most stable form, we can picture the atom as having two corpuscles free and the rest fixed. Similarly, if we had more than two extra corpuscles. Thus we may regard the atom as possessing 0, 1, 2, 3 corpuscles which are able to move about with more or less facility, and the free corpuscles will give to the atom the power of exerting attractions on electrical charges to an extent which depends on both the number of corpuscles and the freedom with which they can move about. On the theory to which I have alluded, the number of these "free" corpuscles determines the valency of the atom.

Now let us suppose that two such atoms come into such close connection that the corpuscles in the one exert considerable forces on those in the other. The system consisting of the two atoms will rearrange itself so as to get into a more stable form, if necessary, corpuscles passing from one atom to the other to enable it to do so. The greater stability, however, implies a loss of mobility; the free corpuscles have become parts of a more stable system, and have therefore lost to a greater or less extent their mobility. But with the mobility of the corpuscles goes their power of exerting forces on electrical charges, and thus the combination of the atoms diminishes to a great extent the attractions they exert outside them. Speaking generally, we may say that on this view the combination of atoms to form molecules, either of compounds or elements, fixes corpuscles which were previously mobile and converts the atoms from conductors of electricity into insulators with a small specific induction capacity.

FIG. 7.

I have brought these illustrations before you with the object of showing that we have now methods which are capable of dealing with much smaller quantities of matter than the methods now used by chemists, methods which are capable of detecting transient phases in the processes of chemical combination, and I am hopeful may be of service in throwing light on one of the most interesting and mysterious problems in either physics or chemistry—the nature of chemical combination.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

EDINBURGH.—Mr. A. D. Darbishire has been appointed to the newly instituted lectureship in genetics, and will deliver a course of six lectures on heredity during the summer session, the course to be free to all matriculated students. Dr. W. G. Smith has been reappointed Combe lecturer in psychology. The executive committee of the Chiene portrait fund has resolved to hand to the University the balance of the fund (a sum of from 310*l.* to 320*l.*) for the foundation of a bronze medal, to be called the "Chiene medal in surgery."

M. TISSOT, an assistant in the Paris Museum of Natural History, has been appointed professor of physiology in the museum.

DR. D. FRASER HARRIS, lecturer on physiology in the University of Birmingham, has been appointed the Thompson lecturer in natural science for 1911–12 at the United Free Church College, Aberdeen.

SIR J. CAMERON LAMB, C.B., C.M.G., has been appointed to represent the Royal Society of Arts at the forthcoming

five hundredth anniversary of the foundation of the University of St. Andrews.

MR. R. NEWSTEAD, lecturer in economic entomology and parasitology in the Liverpool School of Tropical Medicine, has been appointed to the newly established Dutton memorial chair of entomology in the University of Liverpool.

THE Mathematical Society and the Society of Applied Physics of Göttingen have given 100,000 marks to a fund for the creation of an Institute of Mathematics in connection with the University of Göttingen. Two donations of 50,000 marks from manufacturing houses have also been received.

WE learn from *Science* that the Alabama legislature has made the University of Alabama an additional grant of 60,000*l.*, to be expended during the next four years for maintenance and new buildings. On his recent visit to Pittsburg, Mr. Carnegie presented the Carnegie Technical Schools with a valuable 725-acre tract of land that he had owned for some years, twenty-five miles up the Allegheny River from Pittsburg. It will be converted at once into an experimental station and engineering camp.

WE learn from the Journal of the Royal Society of Arts that a system of schools and stations to teach agriculture in the several States, in harmony with the plan for apprenticeship trade-schools, has recently been sanctioned by the Brazilian Government. At the head is to be a higher school of agriculture and veterinary surgery, situated at Rio de Janeiro. The school will give education fitting students for places as experts in the general extension of agricultural training. With the cooperation of the State Government, agricultural schools, experimental stations, model farms, and stock ranches will be established as soon as the general working out of the plans justifies such work. Elementary instruction in rural industries will be encouraged in schools for elementary education already established. By demonstrations at experimental stations and elsewhere it is intended to instruct farmers in the use of modern implements and methods necessary to success in farming.

THE Education (School and Continuation Class Attendance) Bill was presented to the House of Commons by Mr. Runciman on May 26. The principal objects of the Bill are to abolish the existing half-time system, to enable local education authorities to compel the attendance at continuation classes up to the age of sixteen of children who have ceased to attend a public elementary school, and, where this compulsion is not applied, to make fourteen the normal age for leaving school. At present a child under fourteen years of age can obtain exemption from school attendance in different ways, according to the district. These methods depend upon previous attendance at school, or proficiency, or a combination of the two. The Bill proposes that compulsory attendance at school up to the age of thirteen shall be universal, and not dependent upon local by-laws. Beyond thirteen years, under the Bill, every child must either continue to attend school up to the age of fourteen, or—where the principle of compulsion to attend continuation classes to the age of sixteen has been adopted in the locality—obtain special exemption from school attendance on the ground that he is entering beneficial employment, when he will, of course, attend the continuation school until the age of sixteen. An exception is made in the case of children beneficially employed in agriculture, for these may be specially exempted from school attendance at thirteen, even when there is no provision for compulsory attendance at continuation classes. If the Bill is passed, the half-time system disappears by which children employed during part of the day or week are compelled also to attend an ordinary elementary school for other parts of the day or week.

THE recently published report of the Apprenticeship and Skilled Employment Association, which deals with the work accomplished during 1910, is interesting reading. The object of the association is the promotion of the industrial training for boys and girls by apprenticeship and other methods, including arrangements for attendance at trade schools and at technical classes. The central office of the association is intended to bring all local agencies dealing with the skilled employment of boys and girls into cooperation with each other. It supplements, when necessary, the industrial information obtained by local committees; it encourages the formation of new committees; it arouses public interest in the objects of the association by organising conferences, and issues such literature as may be useful. The report shows that the association has been successful in maintaining cordial relations with the Board of Trade, the General Post Office, the London County Council, and other bodies concerned directly or indirectly with the objects of the association. It may be mentioned that the experiment referred to on previous occasions in these columns, of trying to find suitable employment for boys and girls who have hitherto been employed as laboratory monitors in secondary and higher grade schools, continues to receive the attention of the association. During the year under review, out of twenty-nine boys applying, fifteen have been placed by the association in appropriate situations. So far, the efforts to place the girl laboratory monitors have met with no success, although various firms—chiefly dyers and cleaners—have been applied to. The question of employing girls as laboratory attendants is, says the report, a doubtful one, and it would be well if the advisability of employing girls in this capacity were reconsidered. The offices of the association are at 36 and 37 Denison House, Vauxhall Bridge Road, S.W.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society May 25.—Sir Archibald Geikie, K.C.B., president, in the chair.—The Hon. C. A. **Parsons** and S. S. **Cook**: Experiments on the compression of liquids at high pressures. During the experiments on the behaviour of carbon under high pressures and temperatures, described in a paper by Mrs. C. A. Parsons, June 27, 1907, to the Royal Society, very considerable volumetric compressions were observed in the case of oils and other liquids. The present paper records some investigations into those compressibilities. The apparatus consists of a hydraulic press capable of exerting a maximum force of 2000 tons. Under the press is placed a massive block of gun steel, with a 4-inch hole and plunger of tool steel packed with a cup leather reinforced by a brass cup, which has been found to be satisfactory up to pressures of 40 tons per square inch, and quite tight for fluids. The estimation of the total friction by the method of the loop diagram, and the correction for the elasticity of the mould packings and ram by the method of replacing a known volume of the fluid by steel, are fully described, and the pressure in the mould is given by the water-gauge pressure on the rams of the press, plus the weight of the moving parts multiplied by the constants. The fall of temperature on sudden removal of pressure, and the curves for isothermal and adiabatic compression, are given for some fluids. From these data the internal work of the fluid is calculated for water, ether, and paraffin oil. In the preliminary experiments the pressure was carried up to 40 tons per square inch, but because no advantage was apparent and some inconvenience was involved, the pressure was limited to 4550 atmospheres, under which water is compressed to 87 per cent. of original bulk. The results as to compressibility are in close agreement with those of Amagat, so far as the latter were carried, *i.e.* 3000 atmospheres.—Prof. W. H. **Bragg** and H. L. **Porter**: Energy transformations of X-rays. There seems to be good reason to suppose that the energy of the secondary kathode ray comes from the energy of the primary X-ray. This leads to the "corpuscular" theory of the X-ray (and similarly of the γ ray). Each such ray must move without gradual change of form or energy until at last an atom through which it is passing causes the conversion of form, that is to say, the transformation to kathode-ray energy. On this view (1) the absorption of X-rays means simply the transformation of energy, and (2) the X-ray itself does not ionise at all. The pre-

sent paper describes experiments intended to test these deductions. The results show that in the cases considered the second deduction is verified, and the first also, when the test can be pushed to completeness. In some cases insufficient knowledge of the law of absorption of the kathode rays, and of other important processes, prevent the full application of the test, but it is satisfactory so far as it goes.—Prof. A. **Fowler** and the Hon. R. J. **Strutt**: Spectroscopic investigations in connection with the active modification of nitrogen. I.—Spectrum of the afterglow. (1) The paper gives a detailed account of the spectrum of the afterglow of pure nitrogen, with wave-length determinations of sufficient accuracy to indicate the series relationships of the various bands. (2) The characteristic bands of the afterglow in the red, yellow, and green are complex groups which have been found to be identical with some of the bands forming the sequence known as the first positive group of nitrogen. They represent a special development of three of the numerous series into which the first positive bands have been divided. (3) The second group of afterglow bands, extending from 4312 to 2503, corresponds with a group of faint bands which occur in the uncondensed discharge in air or nitrogen, and the third group is identical with the third positive group of nitrogen bands, as previously shown by Lewis. (4) The most characteristic feature of the condensed discharge which produces the afterglow is a series of seven complex bands, occupying the region 2904 to 2256, which have not previously been recorded as belonging to nitrogen. It is suggested that these should be designated the "fourth positive" group of nitrogen bands. (5) No afterglow is excited when the discharge is such as to give only the line spectrum of nitrogen.—C. **Cuthbertson** and Mrs. M. **Cuthbertson**: An optical method of measuring vapour pressures: vapour pressure and apparent superheating of solid bromine. The vapour pressures of solid bromine between $-80°$ C. and the melting point have been measured by counting the number of interference bands which pass across the field of a Jamin refractometer as the temperature of the solid is gradually raised. The vapour-pressure curve obtained agrees well with that observed by Ramsay and Young down to $-17°$ C. The behaviour of the vapour pressure near the melting point is remarkable, and suggests the inference that superheating of the solid occurs.—Dr. Frank **Horton**: The vacuum-tube spectra of mercury. Under certain conditions, mercury vapour may be made to give several different line spectra in which the number of lines appearing ranges from 5 in the simplest case (the yellows 5791, 5770, the green 5461, the blue 4916, and the violet 4359) to a very large number in the case of the "many-lined spectrum" first observed by Eder and Valenta. The observations were made directly by means of a direct wave-length reading spectroscope, and several new bright lines are recorded in the red and orange regions of the spectrum. The luminosity was excited in three different ways:—(1) by means of the discharge from a glowing lime kathode; (2) by an induction-coil discharge through the vapour at different pressures, and with different amounts of capacity in the circuit; (3) by means of the electrodeless ring discharge. Five distinct spectra were recognised, all of which may be obtained with the induction-coil discharge by suitably regulating the conditions. The glowing lime discharge gives one of the simplest spectra; the electrodeless ring discharge gives the spectrum containing most lines.—R. **Whiddington**: The production of characteristic Röntgen radiations. A characteristic radiation can usually only be excited when the velocity of the kathode rays within the X-ray tube supplying the primary rays exceeds a certain value, depending on the radiator. The value of this critical speed, v_c, has been accurately determined for the radiators Cr, Fe, Ni, Cu, Zn, Se; that for Al has been given in a previous paper. It appears that, for the radiators studied, v_c is proportional to the atomic weight of the emitting element, being very nearly 10^8 times the atomic weight. The potentials corresponding to these velocities range between 7320 volts and 15,400 volts. An interesting result obtained during the course of the investigation is that the energy emitted in the form of Röntgen radiation by a kathode particle when suddenly stopped is proportional to the fourth power of its velocity.

Linnean Society, May 4.—Dr. D. H. Scott, F.R.S., president, in the chair, afterwards Prof. Poulton, F.R.S., vice-president.—Rev. T. R. R. **Stebbing**: John Vaughan Thompson and his polyzoa, and on Vaunthompsonia, a genus of sympoda. In comparing the claims of polyzoa and bryozoa to be the name of a class, the paper submits the following propositions:—(1) A majority of writers use bryozoa. (2) As used by Thompson, *polyzoa* is a word in the singular number; as used by Busk and his followers, it is in the plural; therefore, as Busk candidly points out, the words are not synonymous. (3) For a class-name the plural is essential, and thereby Ehrenberg's bryozoa obtains priority. (4) *Polyzoa* in the singular was first used by Lesson, who gave the name to a genus of compound ascidians. (5) Thompson himself placed the genera and species in which he had observed "*Polyzoae*" in the class *Mollusca acephala.* (6) It was not Thompson, but Grant (in his observations on Flustræ) who first drew the distinction between these polyps and the hydroid polyps with which they had been confused. This again is pointed out by Busk. (7) As Waters long ago, and again recently, has insisted, Thompson meant by Polyzoa, not a class, but a polypide, a structural element in certain organisms. Possession of vertebræ distinguishes a codfish from a crab-fish and a shellfish, but no one would think of proposing Vertebra as a plural word for the name of a class or phylum. A supplementary notice vindicates Vaunthompsonia as the correct form for Bate's sympodan genus in opposition to Vauntompsonia of later introduction, and gives reasons for discarding the term cumacea in favour of sympoda.—Dr. F. E. **Fritsch**: Fresh-water algæ collected in the South Orkneys by Mr. R. N. Rudmose Brown. Comparison was made between the algal floras of the South Orkneys and South Georgia, and special attention was directed to the constituents of the "Yellow Snow."—Prof. Sydney J. **Hickson**: Polytrema and some allied genera. The discovery of some very large specimens of foraminifera belonging to the species described by Carter as *Polytrema cylindricum* in the material collected by Prof. Stanley Gardiner in the Indian Ocean led the author to make a careful examination of this and of other species attributed to the genus Polytrema. The result of this examination was to prove that the specimens usually labelled Polytrema in collections may belong to three quite distinct genera. *Polytrema cylindricum* of Carter is the type of a genus for which the generic name Sporadotrema is proposed. The specimen described by Carpenter under the name *Polytrema rubra* (Lamk.), and many other specimens that are labelled *Polytrema miniaceum* (Pallas) in collections belong to another genus, for which the generic name Homotrema is proposed. The specimens described by Merkel, Lister, and others under the name *Polytrema miniaceum* belong to a genus distinct from the other two, and for this it is proposed that the generic name Polytrema be retained. A description of the principal characters separating the three genera is given in the paper.—J. M. **Brown**: Observations on some new and little known British rhizopods.—R. **Shelford**: The British Museum collection of Blattidæ enclosed in amber.

British Psychological Society, May 6.—Prof. Carveth **Read**: The psychology of genius. The chief condition of genius is sensitiveness to analogy supported by extraordinary power of registering experiences, perhaps without consciously attending to them, in such a way that, although they cannot normally be reproduced, they influence by analogy future constructive or analytic processes.—Miss E. M. **Smith**: Some observations concerning colour vision in dogs.—W. H. **Winch**: Some new exercises in reasoning suitable for the mental diagnosis of school children.

Zoological Society, May 9.—Mr. E. G. B. Meade-Waldo, vice-president, in the chair.—Lieut.-Colonel Neville **Manders**: The phenomena of mimicry amongst butterflies in Bourbon, Mauritius, and Ceylon. The author had investigated the habits by observation and experiment of the insectivorous reptiles and birds of these islands, and had been unable to accept the view that their relations to butterflies were such as to be effective in producing Batesian or Müllerian mimicry.—R. I. **Pocock**, F.R.S.: The palatability of some British insects, with notes on

the significance of mimetic resemblances. At Prof. Poulton's request the author undertook in the summers of 1909 and 1910 to make a series of experiments in the gardens of the society to test the edibility of various British insects, most of which were sent to him, together with some slugs, by Dr. G. B. Longstaff. The insects comprised Lepidoptera, Coleoptera, Orthoptera, Hemiptera, Diptera, and Hymenoptera, and the most interesting of the experiments were those made with the bumble-bee (Bombus) and its mimetic fly (*Volucella bombylans*) to test the theory of mimicry. The Bombus proved to be unpalatable to nearly all birds. The birds would try them a varying number of times. When they had learnt their distastefulness by experience, they refused to touch them, and then when offered the Volucella refused that likewise. A considerable number of species of insectivorous birds were tested in this way, and always with the same result; and the one specimen of *Volucella bombylans* that did duty for some thirty or forty experiments went through the ordeal untouched.—Prof. G. C. **Bourne**, F.R.S.: The second portion of his paper on the morphology of the group Neritoidea of the aspidobranch gastropods, which dealt with the Helicinidæ. The author stated that this family was capable, by some unknown means, of wide dispersal across seas and oceans, and that the conditions most suitable to its existence were found in proximity to the sea. In describing the anatomy, the genus Alcadia was taken as the type, and the differences between it and the other genera were pointed out, but the species, and even the genera, of Helicinidæ were closely similar, anatomically, from whatever part of the world they came.—J. J. **Lister**, F.R.S.: The distribution in the Pacific of the avian family Megapodidæ.

Mathematical Society, May 11.—Dr. H. F. Baker, F.R.S., president, in the chair.—G. T. **Bennett**: The kinematical and geometrical theory of a deformable octahedron.—J. W. **Nicholson**: The scattering of light by a large conducting sphere (second paper).

Physical Society, May 12.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Sir G. **Greenhill** and Colonel R. L. **Hippisley**: Diagrams of stream lines past an elliptic cylinder.—J. T. **Morris** and T. H. **Langford**: The method of constant rate of change of flux as a standard for determining magnetisation curves of iron. The research described was instituted with the object of finding what differences there were between the magnetisation curves for a given sample of iron when determined (1) by the older methods in which the flux is changed suddenly, (2) by a method in which it is changed exceedingly slowly and at a uniform rate. The methods experimentally examined were:—(1) method of constant rate of change of flux; (2) "slow cyclic" hysteresis loops by method (1); (3) "step by step" magnetisation curve; (4) "step by step" hysteresis loops; (5) method of reversals"; (6) alternating-current magnetisation curve. Details are given of the theory and practical working of method (1). In this method the magnetising current is continuously increased through a primary winding by a specially designed resistance at such a varying rate as to maintain a constant voltage generated in a secondary winding. A certain amount of skill is required in operating the resistance, but an average experimenter may easily acquire this with a little practice. The complete change of the current occupied times varying from one up to some five minutes. Tables are given of the magnetisation curve determined by the six different methods at a number of values from **H** 0·3 up to 70·0, and of the permeability from **B** 500 up to 17,000. At low values of the magnetising force the uniformly varying flux method gives results of some 200 lines per square centimetre in excess of the older methods. As regards the time required for determinations by the various methods experimentally examined, ballistic methods are undoubtedly the most tedious. The alternating-current method (method 6) has considerable advantages in this respect, a full set of readings of magnetising current and induced voltage occupying a very short time. When, however, it is necessary to take oscillograms at various points in order to plot curves of form factors, the time required is enormously increased. The method of uniformly varying flux (method 1) is peculiarly adapted for use where time is a consideration, and at the same time a high degree of accuracy is desired. A complete magnetisation curve may be taken in a very few minutes, and the mean of many such curves obtained in, say, one hour, the iron being demagnetised between each test. The method of "uniformly varying flux" appears to possess advantages, both scientific and practical, over the older methods in use for the testing of ring samples of magnetic materials. It avoids difficulties due to eddy currents and magnetic viscosity, which effects are themselves due primarily to rapid or irregular changes of flux. Besides rapidity of experiment, it also has the advantage of accuracy of repetition under standard or predetermined conditions of magnetic change. The method is, therefore, commended for the carrying out of magnetic tests, especially where great accuracy under definitely known conditions of experiment are essential.

Royal Anthropological Institute, May 23.—Dr. A. C. Haddon in the chair.—S. H. **Warren**: The classification of the prehistoric remains of east Essex. The district of eastern Essex is formed of a plateau deeply trenched by river valleys. On the plateau, and also at lower levels, are numerous Palæolithic deposits. The paper deals in detail with the later prehistoric remains only. The river valleys were cut at a time when the land stood higher, relatively to the sea, than it stands to-day. As submergence set in, the lower reaches of the valleys were invaded by the sea, and they became partially silted up with tidal clay. Upon the former dry land surface, now buried beneath the tidal clay, large numbers of prehistoric remains have been found. These include polished axe-heads, knives, arrow-points, and other flint implements. Among the pottery, some remains of the "drinking-cup," or "beaker," have been found, and it is to this archæological stage that this buried prehistoric surface is referred. Beneath this surface, deposits of rain-wash are found which yield an earlier series of prehistoric remains. These are post-Palæolithic, as they include polished stone axes, barbed arrow-points, and pottery. The question of the position which these remains should occupy in the prehistoric succession was discussed. The advantage of using a sequence date scale, rather than a succession of epochs with indefinite and overlapping boundaries, was insisted upon.—Dr. A. **Keith**: A prehistoric skeleton. The skeleton, described in an appendix to the foregoing paper, belonged to the horizon of the buried surface. It was remarkably perfect, and was that of a woman of about twenty-five to thirty years of age. Although of small cranial capacity, it was of fairly high type. The skull inclined to the round-headed form, the index being 77·8. The stature, 5 feet 4 inches, or slightly less, the limb bones slender, the hands and feet small. It was buried in the contracted position. The body had been swathed in the tough roots of the sand-grass, while within the cavity of the body a considerable quantity of the seeds of the blackberry and the dog-rose was found. These were undoubtedly the remains of food.

CAMBRIDGE.

Philosophical Society, May 8.—Prof. Seward, F.R.S., vice-president, in the chair.—H. Hamshaw **Thomas**: The spores of some Jurassic ferns. A preliminary note recording the discovery in the estuarine shales of the Yorkshire coast of the spores and sporangia of *Coniopteris hymenophylloides* (Brongn) and *Todites Williamsoni* (Brongn). In the case of the former species, further evidence is afforded for the inclusion of this Jurassic type in the Cyatheaceæ, while the spores of Todites are shown to be almost identical with those of the recent *Todea barbara*.—C. E. **Moss**: A new species of Salicornia from Angola. The specimens on which this communication is based were collected by Welwitsch during his travels in Angola between 1853 and 1861, and are preserved in the British Museum (Natural History). By Mr. Hiern ("Catalogue of African Plants collected by Dr. Friedrich Welwitsch," iv., 1900, pp. 899–900), the plant is referred to *Arthrocnemum macrostachyum* (= *Salicornia glauca*). Welwitsch himself regarded it as a species new to science, wrote out a full description of it in Latin, and provisionally named it (in MSS.) *Arthrocnemum angolense*. There can be no doubt that Welwitsch's surmise was correct, as

the plant differs from all described species of Arthrocnemum and Salicornia in habit, colour, vegetative segments, flowers, and seeds. Moreover, *A. macrostachyum* is not known outside the Mediterranean region. As Arthrocnemum (Moquin-Tandon, Mon. Chen. Enum., 1840) is better regarded as a subgenus of Salicornia than as a separate genus, it is proposed to describe Welwitsch's Angolan plant under the name of *Salicornia angolensis*.—S. **Mangham**: The detection of maltose in the tissues of certain angiosperms. By the method of forming osazones *in situ* introduced by Senft in 1904, it is possible to distinguish between maltose and other plant sugars. The formation of maltose phenylosazone in definite crystalline masses closely associated with the phlœm of the vascular bundles in the midribs and petioles of several starch-forming plants, together with the occurrence in the sieve-tubes of a yellow semi-crystalline liquid like that from which the crystals arise, suggests that maltose is translocated as such in the sieve-tubes. It has been observed that while the distal portions of the sieve-tubes frequently contain only the yellow, syrupy liquid, this to some extent is replaced by definitely crystalline osazones [dextrose?] further down the sieve-tubes, as if in the course of translocation the maltose were hydrolysed.

MANCHESTER.

Literary and Philosophical Society, April 25.—Mr. Francis Jones, president, in the chair.—Dr. Henry **Wilde**: The periodic times of Saturn's rings. In the paper on the origin of Saturn's rings, read by the author last year, a new determination was made of the periodic times of the rings based on the commonly accepted distance of Mimas, 3·36 Saturnian units, from observations made by Herschel, and subsequently adopted by all astronomical writers. Recent observations of American astronomers have reduced the distance of Mimas to 3·16 units, with the consequent increase in the times of rotation of the rings. The difference between the older and later determinations is sufficiently large to induce the author to place on record the results computed from both observations and Kepler's third law. The later result shows for the outermost circumference of the outer ring a periodic time of 14h. 4m., and for the inner edge of the dusky ring a period of 5h. 45m. It is evident that the rings are ejectamenta from the interior of Saturn. The same conclusion may also be drawn with reference to the origin of the two satellites of Mars.—Dr. A. N. **Meldrum**: The development of the atomic theory: (7) the rival claims of William Higgins and John Dalton to the chemical theory. The resemblance between William Higgins's chemical theory, published in 1789, and John Dalton's, formed in 1803, is so close that there is no denying that Dalton was forestalled by Higgins. The closeness of the resemblance is accounted for by the fact that in their speculations Higgins and Dalton each took Newton's atomic theory as a starting point. Dalton's unquestionable merits in connection with the atomic theory are based, first, on his persistent efforts to bring the theory to bear in every direction both in physics and chemistry. He was the first to draw up a table of atomic weights. Again, the utmost credit is due to Dalton for his attempts, again and again renewed, to arouse the attention of scientific men to the value of the theory.

DUBLIN.

Royal Irish Academy, April 24.—Rev. Dr. J. P. Mahaffy, president, in the chair.—James **Murray**: Clare Island Survey—Arctiscoida. The author adopts this name instead of the better known Tardigrada, which is preoccupied. Thirty-three species were collected in the Clare Island district, of which five are described as new species—*Macrobiotus richtersii*, *M. scabrosus*, *M. hibernicus*, *Echiniscus militaris*, and *E. columinis*. In the list are several Canadian species hitherto unknown in Europe. *Echiniscoides sigismundi* is the first marine water-bear recorded from the British Isles.

PARIS.

Academy of Sciences, May 22.—M. Armand Gautier in the chair.—Pierre **Termier** and Jean **Boussac**: The existence, in the Ligurian Apennines to the north-west of Gênes, of a lateral passage of the crystallophyllian series, the so-called *schistes lustrés*.—A. **Perot** and Mlle. **Lindstedt**: The wave-length of the solar line b_2. The wave-length measurements of the magnesium line b_2 were obtained by the interference method previously used by Perot for one of the iron lines. The method has the great advantage of not making use of the terrestrial line, which cannot be produced under the same conditions of temperature, pressure, and density. If the centres of absorption of the line are animated by a centripetal movement in addition to their movement of rotation, the wave-lengths at different points would be of the same order as those actually found.—Léon **Autonne**: Certain commutative groups and pseudo-zeros of hypercomplex quantities.—L. **Creux**: The transformation of the movement of expansion into a movement of rotation by the development of the circle.—L. **Riéty**: The electromotive force produced by the flow of a solution of sulphate of copper through a capillary tube. A solution containing 1 per cent. of crystallised copper sulphate, when forced through a capillary tube under a pressure of 90 atmospheres, develops a difference of potential of about 0·03 volt. The potential is proportional to the difference of pressure between the two ends of the tube. For solutions containing between 0·2 and 2 per cent., the product of the conductivity by the potential difference reduced to one atmosphere is practically constant.—Georges **Claude**: Luminescent neon tubes. The use of an electromagnetic valve, proposed by Moore, for the automatic admission of fresh neon to a tube which has been in use for some time, although ingenious, the author regards as impracticable, and proposes a simpler alternative arrangement. The disappearance of the neon is directly connected with the vaporisation of the metal of the electrodes, and if the dimensions of these are increased, the vaporisation is correspondingly reduced, and the life of the tube increased.—Jean **Perrin**: New measurements of molecular magnitudes. Starting with an emulsion of gutta formed by the precipitation of an alcoholic solution by water, by a prolonged process of fractional centrifugation, particles of magnitudes between 0·5 μ and 2 μ were obtained. A further process of fractionation gave particles of a uniform size, 0·75 micron. The application of Einstein's formula to measurements of Brownian motion made with these particles gave for the electrostatic charge of the electron the value $4{\cdot}2\times10^{-10}$.—M. **Bancelin**: The viscosity of emulsions. In an emulsion formed of a liquid with a coefficient of viscosity k, containing small solid spheres in suspension of total volume ϕ, the coefficient of viscosity of the emulsion k', according to the calculations of Einstein, will be $k'=k(1+\phi)$. The author gives an experimental verification of this formula with uniform emulsions of gutta obtained by the methods of Jean Perrin, described in the preceding paper. In accordance with the Einstein theory, the increase of viscosity is found to be independent of the size of the particles, and depends only on the total volume of the particles per unit volume. Instead of the increase of viscosity, however, being proportional to $(1+\phi)$, it was found to be in the ratio $(1+2{\cdot}9\phi)$. A colloidal solution of methylene blue gave analogous results.—E. **Henriot**: The radiation from rubidium. As in the case of potassium, the greater portion of the radiation is distinct from the α rays. The 10 per cent. of the radiation which is more easily absorbed may be the α rays, but the examination of the salts did not admit of the proof of the existence of these rays by their radiations. As showing the atomicity of the phenomenon, various salts from different sources were examined, and there was found to be a good proportionality between the radiation and the percentage of rubidium.—Paul **Bary**: The mode of solution of colloidal materials.—Jacques **Duclaux**: The constitution of water. According to the conception of Röntgen, now generally admitted, water is a solution of ice in hydrol. Ice would have the formula $n(H_2O)$, and the accepted value for n is 3. Evidence is adduced to show that this is too low a value, 12 being a more probable value, if it be assumed that ice retains its density in solution.—Marcel **Delépine**: The pyridinepentachloro-iridites.—A. **Duffour**: Some new complex derivatives of iridium: iridotetrachloroxalates and tetrachloroiridites.—L. **Barthe**: Phosphates of uranyl and amines. Definite compounds of uranyl phosphate with methylamine,

ethylamine, and trimethylamine have been prepared and analysed.—M. **Hanriot** and A. **Kling**: The action of alkalis on the chloraloses.—James **Lavaux**: The action of methylene chloride upon *pp*-ditolylmethane.—P. **Lemoult**: Researches on derivatives of styrolene: rectification of some experimental errors. Some new determinations of the heats of combustion of some unsaturated hydrocarbons.—A. **de Schulten**: The determination of the crystallographic constants of some artificial apatites.—E. **Decrock**: Silica in the seminal tegument of Ravenala.—R. **Robinson**: Studies on the question of the determination of sex. Deficient secretion of the suprarenal glands appears to lead to an excess of female births. The use of adrenaline is suggested in cases where there are troubles in nutrition, excessive vomiting, &c.—Jules **Regnault**: Suprarenal optherapy in the vomiting of pregnancy. *Rôle* of the internal secretions in the determination of sex.—Henri **Piéron**: The determination of the period of establishment in mnemonic acquisitons.—F. **d'Herelle**: An epidemic of a bacterial nature ravaging the grasshoppers of Mexico.—L. **Mercier** and Ph. **Lasseur**: The experimental variation of the chromogenic power of a bacterium, *Bacillus chlororaphis*.—Ch. **Gravier**: Some incubating annelids arising from the second French Antarctic expedition.—P. **Achalme** and M. **Bresson**: The function of viscosity in the variations of the action of invertine according to the concentrations in saccharose. By taking into account the effect of viscosity of sugar solutions on diastatic action, the influence of concentration can be reduced to a simple and general law.—E. **Kayser**: The disease of cider known as *la graisse*.—Pierre **Thomas**: Some substances which accompany oxyhæmoglobin in its crystallisation.—G. **Vasseur**: The *facies* of the marine Stampian formation in the Aquitaine basin.—V. **Roussanof**: The goniatite fauna of the Lower Carboniferous and Upper Devonian found in Nova Zembla.

DIARY OF SOCIETIES.

THURSDAY, JUNE 1.

ROYAL SOCIETY, at 4.30.—Experiments on the Restoration of Paralysed Muscles by means of Nerve Anastomosis: Dr. R. Kennedy.—The Morphology of *Trypanosoma evansi* (Steel): Col. Sir D. Bruce, C.B., F.R.S.—The Pathogenic Agent in a Case of Human Trypanosomiasis in Nyasaland: H. S. Stannus and Dr. W. Yorke.—The Experimental Transmission of Goitre from Man to Animals: Capt. R. McCarrison.—The Action of Radium Radiations upon some of the Main Constituents of Normal Blood: Dr. Helen Chambers and Dr. S. Russ.—The Mechanism of Carbon Assimilation. Part III.: F. L. Usher and J. H. Priestley.—A Contribution to our Knowledge of the Protozoa of the Soil: T. Goodey.

ROYAL INSTITUTION, at 3.—Changes Effected by Light: T. Thorne Baker.

RÖNTGEN SOCIETY, at 8.15.—On a Possible Therapeutic Use of Strongly Ionised Air: C. E. S. Phillips.—The Photographic Investigation of the Forms assumed by the Brush Discharge in Air at Reduced Pressure: C. W. Raffety.

LINNEAN SOCIETY, at 8.—On the Occurrence of Amphidinium in Quantity at Port Erin: Prof. W. A. Herdman, F.R.S.—The Fauna of the Coal Measures: Dr. A. Smith Woodward, F.R.S.

INSTITUTION OF MINING ENGINEERS, at 11 a.m.—A Flame Test for the Estimation of Oxygen and Black-damp in Naked-light Mines: Dr. J. S. Haldane, F.R.S.—An Experiment on the Effect of Reversing the Main Air-current: James Bain and Dr. J. S. Haldane, F.R.S.—Notes on Contrivances Designed to Prevent Overwinding, with some Instances of their Failure: W. H. Pickering and Granville Poole.—The Otto-Hilgenstock Direct-recovery Process and its Application: Ernest Bury.

FRIDAY, JUNE 2.

ROYAL INSTITUTION, at 9.—Radiotelegraphy: G. Marconi.

SATURDAY, JUNE 3.

ROYAL INSTITUTION, at 3.—Types of Greek Women: Dr. W. L. Courtney.

TUESDAY, JUNE 6.

ROYAL INSTITUTION, at 3.—Charnwood Forest and its Fossil Landscape: Prof. W. W. Watts, F.R.S.

WEDNESDAY, JUNE 7.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, JUNE 8.

ROYAL INSTITUTION, at 3.—Practical Progress in Wireless Telegraphy: T. Thorne Baker.

MATHEMATICAL SOCIETY, at 5.30.—On the Multiplication of Dirichlet's Series: G. H. Hardy.—On the Range of Borel's Method for the Summation of Series: G. H. Hardy and J. E. Littlewood.—On the Convergence of Fourier Series and of the Allied Series: Dr. W. H. Young.—On some Two-dimensional Problems in Electrostatics and Hydrodynamics: W. M. Page.

FRIDAY, JUNE 9.

ROYAL INSTITUTION, at 9.—Applications of Physical Chemistry to the Doctrine of Immunity: Prof. S. Arrhenius.

ROYAL ASTRONOMICAL SOCIETY, at 5.

PHYSICAL SOCIETY, at 8.—The Lüders Lines on Mild Steel: W. Mason.—Exhibition of a Model illustrating the Passage of a Light Wave through Quartz: Dr. H. S. Allen.—Tables of Circular and Hyperbolic Functions for Complex Values of the Argument: A. Johnstone.—On the Measurement of Contact Differences of Potential: Prof. Anderson and J. G. Bowen.—Exhibition of Gyroscopic Apparatus: Sir G. Greenhill.—A New Method of Approximate Harmonic Analysis by Selected Ordinates: Prof. S. P. Thompson, F.R.S.

MALACOLOGICAL SOCIETY, at 8.—Description of a New Species of Acmæa from Bombay and Notes on other Forms from that locality: E. A. Smith.—Description of Three New Species of Operculate Land Shells from Grand Cayman Island: H. B. Preston.—Further note on Preoccupied Molluscan Generic Names and Proposed New Names: G. K. Gude.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology of the District of the Bergen Arches: Dr. C. F. Kolderup.—The Rock Formation of the Bergen District: Horace W. Monckton.

SATURDAY, JUNE 10.

ROYAL INSTITUTION, at 3.—Types of Greek Women: Dr. W. L. Courtney.

ARISTOTELIAN SOCIETY (at Corpus Christi College, Oxford), at 9.—Real Being and the Object of Thought: G. F. Stout.

CONTENTS.

THURSDAY, JUNE 8, 1911.

THE "PERSONAL FACTOR" IN THE WAR AGAINST CONSUMPTION.

(1) *Pulmonary Tuberculosis and Sanatorium Treatment.* By Dr. C. Muthu. Pp. vi+201. (London: Baillière, Tindall and Cox, 1910.) Price 3*s*. 6*d*. net.

(2) *Conquering Consumption.* By Dr. Woods Hutchinson. Pp. 138. (London: Constable and Co., Ltd. Boston and New York: Houghton Mifflin Company, 1910.) Price 4*s*. 6*d*. net.

(1) SOME twenty years ago the sanatorium treatment of consumptive patients was but in its infancy, and, with the exception of Dr. Walther's disciples who had studied at Nordrach, there were few who understood the real inwardness of this method of treatment. The result was, necessarily perhaps, a somewhat hide-bound method, and although a certain proportion of patients did well, others, even those in the earlier stages of the disease, seemed to be unaffected, favourably, at any rate, by prolonged treatment. Indiscriminate over-feeding, irrational exercise, inattention to details, and imperfect understanding of the general principles upon which the sanatorium treatment is based were accountable for many of the failures.

During the last ten years a number of physicians, especially young men, have devoted themselves very thoroughly to the study of sanatorium and after sanatorium treatment, and we are now reaping, as the results of the observations and experience of these observers, an extensive literature, some of which has been embodied in what may be called the consumptives' liturgy. Amongst those who have written such text-books is Dr. C. Muthu, late physician to the Inglewood Sanatorium, Isle of Wight, and at present physician to the Mendip Hills Sanatorium, Wells, Somerset. Dr. Muthu, who is not only a physician but a philosopher, gives a record of ten years' observations and work in open-air sanatoria.

As regards the pathology and etiology of tuberculosis, he has here written many things with which certain, probably the majority of, pathologists and physicians will disagree. This, no doubt, arises from the fact that Dr. Muthu looks at the question from the point of view of his patient, and we may accept it that from the point of view of treatment what is lost thereby is perhaps more than gained in another direction. One gathers from a perusal of this work that Dr. Muthu looks upon the successful treatment of pulmonary tuberculosis as being possible only when an intimate partnership and cooperative movement between physician and patient can be agreed upon and carried out. If the will of the patient be strong the firmness of the doctor is not so important a factor, but in the case of the inexperienced and vacillating patient the personality of the physician and his power of dominating his patient come to be of prime importance. The patient must be lifted out of his diseased condition, not only as regards body, but as regards mind. He must not dwell upon its course but upon its cure.

The keynote as to Dr. Muthu's ideas on the pathology of the disease is given in a statement put in opposition to von Ziemssen's dictum, "no tubercle bacilli, no tuberculosis," Dr. Muthu contending that it will be nearer the truth to say, "no soil, no tuberculosis," which one supposes should really read, "no suitable soil, no tuberculosis." Dr. Muthu's own statement is perhaps considerably stronger than he really wishes those who read his book to accept, for it is only fair to him to state that he still appears to have some belief in von Ziemssen's dictum. It is, however, the function and the appropriate function, of the sanatorium physician to preach the doctrine that the soil much more than the seed controls the disease, for, after all, it is the cure of the patient that he has to effect. One cannot help feeling, however, that it is a dangerous doctrine to preach that pulmonary tuberculosis is not a contagious disease. That the infective material takes long to manifest its presence all will accept, that it is not so infective as the ordinary zymotic diseases may also be taken for granted; but that it is infective, and, under certain conditions, highly infective, should never be ignored. However, those who read the chapters on the predisposing factors, on early diagnosis, and on the prognosis of tuberculosis will be interested whether they agree with the author or not.

When we come to the principles of open-air treatment we are in hearty accordance with almost every word Dr. Muthu writes. His experience is wide, he has entered into his work with enthusiasm, and apparently has recorded his results accurately. The special chapters on treatment are of interest rather to the medical profession than to the general public, and their value can only be fully appreciated by the medical man, as their complete understanding involves a knowledge not usually acquired by a layman. Dr. Muthu deals with the social aspect of tuberculosis in the third part of his work, and we can thoroughly recommend this portion to the consideration of all who take an interest in the welfare of their fellows. Dr. Muthu evidently feels deeply, and he certainly expresses himself strongly and clearly. Some may not agree with him on all that he writes, but here again, whether they agree with him or not, they will be interested and often enlightened. The book is well printed and the illustrations are excellent.

(2) In Dr. Woods Hutchinson's work we have an original and hopeful statement of what the Americans call "a difficult proposition." Dr. Hutchinson starts out on the assumption that man is "the toughest, the most resourceful, the most ferocious and dangerous animal that walks upon the face of the globe," and he thinks that we have not yet added bacteria to our conquests simply because we did not know of their existence until about half a century ago. Now he considers that this conquest is only a question of time, especially as the harmful bacteria form such a relatively small proportion of the known microbial organisms. Dr. Woods Hutchinson is a great believer in the tubercle bacillus as the cause of tuberculosis, and he considers that as a cause of

the disease it may be taken into the human system in various ways—in the food we take, the air we breathe, in the dust of the room, of the street, by flies, dirty fingers, filthy garments, and in a dozen other ways in which excreta and dirt may be spread. He considers that eight-tenths of all civilised people have had tuberculosis and have recovered from it without knowing anything at all about it.

In spite of all this, after describing in very popular language tuberculosis of various types, he states his belief that if we could put a stop to the dissemination of the tubercle bacillus we could put an end not only to pulmonary consumption, but could diminish our cripples by two-thirds, cases of scrofula by three-fourths, the fatal convulsions of childhood by a half, and eliminate a very large proportion of the fatal bowel diseases that occur in childhood. His optimism again comes forward when he considers Osler's statement that "we to-day run rather less than half the risk of dying of consumption that our grandfathers did and barely three-fourths of the risk that our parents did."

Dr. Hutchinson now and again drifts into what may be called Dooleyisms, which have a distinctly original flavour about them, and certainly tend to amuse, and, at the same time, to give us "furiously to think." As in the following:—

"If the rich had more sense and the poor more money, and both more public spirit, consumption would soon be a thing of the past. And it would be only one of many evils which would disappear in the process."

Again, when speaking of fresh air, he says:—

"Like other necessities of existence, it goes with the land, somebody else is going to get too little air, not to mention food and other incidentals. This isn't socialism—it's sanitary science. . . . It costs money to have plenty of fresh air to eat, even though the air is free . . . the one thing which no intelligent, civilised community can afford under any circumstances, is to allow any section, or class of it, to grow up without sufficient food to eat, air to breathe, and fuel to burn. . . . Wipe out the conditions which create consumption, and you will at the same stroke abolish half our crime and two-thirds of our pauperism!"

Dr. Hutchinson, after giving his message of hope describing the bacillus as the enemy, the weapons of the war to be waged against him, gives chapters on "Fresh air and how to get it," "Sunlight: the real golden touch," "Food, the greatest foe of consumption," "Work and rest: intelligent idleness," "The camp and the country," "Cash and consumption," "Climate and health," and "Specifications for the open-air treatment at home."

Speaking of the open-air treatment of consumption and camp-life, he says:—

"The cure of consumption is not a drug, or an operation, or a magic method of any sort. It is a *life* that must be lived twenty-three hours and sixty minutes out of the twenty-four, and seventy years out of your threescore and ten. You cannot learn it properly by being told about it, or lectured about it, or advised about it ever so wisely—you must live it."

Referring to the economic aspect of the question, under the heading "Cash and Consumption," the author believes that the community should provide the means for the worker to recover from his tuberculosis, and he contends that it can very well afford to do so, as thereby it escapes supporting his widow and educating his orphan children. It is on this basis that he speaks of poverty as the most expensive thing in the world for any community when quoting the tables of Korosi, which show that of each 10,000 well-to-do persons only forty die annually of consumption; of the same number of moderately well-to-do, 62·7; of poor, 77; and of paupers, 97. He maintains that there is a sound biological basis for our desire to be rich, for he points out that by becoming so "we reduce our chances of dying from tuberculosis fifty per cent."

There is good, sound, common-sense in the chapter on climate and health, which contains the following statement:—

"If anyone goes South to avoid the trouble of ventilating his bedroom properly, or taking sufficiently vigorous exercise in the open air to get up a glow and defy the frost, he is doing himself harm rather than good."

Wherever you go, the author says, go to a place where you can be comfortable, where you can get plenty of good and cheap food, where you can live in the open air without discomfort, where you will not be overworked, and where you can carry out to the full all the lessons learnt in the sanatorium. We have enjoyed reading Dr. Woods Hutchinson's book, and we can recommend it to all who like common-sense and can appreciate the writing of a man who knows his own mind concerning the subject with which he is dealing.

PROGRESS IN GIRLS' EDUCATION.

Public Schools for Girls: a Series of Papers on their History, Aims, and Schemes of Study, by Members of the Association of Headmistresses. Edited by Sara A. Burstall and M. A. Douglas. Pp. xv+302. (London: Longmans, Green, and Co., 1911.) Price 4*s*. 6*d*.

THIS is a book calculated to rejoice the heart of an educational worker, not so much for the wisdom it contains as for the evidence it affords of the spirit animating the educational policy of our leading English schools for girls. Here we have twenty-four essays relating to the subjects of girls' education, written by experienced headmistresses, who one and all seem to have a real zeal for their work, and a humble-minded desire to find the best way of doing it. There is a sense of sincerity, earnestness, and warmth in the essays that is highly pleasing, and a willingness to look at new proposals and plans that contrasts most favourably with the self-confidence, and subacid raillery sometimes affected by the high-placed pedagogue.

The essays are the outcome of a suggestion made by Mrs. Woodhouse, when president of the Association of Head Mistresses for 1907–9, and they are edited by her successor, Miss Burstall, and Miss Douglas, chairman of the curricula subcommittee.

They comprise a chapter dealing with the history of the development of public secondary schools for girls, a series of papers describing the present manner of dealing with the various school subjects, a paper on examinations, and papers on the general aims and ideals in education and suggestions as to possible reforms. The subject of discipline is deliberately omitted.

It will be understood from the foregoing that the amount of material presented affords abundant opportunities for comment and criticism, but the present notice must be restricted to one or two topics.

In the first place, it is noteworthy that in this presentation of views we find distinct evidence of an increasing differentiation between the education of girls and the education of boys. This, in a sense, is nothing new. Long ago there was a differentiation, inasmuch as whilst boys were being substantially taught, girls were being scarcely taught at all. But the first onset of the girls' high-school movement tended to an equalisation, both in quality and quantity, and doubtless there are still a good many people who do not admit that there is good reason for much difference.

The question involved is really one of great importance, both as regards girls and boys. Is a secondary school to be regarded chiefly as preparatory to a university or as a place where formal education is for most people ended? If the destiny of the pupils is assumed to be the university, where, up to now, the professional studies of men and women have been undifferentiated, there does not seem to be much reason for difference between girls' schools and boys' schools, and in both cases the teaching will be on purely academic lines. But surely if we think of the vast majority of pupils, we must realise that this assumption is wholly unwarranted, and we are thrown back on the inquiry—should not our main object in girls' schools be to frame a curriculum which at the end will equip girls, in the fullest degree possible within a school, for the unprofessional life that follows?

If this question is answered in the affirmative, it can scarcely be denied that there is room for distinctive features in the curricula of girls' schools. Whatever happens in connection with what is called the feminist movement, it can scarcely be doubted that for a long time to come the vast majority of women will be concerned with the administration of the home, and it would seem natural that this should be in the minds of those who have to consider the curricula. That this is now much more the case than it was twenty years ago is one of the most gratifying inferences to be drawn from the volume before us, and it is to be hoped that, notwithstanding the deep-seated belief which we profess in what are called disciplinary and humanising studies, our headmistresses may have the courage to specialise studies and equip their girls for women's work so far as it can be properly done in school.

The teaching of science to girls is at present receiving a good deal of attention. The subject is dealt with in the present volume by the able and experienced hand of Mrs. Bryant, and incidentally in home science by Miss Faithfull, and in home arts by Miss Gilliland.

"The prime condition to be fulfilled in a school scheme of natural science study is," according to Mrs. Bryant, "that it shall lend itself with certainty and ease to develop in the immature but plastic mind of average ability this *scientific attitude* of alert *individual inquiry*." For this "the subject-matter should be at each stage as attractive as possible, in the sense of stimulus to inquiry. . . the problems raised by the subject under discussion should not be too difficult for the learner's own powers of intellectual inquiry. . . . So far as possible the natural practical interests of the learners should be enlisted as a powerful additional stimulus to scientific motive."

No one will be likely to find fault with this clear and reasonable doctrine.

I may perhaps be permitted here to fall into the first person and to state that for a long time past I have been endeavouring to assist in making school science for girls comply a little more fully than has been the case with Mrs. Bryant's third requirement, viz., that it shall appeal to the natural practical interest of the learners. In doing this I have been brought into conflict with those who are alarmed for the "purity" of science teaching, and I have been suspected of a desire to introduce a sort of soft and effeminate subject which lacks all the elements of logic and discipline, so dear to the stern educationist. As a matter of fact, my aim has been nothing more or less than to imbue the science teaching in girls' schools with as much illustration from everyday topics, and especially topics of the household, as will give it a living interest and make it a more human, more useful, and more abiding possession. I state it, not as an opinion, but as a fact of experience, that the average science graduate, male or female, coming from an ordinary university course, is extraordinarily ignorant of some of the very simplest applications of science in relation to daily life, and that there is a considerable region of facts, both in physics and chemistry, lying outside the conventional "subject" as understood by degree artists in universities, which it behoves every reasonable school science-teacher to explore. I am not fond of the term domestic science, which rather curiously has been often used as synonymous with the arts of the cook and launderer, but that the principles and discipline of elementary physical science can be inculcated with a large accompaniment of topics and examples relating to the household arts I am perfectly satisfied, and I shall not readily be deterred from advocating this at some sacrifice of Atwood's machine and the oxides of nitrogen.

The question of the teaching of practical household arts in relation to girls' schools is admirably dealt with by Miss Gilliland, but a discussion of this subject and many others must be forgone for lack of space. The essay on examinations by Miss Gadesden deserves a special word of praise. We can, in conclusion, warmly congratulate Miss Burstall and Miss Douglas upon having brought to publication a collection of essays which does great honour to those who are directing the momentous work of educating our future rulers.

A. SMITHELLS.

MODERN GAS MANUFACTURE.

A Text-Book of Gas Manufacture for Students. By J. Hornby. Sixth edition, revised and enlarged. Pp. xi+423. (London: G. Bell and Sons, Ltd., 1911.) Price 7s. 6d. net.

THE fact that a sixth edition of Mr. Hornby's text-book was needed is the most convincing proof of its excellence, more especially as the readers to whom it appeals are necessarily limited in number, and other text-books on the subject exist.

The many alterations and advances which have taken place in gas manufacture during the past ten years have rendered it imperative to remodel the book so as to deal with the various types of vertical retort which are being introduced, and the use of increased charges for horizontals, which are found to give substantial improvement in the quantity and quality of both gas and tar.

The author disclaims any intention of making the book an exhaustive treatise on the subject, but in point of fact he so nearly attains this level that it is a pity he has not gone a little more fully into the theoretical aspect of carbonisation as gleaned from his own experience, rather than to rely on quotations from the work of others, which, although in most part excellent, sometimes give a wrong impression.

For instance, in speaking of the effect of distillation at low temperature, he quotes a paragraph from Dr. Lunge's work on "Coal Tar and Ammonia," to the effect that amongst the liquid, watery products "acetic acid is paramount," which, although true to a certain extent of the products obtained from lignite and peat, gives a wrong impression of the liquor obtained at low temperature from an ordinary gas coal.

After a brief general sketch of the usual procedure in a gas works, the author deals in the first chapter with the formation and general characteristics of the various classes of coal, and in discussing the conversion of vegetable deposits into coal, represents the complete reaction of fermentation and decay on cellulese by the beautifully simple equation,

$$2(C_6H_{10}O_5)=5CO_2+5CH_4+C_2,$$

which certainly does not take into account the feelings of the supporters of any dehydration theories. In discussing the caking coals, it would be worth while in a future edition to mention at any rate the influence of the percentage of oxygen on the gas yield and coking properties of various coals.

In the second chapter the wide subject of carbonisation is attacked, and here the description of the gaseous products of distillation due to primary and secondary actions are not quite in accord with the more modern views on the subject, but the remainder of this and the next chapter are very well done, and the reader is given next a section on labour-saving appliances, amongst which inclined and vertical retort settings are dealt with.

The diagrams of the Dessau, Woodall-Duckham, and Glover-West retorts are excellent, and it is a pity that the author has not dealt more fully with the relative advantages and drawbacks of these systems. There is but little doubt that the continuous systems of carbonisation as represented by the two latter retorts gives the nearest approach to a uniform treatment of coal that is to be found, and that when the general arrangements have been perfected by experience they will show themselves to be far superior to their Continental forerunner, the intermittent Dessau retort.

The author's treatment of the modern practice of filling the retorts with the charge so as to leave no space at the top of the retort, and extending the period of carbonisation is insufficient, and the two reasons which he gives for the improved results obtained are not nearly so important as that the mass of coal provides a cool and easy escape for the hydrocarbon and other gases distilling from the portions in contact with the hot walls, and so prevents the destruction of valuable illuminants.

In this part of the work also some notice ought to be taken of Mr. Glover's Norwich chamber retorts, which for the same reason give excellent results.

It would have been of great advantage to the work if the author had compiled with care a table contrasting the results obtained by the various methods of carbonisation from the horizontal retort with small charges and high heats to the latest types of sloper chamber ovens.

In the appendix on the "Distillation of Tar," the author gives the specific gravity of ordinary tar as ranging from 1·12 to 1·16. Is this a relic of the days when the gas manager was content with 10,000 cubic feet of gas per ton of coal, or is it an up-to-date figure from the vertical retorts and modern processes? Has the author never come across that tar, which a large proportion of our gasworks are making, in which, owing to the degree to which the temperature has been pushed to obtain a large yield of gas, the specific gravity has been raised to 1·2 and above, and the value reduced almost to nil?

Perhaps the most serious fault that can be found with this text-book is that little or no attention is paid to the subject of the thermal value of gas. The day is rapidly approaching when illuminating value will be superseded by calorific value as the test for the quality of gas, when the calorie and thermal unit will be as important to the gas manager as the candle standard is now, and a text-book for the rising generation of gas engineers should certainly deal in full with the subject of how best to transfer the greatest heat value from the coal to the gas.

THE DELINEATION OF THE EARTH'S SURFACE.

Maps and Map-making. By E. A. Reeves. Pp. xiii+145. (London: Royal Geographical Society, 1910.) Price 6s. net.

THE course of instruction in surveying and map-making offered to students and travellers by the Royal Geographical Society is justly esteemed for its useful and practical character. A book on this subject by Mr. Reeves, the map curator of the society, who has for many years carried out the instruction. and under whose direction the system of teaching has

undergone continuous and marked improvement, is certain of a cordial welcome.

We may at once state that the book is no other than it purports to be—a reprint of three lectures, the first on instruments, the second on survey methods, and the third on maps and map-making. It is in no sense a text-book on the science of surveying. It is, for example, not the sort of book that the practical surveyor would take into the field, nor would it be of much value to the student who has passed the elementary stage.

Its true function, we take it, is identical with that of a lecture, not to instruct, but rather to stimulate curiosity, not so much to teach as to show that there are things worth learning. A book of this class has a tendency to fall into a difficult category, being too technical for the ordinary reader and too simple for the expert. At the same time, we may frankly recognise that as regards this particular subject there are a large number of persons—travellers, officers, and officials, whose duties take them into the uncharted regions of the world—to whom a little knowledge of survey methods is a valuable acquisition but who have no desire or capacity to prosecute their studies further.

To these and to all others who desire a general acquaintance with a science which must always remain of great practical importance and of considerable human interest, we can cordially recommend Mr. Reeves's book.

The first chapter, dealing with the history and development of surveying instruments, profusely furnished with illustrations, as indeed is the whole book, will be found full of curious information. The treatment of modern instruments is perhaps too compressed to be thoroughly satisfactory and has a tendency to degenerate into a mere catalogue, wherein the various instruments are briefly described, but no adequate attempt is made to estimate their relative merits or defects. Thus the prismatic sextant is mentioned as an "improvement" on the ordinary form without a hint that, as a matter of fact, it was found to be no improvement, and has passed entirely out of use.

The book is well printed and misprints are not common. We scarcely know whether the spelling *geodecist* (p. 24) is intentional; if so, we must enter a protest against it.

The specimen maps are reproduced with the uniform excellence of style that we are accustomed to in the R.G.S. publications.

In conclusion we may direct attention to the map on p. 131, showing relief by "stereoscopic" colouring, *i.e.* a system wherein the varying altitudes are shown by an ordered sequence of spectrum colours, the high ground red and thence descending through greens and yellows to a blue sea. The effect of relief on such a map is very good. The eye naturally adjusts itself as in viewing near and far objects so that the tops of the hills appear nearest and the bottoms of the valleys farthest from the observer. A neglect of this principle of spectrum colours is a marked defect of the recently published half-inch Ordnance Survey map of England.

E. H. H.

MATHEMATICAL TEXT-BOOKS.

(1) *Elements of Plane and Spherical Trigonometry.* By Prof. D. A. Rothrock. Pp. xi+147+xiv+99. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 6*s.* net.

(2) *Homogeneous Coordinates for Use in Colleges and Schools.* By Dr. W. P. Milne. Pp. xii+164. (London: E. Arnold, 1910.) Price 5*s.* net.

(3) *A Geometry for Schools.* By F. W. Sanderson and G. W. Brewster. Pp. x+336. (Cambridge: University Press, 1910). Price 3*s.*

(4) *Analytic Geometry.* By Prof. N. C. Riggs. Pp. xi+294. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 7*s.* net.

(1) THIS volume contains a fairly through treatment of the numerical aspects of plane and spherical trigonometry. In addition to this, a certain amount of attention is directed to elementary identity work, and some indication is given of the higher analytical developments of the subject, based on Demoivre's theorem, in the concluding chapter of the first part of the book. It is unfortunate that the symbol $e^{i\theta}$ is regarded as equivalent to $\exp(i\theta)$. This is the source of much error in the minds of students, and from the earliest stage it is most desirable to emphasise the distinction between the two forms. With this exception, the mode of presentation is excellent. There are numerous exercises and problems, but at present no answers are given. This is a serious omission, and it should be rectified in a new edition. Five-figure tables of logarithms and trigonometric functions are appended to the book.

(2) The utility of homogeneous coordinates when carefully employed, is undeniable. It so often happens that their properties are sketched in a brief chapter at the end of treatises on Cartesian methods, thus leading the reader to believe that the subject is one of small value and importance. It is, of course, a misuse of this instrument to apply it to metrical results, except in very special circumstances; but its application to properties of a descriptive character is particularly instructive and illuminating. The present volume contains, in a remarkably small compass, a comprehensive account of the subject, treated in exactly the right way. Its wealth of detail will be invaluable to the teacher, who will probably prefer to make selections for his pupils. The correspondence between point and line coordinates is worked out in a thorough fashion, and the part played by ideal and imaginary elements is clearly indicated. Such work as this is well within the range of the scholarship class in secondary schools, and it arouses keen interest, mainly because analysis is very properly subservient to principle. There is an admirable collection of examples. We wish the book all the success it unquestionably deserves.

(3) The plan of this book agrees to a large extent with the recommendations made in the Board of Education circular on the teaching of geometry. The proofs of the fundamental congruence and parallel theorems occupy a subordinate position, thus making it possible for the student to pass rapidly over the

initial stages and advance quickly to simple rider work. There are four main sections in the book; each of these starts with an experimental investigation and ends with the theoretical treatment of the corresponding theorems. There are abundant numerical examples, but some teachers will consider that the supply of riders is inadequate. An excellent innovation is the insertion of circle properties before areas are dealt with. This provides such an excellent field of simple and interesting riders that it is surprising that the Euclidean order has been followed so long. The last section contains as many of the theorems on ratios as are usually given in elementary text-books, the numerical examples, illustrating the use of proportion, are particularly good.

(4) The analytical geometry of the conic is treated in this volume in less detail than is usual in most text-books. For practical purposes, it is far more important for the student to acquire a correct appreciation of the principles which obtain for curves of any degree, and to master the use of infinitesimal methods. The author has therefore employed the calculus freely and applied it both to plane and skew curves and simple surfaces. The examples have been chosen rather to elucidate principles than to test analytical dexterity. The book may be used with confidence by engineering students, with whose needs it is primarily concerned.

SCIENCE AND SPECULATION.

The World of Life: a Manifestation of Creative Power, Directive Mind, and Ultimate Purpose. By Dr. A. R. Wallace, F.R.S. Pp. xvi+408. (London: Chapman and Hall, Ltd., 1910.) Price 12*s*. 6*d*. net.

THE appearance of a new book written by the veteran naturalist in his eighty-eighth year cannot fail to arouse the interest of a wide circle of readers. The work may indeed be regarded as a recapitulation of the opinions on a great variety of topics which, during a long and active literary career, extending over more than fifty years, Dr. Alfred Russel Wallace has put forth in a number of memoirs, books, and magazine articles. But to regard the work as a mere summary of the results of former labours would be to do a great injustice to its author; for there is scarcely a subject referred to in it, in which fresh facts, novel lines of reasoning, or suggestive conclusions are not presented for our consideration.

The book naturally divides itself into two portions, which are of very diverse character and unequal value and importance. As regards the first part, we must state at once that the space at our disposal is altogether insufficient to enumerate—much less to discuss—the numerous interesting problems suggested in it.

After a first chapter, devoted to a somewhat academical discussion of the nature and origin of life, we have five chapters treating on the subject with which Dr. Wallace's name will always be so honourably associated—the distribution of plants and animals. Readers familiar with the author's great work on this subject, and with his "Island Life," will be surprised and delighted to find how many novel facts and lines of treatment have suggested themselves to the author since the publication of his earlier works. Among many interesting discussions in this part of the book we may specially instance the contrasts pointed out between the more uniform floras of temperate climes and the richly diversified floras of tropical lands. These latter are shown in many cases to be in great danger of extinction through human agencies, and the interesting suggestion is made that the British Government might follow the example of the Dutch in Java, by establishing small forest reserves in our tropical colonies; such reserves, Dr. Wallace points out, need not be of anything like the extent of the animal reservations of North America and Africa, for, owing to the crowded and diversified nature of all parts of a tropical forest, small areas of even a square mile would be sufficient for the purpose.

Later chapters devoted to illustrations, extensions, and new applications of the theory of natural selection cannot fail to arrest the attention of all naturalists; we may especially refer to the discussion of "recognition marks," and those on bird life, bird migration and extinction, and the relations of bird to insect life. We may note that even when the author feels compelled to express dissent from the views of Darwin—as in his ideas concerning the origin of man's intellectual and moral faculties—we find his loyalty and devotion to his old friend and fellow-worker displayed as conspicuously as ever.

The three chapters on the geological record, well illustrated as they are by wood-cuts drawn from various sources, abound with interesting observations. We may instance his development of the ideas put forward by Dr. Smith Woodward, in an address to the British Association, concerning the tendency of groups of animals in the periods before their final extinction to run into extravagant and sometimes *bizarre* forms. This is illustrated in the case of the trilobites and ammonites.

Later chapters on the relations of the chemical elements to vital agencies, on the "mystery of the cell," on the parts played by plants, animals, and man respectively in the economy of nature, are eloquent and illuminating; but it is unfortunate that the author is never able to avoid the pitfalls of teleological speculation. This tendency is still more strikingly manifested when the author proceeds to discuss such questions as the existence of pain in the lower animals, of the non-justifiability of vivisection, of the remedies for the overcrowding of cities, and similar problems of the day. On all these and similar questions Dr. Wallace writes very confidently, sometimes intruding his speculative opinions in the midst of the treatment of purely scientific questions.

Most of the author's scientific friends—and they are very numerous—will feel regret that these and similar discussions were not reserved for a separate volume. We are all familiar, from reading his "Man's Place in the Universe," and his autobiographical work—"My Life"—with the author's peculiar views on extra-scientific, social, and political questions. Some of these tendencies to unbridled speculation seem to have reached an extreme limit in the twilight of a noble life, as when it is gravely suggested to sub-

stitute for the idea of a single Creator, orders of angelic beings, each charged with the task of originating and exercising supervision and control over special evolutionary processes! Everyone must feel how incongruous are such incursions into the realms of the unknown and the unknowable with the really valuable and suggestive discussions of the first part of the book. But however much we may regret the intrusion by the author of these wild speculations, and greatly as we may dissent from his social and political panaceas, as hopelessly impracticable, we all recognise that they are inspired by the author's love of humanity and all living things, by a desire to ameliorate the sorrows and sufferings he sees around him, and by a hope—ill-founded though it may be—that such teachings may be of service to his fellow-men.

NATIVES OF THE ARGENTINE REPUBLIC.

Los Aborigenes de la República Argentina. Manual adaptado á los programas de las Escuelas Primarias, Colegios Nacionales y Escuelas Normales. By Prof. F. F. Outes and Prof. C. Bruch. Pp. 149. (Buenos Aires: Angel Estrada y Cia., 1910.)

THIS neat little book, well printed and illustrated, far surpasses its modest subtitle: a manual adapted to the teaching in primary and secondary schools. It is really a condensed account of what is known of the natives of the Argentine Republic, of those who are quite prehistoric, those who were found at the time of the conquest by the Spaniards, and those who "still survive precariously in some far-off districts."

A rapid survey of the earth's history as told by the sedimentary strata and their leading fossils is made the occasion for explaining the meaning of the many indispensable technical terms. Since much of the evidence of the existence of prehistoric man rests upon his primitive implements, the theory of artificially chipped stones is explained and illustrated, and how, at least in Europe, the evolution through polished and carved implements of stone to those of metal can be traced. A roll-call of scientific work in Argentina, from Pigafetta, Magellan's companion in 1520, to the Princeton University expedition, concludes this introduction of twenty-eight pages.

The palæontological account is greatly helped by a coloured diagram. Besides the mystical Tetraprothomo, the pliocene Monte hermoso level has yielded pieces of rock which enthusiasts have taken for examples of intentionally fire-baked clay, whilst others refer their condition to volcanic action. In short, the earliest undoubted human remains and traces date from the Enseñada Loess, lowest pleistocene. The *Homo pampeanus*, of the early American type, seems to have used the carapace of the contemporary Glyptodons for shelter. Post-pampean man was clearly neolithic, and he continued in this state until his discovery by the Spaniards, with the sole exception of the Diaquita in the north-western mountains, which had advanced to the use of bronze. These interesting people are described in the second chapter.

To facilitate the account of the various tribes, each chapter has a little map, and stress is laid upon the prevailing climate, as influencing man through the fauna and flora. Each chapter begins with a description of the physical aspect of the respective district, whether forest, mountain, or plain, with frequent photographs; the tribes are grouped as much as possible according to their relationship. Each group, or tribe, or race, is tersely characterised physically; as a linguistic point the personal pronouns have been selected. Sociologically: the kind of food and how it is prepared, especial attention being paid to the mode of kindling of fire. Then follow the kind of shelter, dress, ornamentation, dances, creeds, and superstitions, family and funeral rites, weapons, and wars. To each chapter is attached a carefully selected and apparently well-nigh exhaustive bibliography, and 146 illustrations, comprising maps, scenery, implements, pictographs, and portraits enhance the text, which in a small compass manages to impart an astonishing amount of information.

OUR BOOK SHELF.

Solectrics: a Theory Explaining the Causes of Tempests, Seismic and Volcanic Disturbances, and how to Calculate their Time and Place. By Alfred J. Cooper. Pp. iv+100; illustrated by over 100 diagrams. (London: J. D. Potter, 1910.) Price 10s.

THE "solectric theory" postulates a force which in some sense corresponds to the sun's radiant energy, giving rise to light, heat, chemical action, and magnetism, but the author also inserts gravity and vital force. Having introduced such a force, the author is able to explain the rotation of the earth, the obliquity of the ecliptic, and many other things. This solectric energy penetrates the whole solar system, and there is a constant adjustment of this force according to the configuration of the planets and moon. The sum is constant, the whole passing continually from and to the sun; only local disturbances have to be considered. At intervals the earth becomes charged with solectric energy, both directly from the sun and indirectly from the planets and moon. According to the length of time that the earth is submitted to this force, so its manifestation will vary. If the accumulated energy is spread over a large flat country or an ocean, a storm occurs; if the energy has been gathering for ten or twelve days, and is concentrated in a mountainous district, an earthquake takes place; if the earth has been surcharged for a month or more, volcanic eruptions follow. But whatever the form of the disturbance, it is necessary that the sun or moon should be $57\frac{1}{2}°$ or 88° from the position affected at the critical moment.

If we have correctly interpreted the author, this expression means that the place must lie on a circle $57\frac{1}{2}°$ or 88° from the position in which the sun or moon is vertical. We have not been able to follow the process by which the position on either of these circles is definitely located, but evidently the operation is not a simple one, for the author intimates that a body of expert calculators will be required in order to apply the theory. But if the instructions are pursued rigorously, it will be possible to issue warnings to any state threatened by an earthquake, or to ships likely to be overtaken by a tempest.

Differing from many theories, the aim here is eminently practical, but if the author entertains any hope that it will be tested, we are afraid he is doomed to disappointment. Though we cannot agree with his conclusions, we should wish to treat Capt. Cooper

with great respect. He has witnessed many storms and startling phenomena in all parts of the world, and has sought to ascertain the causes according to his lights. Not being sufficiently acquainted with phenomena outside his own experience, and perhaps misled by the "long arm of coincidence," he has gone wrong, but the spirit of inquiry exhibited is very creditable, and much to be preferred to the display of indifference so often manifested by seamen and others.

Die Cnidosporidien (Myxosporidien, Actinomyxidien, Microsporidien). Eine monographische Studie. By Dr. M. Auerbach. Pp. viii+261. (Leipzig: Verlag von Dr. Werner Klinkhardt, 1910.) Price 18 marks.

This memoir deals with an important group of parasitic Protozoa, associated with disease in cold-blooded vertebrates, especially fishes, and in invertebrates, for instance, pébrine in silkworms. The spores of these Sporozoa are enclosed in a valvate shell (the valves of which are shown to arise from two or three special cells in the sporoblast), which contains, besides one or more masses of spore-plasm, one to four polar capsules, each with a spirally-wound filament. The assertions of some workers that the polar filaments can be extruded and subsequently retracted are not borne out by the author's experience. The morphology of the vegetative forms and spores and the multiplicative and propagative reproduction are fully described; some form of sexual reproduction is now known to occur in members of each of the three subdivisions of the Cnidosporidia.

In the biological portion of the work the occurrence of the parasites is discussed, and an excellent host-index is given showing the Cnidosporidia recorded from each, with references to the records; the situation of the parasite and its pathological effects are described. In the systematic section an account is given of the genera and species described subsequent to 1897, which thus serves as a supplement to Labbé's account in "Das Tierreich" (1899). There are useful hints on technique, a list of 530 memoirs dealing with this group of parasites up to August, 1909, and an appendix giving a summary of the literature issued between that date and the time of printing. A comprehensive index completes this admirably arranged and useful monograph, which is illustrated with eighty-three half-tone figures.

Lehrbuch der Botanik für höhere Lehranstalten und die Hand des Lehrers, sowie für alle Freunde der Natur. By Prof. O. Schmeil. (Sechsundzwanzigste Auflage.) Pp. xvi+534. (Leipzig: Quelle and Meyer, 1910.) Price 5.40 marks.

The author of a book that passes through twenty-five editions in seven years has reason to be satisfied. Such is the record of Dr. Schmeil's "Text-book of Botany," which is intended for use in high schools and similar institutions, as well as for teachers and home students. It is largely a systematic compilation treating of phanerogams, with a shorter review of cryptogamic types; to this is added an account of general morphology and physiology, and a brief appendix on plant systems and geographical distribution. The success of the book may be attributed to the training value of systematic botany in a general course of education. The information proceeds by families, for which one or more of the important members is taken for tolerably full description, especially with regard to features of biological interest, while others, particularly those of economic interest, are mentioned, and in many cases figured. Among the numerous illustrations those portraying general habit and appearance are a notable feature. Most of the coloured plates refer to an individual species, but one is a representation of a wood in the carboniferous epoch. It would be useful if general characters were given for each family mentioned; as it is, they are omitted in those cases where they are not readily obtainable.

Four-Figure Logarithms on a New Graphic System, dispensing with Interpolations. By Dr. R. C. Farmer and M. M. Farmer. Pp. 8. (London: Longmans and Co., 1910.) Price 6d. net.

The authors of these tables have attempted to avoid the necessity of employing difference columns. With this end in view, numbers are printed on one side of a graduated line, drawn down the page, and the corresponding logarithms are placed opposite to them. The difference between successive printed numbers is 10 and the intermediate spaces are divided into ten parts. The logarithms are also printed at intervals of ten, and the correct subdivisions are indicated. It is claimed that more accurate readings will be made in this way than from the ordinary tables where a slight error in the fourth place occasionally occurs. But we must confess that we have found this new method a considerable strain on the eyesight, and there is the additional inconvenience of having three pages to consult instead of one. For practical purposes, ordinary tables give a sufficient degree of accuracy; we therefore doubt whether this new graphic system, in itself distinctly ingenious, will receive much support.

Die Abstammungslehre. By Dr. P. G. Buekers. Pp. xi+354. (Leipzig: Quelle and Meyer, 1909.) Price 4.40 marks.

This is a very good little book. It presents the main facts bearing on the theory of descent, which have been ascertained of recent years, within a convenient compass. The account of variability is very useful, but what will probably be found of greatest use to German readers will be the author's epitome of the mutation theory and his account of elementary species in Draba and Viola, of which there are some very useful figures. His chapter on the natural system of classification is very interestingly written; he deals at length and is evidently very much interested in the question of the minute discrimination rendered possible by a long training of the observation, and he mentions a bulb dealer who knows more than a thousand varieties of hyacinths from the dry bulbs alone. His concluding chapter embodies an attempt to hold the scales between the mutation theory and the theory of the selection of continuous variations. The author makes an unequivocal declaration in favour of the theory of mutation; his thoughtful analysis of the evidence on this question should ensure the book a wide circulation. It is to be hoped that it may be translated into English.

The Cornish Riviera. Described by Sidney Heath. Pp. 64. *The Peak District.* Described by R. M. Gilchrist. Pp. 64. *Dickens Land.* Described by J. A. Nicklin. Pp. 64. All pictured by Ernest Haslehust. (London: Blackie and Son, Ltd., 1911.) Price 2s. net.

These additions to the "Beautiful England" series which Messrs. Blackie are publishing contain all the attractive features to which attention has been directed in noticing previous volumes. Mr. Haslehust's beautiful pictures in colour, supplemented as they are by bright, entertaining letterpress, should assure the popularity of the volumes.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A House divided against itself.

MOST of your readers have doubtless heard of a question relating to the site of the Natural History Museum at South Kensington, and to a site for a new Science Museum. For the latter it is proposed to utilise the waste land behind the Natural History Museum, together with a portion of the site assigned to the Natural History Museum. The supporters of this scheme state that there is plenty of land for both museums, and have presented a memorial to the Government to this effect. Biologists learnt of this memorial largely owing to a Question and Answer in the House of Commons. They considered that such a proposal seriously imperils the future of the Natural History Museum. A second equally influentially signed memorial expressing these views is sent to the Prime Minister.

The spectacle is an edifying one. The scientific men of the country are roughly divided into two camps opposed to one another, while, as Sir Norman Lockyer says in a letter to *The Times*, May 30, "there should be no contention between these persons—their aims are the same; they desire to afford the best facilities for the increase and coordination of knowledge in all its branches." Is there no machinery which can make such contention only possible as a last resort? The records of the Royal Society and the British Association afford a hundred instances of the cooperation of all sections of scientific men, while the search for instances of the pitting of the different sciences against one another is almost vain. In questions which affect several sciences, surely it is possible for representatives to come together privately and discuss them freely. Probably in 90 per cent. of the cases an agreement would be reached, and both sides would cooperate for the good of science as a whole. For the due progress of human knowledge the cooperation of the different sections of science is more needed to-day than it has ever been in the past. All branches are becoming more and more woven together, and public contention between sections can only weaken the influence of science as a whole.

J. STANLEY GARDINER.

Cambridge, May 31.

Fishes and Medusæ of the Intermediate Depths. A note on the work of the *Michael Sars*.

DR. HJORT's account of the work of the *Michael Sars* during last summer's cruise [1] is of the very greatest importance to the marine geographer: it is the most illuminating article of its kind which has appeared within recent years.

Among the many interesting questions which are raised, I wish to direct attention here to one only, which is of particular interest to me because of my studies on the Medusæ of the intermediate waters, or the mesoplankton, if that term be preferred. This is the observations on the vertical range of the "black fishes," "shining silvery fishes," and "red prawns" of the intermediate depths.

Briefly stated, the result of Dr. Hjort's observations is that the adult black fishes and red prawns form an important community, the upper limit of which everywhere corresponds with the same intensity of light, *i.e.* practically with the lower limit to which sunlight penetrates with strength demonstrable by the photographic plate. This limit is deeper in low latitudes, nearer the surface in high, that is, about 500 metres between Newfoundland and Ireland; 700–800 metres at 33° N.; and when black fishes were taken from lesser depths, such captures were made at night.

The silvery fishes dwell at a higher level, where the light of the violet end of the spectrum penetrates with considerable strength.

These generalisations rest on such a mass of observation, and the methods of investigation were so well chosen, that they seem to me altogether deserving of acceptance; indeed, they form one of the most important of recent additions to our knowledge of oceanic biology.

Now, among the "intermediate" or "mesoplanktonic" Medusæ there are two similar colour groups, one unpigmented, or faintly pigmented, but often highly iridescent, as, for example, *Colobonema sericeum*, *Rhopalonema funerarium*, *Halicreas papillosum*; the second, characterised by very dense entodermic pigmentation, of a deep red, reddish-brown, or chocolate colour. Conspicuous genera among the latter are Atolla, Periphylla, Crossota, and Æginura.

Dr. Hjort's paper raises the question, Do the intermediate Medusæ, like the intermediate fishes, fall into two classes in their vertical distribution as well as in colour, and, if so, do the depth limits of the two correspond with those of the fishes and crustaceans?

Unfortunately, our knowledge of the bathymetric range of all the Medusæ in question is still extremely scanty. We know that they do not normally come to the surface except in very high latitudes, as, for example, Periphylla from the surface off Cape Adare in December, 1899, and January, 1900, the ice then being broken up, and in McMurdo Sound. On the other hand, the evidence which I have collated [1] shows that they are by no means exclusively abyssal. During the *Albatross* Eastern Pacific Expedition they were taken abundantly between 300 fathoms and the surface, and I have recently received an extensive collection from the north-western Pacific from the same depth zone.

Closing-net records are too few in number to be conclusive, but it is at least suggestive that in the eastern Pacific the *Albatross* took three genera of red Medusæ in a Tanner-net haul at 400 fathoms, one of which was also taken in the open net from 300 fathoms, but none of the transparent group, while at the same station two genera of the iridescent-transparent group were taken in a Tanner-net haul at 300 fathoms, and three specimens of a third transparent form, *Halicreas papillosum*, and one of a fourth, *Homoeonema alba*, were taken in the open-net haul from 300 fathoms to the surface.

These records certainly suggest that at this locality the red forms occurred, as a whole, below the transparent-iridescent ones, but that the two groups overlapped at, say, 250–300 fathoms.

In my discussion of the bathymetric range of the eastern Pacific Medusæ, I concluded that the upper limit of the intermediate forms probably corresponded, roughly at least, with the depth to which sunlight penetrates with appreciable strength. But the facts with regard to fishes brought out by Dr. Hjort suggests that my generalisation may not hold for the intermediate Medusæ as a whole, but only for the "red" genera.

This question can be settled only by further records; such, we hope, will be afforded by the *Michael Sars* Medusæ when they are worked up. But I direct attention to it here because, if it proves that red prawns, red or brown Medusæ, and black fish form a rather definite faunal group dwelling below the limits of light, as now seems likely, to which, too, the pelagic holothurian Pelagothuria probably belongs, the similarly excessive development of pigment in such divergent groups, in an environment of practical darkness, is a phenomena of great interest.

Such cases as this only emphasise the gaps in our knowledge of the life of the deep seas, and how rich a harvest of discovery still awaits the student who will explore the intermediate waters with a well-matured plan of operations.

HENRY B. BIGELOW.

Museum of Comparative Zoology, Cambridge, Mass.

Musical Sand.

WORKING with sand obtained from the beach at Barmouth, North Wales, I have been able to confirm most of the conclusions arrived at by Mr. Carus Wilson (NATURE, vol. xliv., p. 322) and by Mr. Skinner (NATURE, vol.

[1] *The Geographical Journal*, vol. xxxviii., pp. 349–377, 500–523, and NATURE, January 19, 1911.

[1] Reports on the scientific results of the expedition to the Eastern Tropical Pacific, in charge of Alexander Agassiz, by the U.S.F.C. steamer *Albatross*, ... XVI. The Medusæ, by Henry B. Bigelow. Memoirs Museum Comp. Zoology, vol. xxxvii.

lxxvii., p. 188), while the following additional observations have been made.

Distribution.—I found musical sand at intervals along the shore for more than ten miles north of Barmouth, at Whitesands Bay, Pembrokeshire, and at the North and South Sands, Tenby. This suggests that it is much more widely distributed along the shores of the British Isles than has hitherto been supposed.

Conditions affecting Pitch of Note.—I obtained the note by plunging a flattish pestle into an evaporating basin containing some of the sand, and there appears to be a definite relation between the curvature of the vessel and the pitch of the note produced. The following typical numbers were obtained with vessels of different material, which were approximately hemispherical in shape, the same pestle being used in each case:—

Vessels	A	B	C	D	E
Radius of curvature in cm....	5·4	5·1	4·7	4·4	4·2
Frequency of note (about) ...	1280	1440	1700	2180	2300
Inverse ratios of squares of radii	1·12	1·32	1·18	1·25	1·06
Ratios of frequencies	1·13	1·33	1·18	1·35	1·10
Vessels	A & B	A & C	B & C	C & E	D & E

When round-bottomed glass flasks are plunged into a milk-bowl containing sand, the pitch appears to depend on the curvature of the flask; *e.g.* flask

$$R = 3·5 \text{ cm gives note } n = 2050$$
$$R' = 4·2 \text{ cm gives note } n' = 1370$$
$$\frac{R'^2}{R^2} = 1·44 \qquad \frac{n}{n'} = 1·49$$

Within certain limits, a change in the temperature, the quantity of sand moved, or the gas present between the sand particles, appears to have no appreciable effect upon the pitch.

The Protective Value of the Sticky Hairs on Young Leaves and Shoots.

IT is often difficult to imagine, and still more so to discover, the particular foes against which the hairs of young plants are a defence. In the course of the last two days I have noticed two instances in which the same foes have been successfully vanquished by a similar device on two widely different plants. The first instance was afforded by plants of *Salvia patens*, which had been removed from a cool frame to the shelter of a wall prior to being planted out in the borders; the second by the young leaves and shoots of several species of Rhododendron growing in my garden. The hairs of both these plants were abundantly laden with dead and dying hymenopterous gall-flies of several different species (? of the genus Andricus). I examined several individuals, and found them invariably to be females. They were caught by the legs, wings, or indeed almost any portion of the body. I failed to discover any insects other than the gall-flies captured by these hairs; and yet there were a few dipterous flies walking unconcernedly over the leaves, and in no way inconvenienced by the sticky hairs. The evidence would seem to point to these hairs being a special protection against gall-causing insects at a stage when the tender leaves and shoots would otherwise be very vulnerable by these tiny creatures.

Charterhouse, Godalming, May 21.

The Teaching of Science in Secondary Schools.

THE report of the Board of Education on the above subject (see NATURE, May 4) contains many expressions of opinion with which I heartily agree. But I must beg respectfully to differ from the authors as regards the limitations they propose to put upon the use of everyday phenomena in science teaching. The report says:—"They should, of course, be introduced as *illustrations*, that is to say, when, and only when, they may happen to be wanted to give point to the teaching." This dogmatic statement ignores the fact that many well-known teachers strongly prefer the opposite mode of procedure. Upon their view a practical problem should be made the *starting point*, so that the development of the scientific method should follow instead of precede; *e.g.* from a study of the crane the class should discover the triangle of forces. The main argument for this procedure is that the boys actually want to know how a crane works, whereas interest in abstract principles does not, as a rule, outcrop until the age of sixteen or seventeen years. My own experience is distinctly in favour of the appeal to the utilitarian rather than to the scientific motive, except in the case of exceptional boys or of those above the age of seventeen.

G. F. DANIELL.

Oakleigh Park, N.

June Meteors.

THOUGH the long days and twilight nights prevent much attention being given to observations of shooting stars in June, still, important meteoric events are liable to occur in this month. The following are computed details of the four most important meteor showers that take place during the period June 9–30 in the present year:—

Epoch June 8, 17h. (G.M.T.), twenty-sixth order of magnitude. Principal maximum June 9, 9h.; secondary maximum June 9, 19h. 40m.

Epoch June 9, 6h., twenty-second order of magnitude. Principal maximum June 10, 9h. 35m.; secondary maximum June 10, 19h. 40m.

Epoch June 13, 12h. 20m., seventh order of magnitude. Principal maxima June 12, 5h., and June 12, 12h. 15m.; secondary maxima June 10, 23h. 10m., and June 12, 18h. 35m.

Epoch June 14, 4h., eighth order of magnitude. Principal maxima June 12, 23h. 20m., and June 13, 0h. 5m.

June 5. JOHN R. HENRY.

Daylight and Darkness.

I AGREE with Mr. W. T. Lynn that the article in NATURE of May 11 (p. 349) leaves "little to be said with regard to the so-called Daylight Saving Bill"; but there is one remark in it to which exception may be taken. This is the statement (p. 350) that it is "easy" to alter one's watch when travelling into a zone where different time is kept, if by "easy" is meant "not inconvenient." All travellers must have found the inconvenience of the change of time, even when reduced to a minimum through the change being an exact hour. Some inconvenience is unavoidable in travelling, but it is, of course, absurd to cause this inconvenience unnecessarily as the "Daylight Saving Bill" proposes. The inconvenience is such that in a journey to India I found it best never to alter my watch at all, it being simplest to keep to Greenwich time, and mentally make the allowance for local time.

T. W. BACKHOUSE.

West Hendon House, Sunderland, June 1.

HEREDITY AND DESTITUTION.

DURING the past week a conference has been sitting to consider possible means for the prevention of destitution. A general inaugural meeting took place on May 30, at the Albert Hall, and sectional meetings were held on several days at Caxton Hall.

Mr. A. J. Balfour, who delivered the opening address at the general meeting, struck a note of which echoes were heard throughout the congress. He devoted much attention to the bearing of heredity on destitution, and to the influence of the present selective fall in the birth-rate on the average economic efficiency of the nation.

Although Mr. Balfour held that some supposed

deductions from the principle of natural selection among mankind were not supported by facts, those who believe that the importance of heredity and selection in racial qualities has been too much neglected cannot but be grateful to him for raising boldly a question which our statesmen and politicians are only too prone to ignore. Almost anything which directs public attention to the subject is to be welcome.

While according a generous recognition to the importance of racial studies, Mr. Balfour asked the selectionist to face the question why he could perceive no "segregation of efficiency in the past between those who are better off and those who are worse off." Mr. Balfour implied that, unless a satisfactory answer could be given, the theory of natural selection as applied to mankind should be regarded with hesitation if not with suspicion.

Not everyone will share Mr. Balfour's inability to perceive a higher level of ability among the upper half of the nation as compared with the lower. Distinct evidence of segregation of special types of ability might be adduced. But the question why the process has not gone farther, why the upper classes do not show preponderant ability more markedly than they do, is worthy of consideration.

The whole problem of selective action in mankind, and especially civilised mankind, is fraught with difficulty, and tentative considerations alone can at present be put forward. One could imagine a society in which ability possessed full selective value, and a cumulative segregation of mental qualities gave to the best part of the race at all events, a much higher average efficiency than we can now show. But that society would in some respects be unlike our own. It would be more ready to accord all advantages to ability without envy or hesitation; it would be much firmer in visiting weakness of mind or body with appropriate disabilities. It would secure in some way that able men and women should be encouraged to have a full complement of offspring, and should be placed in a position where a hunt for heiresses by themselves or their sons would not be necessary to support the position won by their own ability, for, as Galton pointed out, heiresses usually come of infertile stock, and too often extinguish the family which captures them.

These considerations may serve to give us the clue to Mr. Balfour's problem: Why are not our upper classes more markedly superior in ability to the lower?

First, ability, even ability which leads to achievement, does not necessarily secure a more able partner. A man rising rapidly too often either marries unwisely before he has risen, or, engaged in the struggle to advance, marries not at all, or too late, to leave many offspring. One or two children are not enough to give the hereditary ability a full chance of appearing. Thus the favourable variation is destroyed in the first generation.

Secondly, if he marries appropriately and rears a large family, that family has still many dangers to run. Unless the ability be of the type which wins great wealth, and unless the opportunity for winning that wealth occurs, a search for well-dowered partners will probably extinguish some lines of offspring. Or again, if wealth renders this search unnecessary, some of the children may fall a prey to the needy adventurer with undesirable mental qualities.

Thirdly, when a family becomes firmly established among the upper classes, the pressure of selection becomes less acute. Places are found for the sons, whether their abilities deserve them or not; some of the daughters make good marriages, regardless of whether they possess their share of the family ability. Selection ceases to a great extent, and reversion to a lower level inevitably occurs.

These reasons apply to all the ages during which modern society has been developing. But, during the last forty years, the voluntary and deliberate restriction of the birth-rate among the more successful stocks of the nation has introduced a new cause which affects chiefly those among whom its results are most disastrous from the point of view of the nation and the race.

An able man and an able wife—a pair nearly sure to produce a high proportion of able offspring—too often regard the interests and duties, which their ability thrusts on them from all sides, as a reason or an excuse for restricting severely the number of their children, or for refusing the burden of parenthood altogether. For the last forty years the power of doing so has been changing slowly but surely the whole aspect of racial problems.

But, while we may give reasons to explain the comparative want of segregation of ability, it should be recognised that signs of partial segregation of ability are not totally wanting. At present, it is probable that selection is keenest and most effective in the professional class, and competent observers are to be found who believe that the average ability among the sons of professional men is higher than in any other class in the community.

During the eighteenth and early nineteenth centuries, there were frequent intermarriages between the leading political, administrative, and military families, and a statistical analysis of the entries in the "Dictionary of National Biography" gives us evidence of distinct accumulation of those special types of ability in the governing class during that period. The rarity of such accumulation in other cases may well be due largely to the want, in other sections of the nation, of distinct classes, corresponding to the different types of ability. If mates were naturally sought from within the limits of a definite class, access to which was more and more jealously guarded as its efficiency and ability increased, a similar and more marked segregation of ability might appear in other directions.

But Mr. Balfour saw another difficulty in the path of a selectionistic interpretation of social phenomena. As Dr. Archdall Reid has shown, disease is now one of the most effective selective agencies at work among mankind. By the early elimination of those specially susceptible to a given disease, the race is gradually becoming more and more immune to that special scourge. If we diminish the infection of the disease by improved sanitation and knowledge of hygiene, this process of immunisation will cease, and the race will revert to a more susceptible state. Hence, Mr. Balfour argued, no convinced selectionist should advocate improvement in our sanitary environment.

Doubtless, improvement in the environment has its dangers. It may keep alive to reproductive age many of weak physical or mental constitution, who would, for the sake of the race, be better out of the way. We shall guard against those particular dangers all the better for facing them with open eyes. But immunity from certain special and preventable diseases is not the highest quality of the ideal man. If we can guard against infection in other ways, it may well be that greater aggregate advance will be made when we can prevent the waste now incurred by nature in protecting the race against that particular disease. As our knowledge of inheritance, Mendelian or other, is increased, we may be able to point the

way to combining immunity from the disease with other valuable qualities. Meanwhile, it is unwise to lose the chance of preserving those other qualities, which may now be linked with susceptibility to the disease, for want of the sanitary precautions which advancing knowledge puts in our power. Thus the selectionist escapes from Mr. Balfour's dilemma, and may support with a clear conscience all efforts towards improvement in the environment, provided that it is fully realised that improvements in the environment alone will not necessarily improve the innate qualities of the race, any more than better cow-stalls will of themselves improve without limit our breeds of cattle, and, provided that all efforts are also made deliberately to encourage reproduction among the best stocks, and to discourage it among the worst.

But consideration of these general problems, interesting though they are, is not necessarily essential to the application of the principles of heredity to the treatment of destitution—the immediate object of the conference opened by Mr. Balfour's speech. Whether or no there is a general segregation of ability broadly between the upper and the lower classes in this country, it is undeniable that the ranks of the paupers contain a certain proportion of those who, mentally or physically, are hereditarily unsound. It is the fact that the differential birth-rate is telling in favour of the unsound as against the sound that is so sinister, even more so than its effect on the relative rates of reproduction of different social classes.

No one denies that many fall into reach of the Poor Law through no fault of their own. By seasonal unemployment, by movements of trade, by the pressure of temporary illness or economic misfortune, relief becomes necessary. To meet these cases, every attempt should be made to improve the organisation of the labour market, to obtain more effective education, to prevent blind-alley occupations for boys and girls. Such subjects met with their full share of consideration at the conference, and will always appeal with greater force to the philanthropist, who wishes to relieve immediate distress, and to the politician who wishes to capture votes by doing so.

But, as all those who administer the Poor Law with their eyes open know, these cases are but part of the problem. A large number of the occupants of our workhouses and prisons are congenitally defective in mind or body. Often, for the feeble-minded or unsound themselves, there is no hope of improvement, and, even in cases where, at great expense to the community, they can be taught a trade in special schools, as Mr. Balfour pointed out, their acquired characters will not be inherited, and their offspring will tend to reproduce their infirmities. The feeble-minded are specially prolific, and, in this time of a general fall in the birth-rate, are increasing relatively to the other sections of the community. Several years ago, a Royal Commission reported in favour of the compulsory and permanent care and detention of the mentally defective. That nothing has been done to carry out the recommendations of the Commission, in spite of the urgency of the case, is a standing disgrace to the Government and to the Parliament of this country. Were these unfortunates shielded from the degradation which follows their so-called freedom, and prevented from handing on their defects to future generations, this part of the problem of destitution would be solved, and a heavy burden of incompetence and pauperism removed once for all from the shoulders of the competent, who, there is now reason to fear, often restrict the number of their offspring to meet the increasing load of taxation required to support the inefficient members of the community.

Several of the special papers read to the sections of the conference dealt with the problem of mental defect as a cause of pauperism. On May 30 Dr. F. W. Mott and Dr. A. F. Treadgold dealt with the insane and the feeble-minded in their hereditary aspects. Dr. Mott pointed out the significance of the fact that a considerable proportion of the inmates of the London County Asylums were related to other inmates, while Dr. Treadgold gave evidence that feebleness of mind was more prevalent in the rural districts. It should be noted that rural districts which have specially been depleted by immigration to the towns seem particularly affected in this way. The worst strains get left, and the inbreeding of defective stocks intensifies the evil. Dr. Treadgold said that the real cause of the existence of a certain class of parasitic pauper was germinal defect, and emphasised the folly of allowing such a class to propagate freely. On Wednesday Sir William Chance pointed out that, whatever the cost of segregation, it would be repaid in a generation many times over by the saving in workhouses and prisons. Other papers on mental defect in its bearing on pauperism and crime were read by Mr. T. Holmes, Dr. C. H. Melland, Miss Mary Dendy, and Dr. F. Needham, while Dr. C. W. Saleeby spoke on the eugenic summary and demand.

Whatever be the effect of the conference on legislation or administration, it is impossible to follow its proceedings without perceiving that the thinking world is at last waking up to the fact that biological knowledge has an intimate bearing on sociology. The last few years have seen a great change in this respect, and, though much more is yet to be done, the future is full of hope. W. C. D. W.

PLAGUE.

THE recent epidemic of plague in northern China with its 60,000 deaths, is remarkable in two respects. First it was the most extensive manifestation of pneumonic plague in this pandemic; and, secondly, it was characterised by a more or less sudden cessation. It affords a warning as to the capabilities of the disease. and as to one of its possible developments, and although the outbreak has come to an end for the time being without any great efforts in the direction of prevention, yet it has demonstrated that the plague of the present day is as powerful for mischief and as capricious in action as that of any period in the past centuries. Arising in or close to eastern Mongolia, where the ordinary annual epidemics of plague have for many years shown a tendency to a comparatively high percentage of the pneumonic type, this influenzal form, shorn of the bubonic variety which has hitherto accompanied it and has been its predominant partner, appears to have been conveyed as early as October, 1910, to some of the more recent settlements on the Manchurian portion of the Trans-Siberian Railway.

The increasing mortality in these settlements did not attract any particular attention until December. when, in consequence of panic following an appreciation of the situation, there ensued a great exodus of the Chinese, both by rail and by road, to their homes in the more southern provinces of Shinking, Chili, and Shantung. To the infection thus carried far and wide the rapid and extensive dissemination of the disease and the formation of new centres may be traced. But the virulence and great mortality which characterised the epidemic in some places and its comparative harmlessness in others are not so readily explained. The cause or causes of these variations have always been, and still remain, a per-

plexing problem, and our knowledge regarding the vehicles of infection and the part played by animals, insects, and man in the spread of plague do not at present assist us in its solution.

From the information available it would seem that the early infected centres suffered severely, while those that were infected later suffered but little. Possibly their immunity was because they were infected later in the season, for the disease towards the end of February and beginning of March began everywhere to lose its strength and power of diffusion which could not be attributed to preventive measures. This is no new phenomenon with pneumonic plague, and it is one which is well worthy of close investigation. This occasional self-limitation of pneumonic plague independent of active measures in no sense justifies the conclusion that preventive measures are unnecessary and useless in this form of plague. On the contrary, measures taken earlier would have further curtailed the outbreak. Prompt and early action is important and urgent, because no one can tell when a pneumonic plague is self-limiting and may confine itself to a few villages, or when it may have the force of a pandemic and spread if unchecked from country to country.

While much attention has been directed to the mortality in Manchuria from the pneumonic variety of plague, the ravages of the bubonic form in India have not been noticed, and yet the mortality of the latter far exceeds that of the former. Since 1896, when the disease was imported into Bombay, there have occurred in India seven million deaths from plague. The mortality varies in different years. Some years it is greater and in others less, but never since the disease appeared in the country has any year been free of mortality. Two provinces have been affected more than the others. One is the Punjab, with a population of only twenty millions, the other the United Provinces of Agra and Oudh, with a population of forty-seven millions.

The plague deaths in these two provinces during the past twelve years have been as follows (statistical abstract relating to British India from 1899 to 1909):—

	1899	1900	1901	1902	1903	1904	1905	1906	1907	1908	1909	1910
Punjab	255	572	14,959	171,302	205,462	396,357	334,891	91,712	608,685	30,708	35,655	152,387
United provinces of Agra and Oudh ...	7	135	9,778	40,223	84,499	179,082	383,802	69,660	328,862	22,878	39,394	139,328

In the Punjab the plague mortality increased from 255 in the year 1899 to 396,357 in 1904; then it declined for two years. In 1907 it rose to the enormous number of 608,685, and in 1908 and 1909 fell to a comparatively low figure. In the United Provinces of Agra and Oudh the mortality increased from 7 in the year 1899 to 383,802 in 1905; there was then a decline for one year, a rise to 328,862 in 1907, and a further decline in 1908 and 1909. Both in the Punjab and the United Provinces the deaths in 1910 have again risen, and the upward tendency is being continued in 1911, particularly in the United Provinces, as is shown by the following statement of the plague mortality in January, February, and to the week ending March 25th:—

Months	United Provinces	India
January	35,000	65,000
February	41,000	85,000
March	72,000	131,000
Total ...	148,000	281,000

In the first three months of 1911 the deaths from plague in India were 281,000, and in the United Provinces 148,000, which are respectively nearly five times and more than twice the mortality from the disease in China from October to March inclusive.

With this mortality in China and India it is difficult to realise that only twenty years ago plague was considered to be practically an extinct disease. True, it lingered in some of its old homes, but to such a small extent that it was hoped that even in these it would finally disappear. Now the whole position has changed. The slow but wide dissemination of the disease since it first attacked Canton in 1893 and Hong Kong the following year, and which has been followed by the infection of many countries in different parts of the world is one of the most remarkable and sinister events of the age. Its importance hitherto has not been connected with its mortality, for with the exception of China and India the deaths from the disease have been few, but it lies in the fact that every year the sowing of infection among susceptible and subterranean animals becomes more extensive, and that countries which have for hundreds of years been free of plague infection are no longer in that position.

The danger lies in the disease among animals being permitted to acquire a firm foothold wherever it may be, for the infection in such circumstances is difficult to eradicate. The insidious manner in which the infection gets imported into a country, the ease with which human cases have been hitherto dealt with, and the apparent difficulty the disease has in spreading, or even maintaining its hold, are apt to lull the suspicions of even the most wary. Thus with no immediate results forthcoming it is not surprising for it to be assumed that the twentieth-century civilisation has, so far as the West is concerned, deprived plague of its powers. It was to advancing civilisation the disappearance of plague from Europe was attributed, regardless of the fact that a similar disappearance had taken place in the East, and that recessions and long periods of rest from plague are matters of history. Plague, when it broke out in Bombay, had not been there for 184 years. Until then Bombay had prided itself on its sanitation, with its immense waterworks and drainage; and its external appearance was that of a fine and thriving city. But plague was the most informing sanitary inspector it ever had, and revealed the actual housing condition of the people, and it is just as likely, in due time and under favourable conditions, to visit the crowded and verminous slums of the cities of the West, where the "awakening of the insects" in the houses is as regular in season as that in China.

The disease is one which essentially affects the very poor, whose condition still make the cities of Europe vulnerable. It has always been called the poor man's plague. The one great advantage the West possesses over the East, which it did not possess in former times, is the power of trained organisation. It is on intelligent organisation based on scientific knowledge rather than on any great advance in the housing of the very poor in Europe that reliance will have to be placed to combat the disease and to secure safety from any great epidemic. In the meantime, in addition to systematic and continuous measures against infected animals in places where the disease has been imported, special attention requires to be directed everywhere against verminous houses and verminous people.

W. J. Simpson.

ON THE BLUE AND WHITE NILES.[1]

THE reorganisation of the regions of the Upper Nile after the destruction of the Dervish power and the steady growth of prosperity in every district has profoundly impressed all who have travelled in the Sudan. The history of these last twelve years' work has yet to be written, for the account of Mahdi-ism, by Sir Reginald Wingate, the present Governor-General, only dealt with the events which led up to the re-conquest of the country to the south of Wadi Halfa. Yacoub Pasha Artin, for many years Under-Secretary of State of the Ministry of Public Instruction in Egypt, does not attempt to provide such a survey, for which perhaps the time has not yet arrived, but has given us instead a series of delightful sketches of these lands, which are being more and more visited each year. Written in form of letters setting forth his daily experiences, his conversations with those he met, Europeans, Egyptians, or Sudanese, first impressions noted on the spot when all was fresh and vivid, this account of the regions of the Blue and White Niles is not only of interest but has a special value on account of the author's intimate knowledge of Oriental life and history.

FIG. 1.—A "Sadd" on the River. From "England in the Sudan."

Starting early in November, Artin Pasha, accompanied by Prof. Sayce, was able to take advantage of the favourable flood of 1908 and reach Roseires, on the Blue Nile, by steamer; thence, returning to Khartoum, he traversed the White Nile as far as Gondokoro, on the northern frontier of Uganda, thus visiting the two main lines of communication and many of the stations on their banks. All attempt at a scientific account of the country is disclaimed, but indications appear frequently that the systematic study of the country and its resources is everywhere being carried on so far as means are available. Mention of the Department of Woods and Forests bears witness to this, for the demand made upon the trees on the banks of both Blue and White Niles for the steamer traffic can only be prudently met by careful conservation of the present supply. Inspectors have been appointed, and though difficulty was experienced at first in obtaining local labour, this has been overcome, and now funds alone put a limit to the conservation possible. Both here and on the White Nile forest fires constitute the greatest danger to the young growth, but even these are being to some extent controlled.

The efficiency of the present administration is dwelt upon, though mention is made of cases where the Oriental foot finds the Western shoe to pinch inconveniently. In the area occupied by Arab tribes the question of slavery outweighs all others. An Arab sheikh discussed it frankly with the author, laying down that Arab landowners were incapable by habit and custom of working their land themselves, that they have always had negro slaves as cultivators, and that losing the slaves ruin will stare them in the face. Such changes can but be made slowly, but with the present increasing prosperity of the country and the suppression of inter-tribal warfare, even the Arab tribes will shortly accommodate themselves to new conditions. The author is especially qualified to present the local opinion, but he rarely states his own view of the merits of the questions raised.

On the White Nile a short stay was made at Kodok (formerly Fashoda), where the pastoral tribe of Shilluks has its headquarters, and descriptions of these interesting people are given. Under their own chief, the Mek, they have readily fallen in with the new *régime*, by which their tribal customs are respected, but retain the deepest hatred of those whom they call Turks, the slave merchants and slave-hunters of former days. Between this point and Gondokoro the Nile flows through a narrow valley plain, mainly occupied by marshes and lagoons, which provide the drift marsh vegetation, which at times is carried by wind and current into narrow channels or acute bends of the river, there to form a dense obstruction, the "sadd" proper. Loose application of this term to the region generally, to marsh vegetation, and to drifting vegetable matter, is to be deprecated, and even in the present account it is employed with some latitude. These obstructions have often been described, and Marno gave a very full account of them in 1880 and 1881. Though more understood to-day, the conditions which determine their formation are not controlable, so that during the late summer and autumn months, when rain and stormy weather prevail, constant care has to be exercised by the steamers passing up and down to remove any block that may be forming before it grows too solid. Among the illustra-

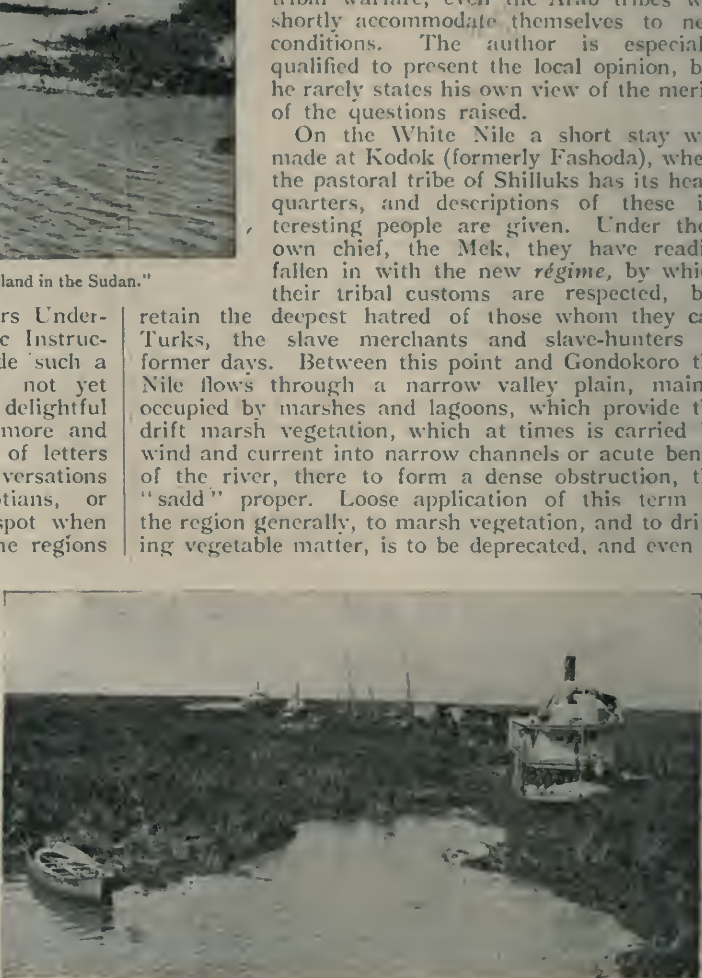

FIG. 2.—Stuck in the "Sadd." From "England in the Sudan."

[1] "England in the Sudan" By Yacoub Pasha Artin. Translated from the French of the author by G. Robb. Pp. xvi+251+map. (London: Macmillan and Co., Ltd., 1911.) Price 10s. net.

tions are two which are here reproduced by permission of the publishers. One shows a "sadd" sufficiently solid to check the flow of the river and form a lagoon; in the other both steamers and sailing boats have been brought up by a more compacted barrier of the same kind.

Khartoum is fully described, and the scientific work carried on at the Wellcome Laboratories is referred to. So many points of scientific interest are alluded to, having a bearing on various branches of knowledge, that we can only regret that the results have not a wider circulation and greater accessibility than is afforded by the annual official reports. The founder of the Wellcome Laboratory renders the results of its staff available, but in forestry, hydrography, and also in all that concerns the native races of the Sudan those who are working there are gaining data which have a value and importance beyond their own region. The illustrations greatly assist in forming an idea of the country described, but the map is not so satisfactory; it would be of more use if the modern place-names were correctly given and a consistent orthography employed.

H. G. L.

THE STRUCTURE OF HAUSALAND AND ITS NEIGHBOURHOOD.[1]

IF there is one point more than another which calls for the attention of the geologist in West Africa it is the position and age of the older sedimentary series, *i.e.* the beds between the presumably Archæan gneiss and the Cretaceous strata.

Such information as is available about these rocks, quartzites and argillites, grits and phyllites, is fragmentary, and obtained from a variety of sources throughout West Africa, often from localities where no recognised survey has taken place, and where the relations of the component rock groups are unknown.

On the western side of northern Nigeria we have such a sedimentary series frequently exposed, and with this Dr. Falconer, in his book, "The Geology and Geography of Northern Nigeria," has dealt at length. He regards these rocks as the scarcely altered representatives of a group of schists and sedimentary gneisses, termed the "softer" gneisses, because of their relatively low capacity for resisting erosion, and believes that they were deposited upon a surface of Archæan gneiss—the "hard" gneiss—and affected thereafter (*a*) by regional metamorphism, and (*b*) by folding.

It can scarcely be doubted that the quartz-schists and quartz-muscovite-schists of Kabba and Ilorin are the same as those of the Central Province of southern Nigeria, a correlation which can probably be extended to the rocks of the Eastern Province, and possibly—for the general character of these schists is exceedingly constant—to other parts of West Africa.

Dr. Falconer, who states his case with great fairness, has accordingly advanced an hypothesis of considerable importance, but it would have greatly aided the reader and enhanced the value of the work as a book of reference if some plates had been included showing the minute structure of the rocks.

The book is technical and solely for the geologist, and, though one would be loth to lose any of the excellent photographs with which the author has embellished his work, one ventures to think that in some instances microscopy might have taken precedence.

The granite intrusions (see Fig. 1) are pre-Cretaceous in age, and fall into two subdivisions: an older foliated, and a younger non-foliated group, which includes soda-granites. The pneumatolytic modification of some of these granites, as at Bukuru, has as a distinguishing feature cassiterite and sulphides of copper, zinc, and lead.

The Cretaceous beds, confined to parts of the valleys of the Benue and its tributary, the Gongola, fall into an upper and a lower series of grits and sandstones, divided by a limestone-shale series of Turonian age. It is interesting to note the presence of salt in the

FIG. 1.—Exfoliation in the Kilba Hills. From "The Geology and Geography of Northern Nigeria."

lower grit series, and of veins of galena and blende at Arofu, doubtless connected with a small inlier of granite near the town.

Salt occurs in the north-eastern part of southern Nigeria, as do also galena and blende, which facts, together with the probable existence of Turonian beds in the same neighbourhood, suggest a general similarity in history.

In both Protectorates the Cretaceous beds are pierced by dykes and sills of dolerite.

Dr. Falconer lays some stress on the unconformity which he believes to exist between the Cretaceous and Eocene beds; and is worthy of note, in view of Mr. Kitson's opinion that a passage exists in southern Nigeria between the Mesozoic and Cainozoic.

There are three groups of Eocene beds in northern Nigeria, of which the western only has yielded fossils; the others are correlated with them on petrographical grounds, and on their position as regards the known Cretaceous.

Of these beds the first, especially around Sokoto, where limestones and calcareous clays and shales occur with efflorescences of alum and gypsum, is the most interesting; the beds of other localities consist largely of ferruginous sandstones and grits, types only too prevalent in either of the two Nigerias.

[1] "The Geology and Geography of Northern Nigeria." By Dr. J. D. Falconer, with notes by the late A. Longbottom and an appendix on the Palæontology of the Cretaceous Deposits by H. Woods. Pp. xv+295+24 plates. (London: Macmillan and Co., Ltd., 1911.) Price 10s. net.

These sandstones are unfossiliferous, and an absolute proof of their Eocene age must accordingly be wanting; but, *faute de mieux*, Dr. Falconer makes out an excellent case and presents his facts clearly.

The book concludes with chapters on "The Superficial Accumulations," "Tertiary Crustal Movements," and "Tertiary Volcanic Action," each worthy of the close attention of the student of African geology. Two periods of Tertiary volcanic activity are recognised, respectively middle Eocene and late Pliocene; to the latter are referred some excellently preserved puys (Fig. 2) developed in the Province of Yola, the middle Benue valley and on the Bauchi plateau.

The rocks of the earlier outburst are an interesting series of phonolites and nepheline-basalts, of which the conspicuous stumps of the Tangale Peak and the Wase rock may be taken as typical examples.

In regard to the late earth movements, one conclusion of general interest may be recorded here, viz., that the culmination of the Tertiary oscillation resulted in the formation of the Bauchi plateau and the establishment of the present river system.

Fig. 2.—Craters in the Mboi Hills. From "The Geology and Geography of Northern Nigeria."

The Bauchi district is inseparably connected with the tin industry, and we could wish that Dr. Falconer had seen his way to more details, put in plain and concise phraseology, of the alluvium-containing cassiterite.

The sudden prominence into which the tin-mining industry has burst in northern Nigeria naturally leads the reader, in such a work as this, to expect authoritative information in a form to be readily assimilated.

Mr. Henry Woods has contributed an appendix on the palæontology, and the book as a whole is full of valuable information to the student; the geological map on a scale of 1 : 2,000,000 is indispensable to those interested in the structure of this part of Africa.

As Dr. Falconer himself readily admits, his work may require some modification in the future, but all who are acquainted with the difficulties of the African pioneer will give him full measure of praise for the results he has attained. In such circumstances to quibble over detail is an ill task, but the first chapter on the "Physical Geography" might be compressed and summarised with advantage to the general reader, and perhaps many will find a too great elaboration of detail throughout the work. John Parkinson.

DR. HARRY BOLUS.

The name of Dr. Harry Bolus is closely associated with the story of South African botany for the last forty years. In April, 1874, a letter to Sir Joseph Hooker was read at a meeting of the Linnean Society, of which Bolus had recently been elected a fellow (December 18, 1873), in which he criticised Grisebach's limitation of the Cape and Kalahari floral provinces (see Journ. Linn. Soc., xiv.). This was the beginning of a series of publications embodying the results of his observations on the flora of a peculiarly rich and attractive botanical area. In 1886 Bolus wrote for the official handbook of the Cape of Good Hope a valuable "Sketch of the Flora of South Africa," in which he proposed a series of natural botanical divisions, forming, roughly, successive zones from the coast northwards. From 1881 to 1889 he communicated to the Linnean Society a number of contributions to South African botany, containing critical notes on various genera and species, as well as descriptions of many novelties; but it was to the heaths and orchids that he was especially devoted. The results of his study of the large and intricate genus Erica are found in his monograph (in part of which he had the help of the late Prof. Guthrie) in the "Flora Capensis" (vol. iv., sect. 1, issued in 1905), where the 469 species are described in detail, and arranged under forty-one sections.

In his volumes on South African orchids, Dr. Bolus has established a model of detailed description and illustration; accompanying each species is a plate, drawn by Dr. Bolus himself, in which a judicious combination of outline and colour gives exactly what is wanted by the botanical student. Dr. Bolus had just completed this important work at the time of his death, which occurred on May 25, when on a visit to England. Mention should also be made of the excellent series of specimens illustrating the Cape flora, by the distribution of which to various great herbaria Dr. Bolus brought his collections within reach of a large number of students of systematic botany. An account of his services to botany would be incomplete without a reference to his generous support of the Cape University, which owes to him the foundation of its chair of botany; and Dr. Bolus himself would have wished some acknowledgment to be made of the help which he received in all his later work from his niece and pupil, Miss Louisa Kensit. A. B. R.

NOTES.

The Croonian lecture of the Royal Society will be delivered on June 15 by Prof. T. G. Brodie, F.R.S., on "A New Conception of the Glomerular Activity."

On Tuesday, June 13, Prof. Ernst Cohen, of the University of Utrecht, will give an illustrated lecture before the Faraday Society on "Allotropic Forms of Metals." Prof. T. W. Richards, of Harvard College, has been invited to take the chair on this occasion. Applications for tickets should be made to the secretary, 82 Victoria Street, London, S.W.

PROF. A. WILLEY, F.R.S., of McGill University, Montreal, has directed our attention to the inclusion in his article "Amphioxus" in the eleventh edition of the "Encyclopædia Britannica" of two cuts (Figs. 2 and 3) which, though described there as "original," and therefore inferentially as drawn by himself, are really reproduced from Sir E. Ray Lankester's article "Vertebrata" in the ninth edition. We understand that these illustrations of amphioxus were added to Dr. Willey's article without his knowledge by the editor of the zoological section of the eleventh edition, in accordance with his scheme for the reorganisation of the whole series of articles; but, by an oversight, the description "original" was not altered to "Lankester," as it should have been. We have received a letter from the editor-in-chief regretting the error, which will now be corrected, and making it clear that Dr. Willey himself is not responsible for what might appear to ignore the original work of another distinguished zoologist.

THE fine collection of African birds formed by the late Mr. Boyd Alexander, and bequeathed by him to the Natural History Museum, has now been handed over to that institution by his executor, Mr. Robert Alexander. The collection includes the birds obtained by Mr. Alexander during his expeditions to the Cape Verde Islands, the Zambezi and Kafue Rivers, the Gold Coast Hinterland, and the Island of Fernando Po, as well as those secured during the Alexander-Gosling expedition in 1904–7 from the Niger to the Nile. The collection includes, also, all the specimens obtained during his last journey to the islands of San Thomé, Principe, and Annobon, in the Gulf of Guinea; on the Peak of Cameroon and mountains to the north; and in Wadai up to the time of Mr. Alexander's death. This bequest to the Natural History Museum is of great value, for it supplies beautifully prepared skins and complete series of the avifauna of islands and countries hitherto very imperfectly represented in the national collection of birds. The present collection comprises nearly 4000 bird-skins, and includes the type-specimens of no fewer than eighty species described for the first time by the late Mr. Alexander in his papers published in *The Ibis* and elsewhere.

WITH the object of promoting and systematising chemical work of general importance to all engaged in the development of that science by research or by teaching, an International Association of Chemical Societies has been formed as the result of a conference of delegates from the chemical societies of England, France, and Germany, held in Paris on April 25 and 26. The three leading societies of the countries named had been invited by the president of the Chemical Society of France to cooperate in this movement and to nominate delegates to represent their respective societies at the inaugural meeting. The representatives of the Chemical Society of London were Prof. P. F. Frankland (president), Prof. Meldola, and Sir Wm. Ramsay. The Chemical Society of France was represented by Profs. Béhal, Haller, and Hanriot, and the German Chemical Society by Profs. Jacobson, Ostwald, and Wichelhaus. With the exception of Prof. Meldola, who was unable to attend, all the delegates were present at the opening meeting, when the association was formally founded and the statutes framed and adopted. From these statutes we learn that the objects of the association are to be promoted by the appointment of committees charged with the consideration and investigation of questions submitted by the council, by the publication of the results of such investigations, and by the holding of conferences and congresses. It was decided at the opening meeting that the first international committees should be appointed for dealing with the questions of nomenclature in mineral and organic chemistry, and with the unification of the modes of stating physical constants. The next meeting of the association is to be held in Berlin on April 13, 1912, with Prof. Ostwald as president, and the 1913 meeting is to be held in Great Britain.

THE death is announced, at seventy-two years of age, of Dr. A. E. Törnebohm, the Swedish geologist.

THE twenty-second annual conference of the Museums Association will be held at Brighton on July 10–15 under the presidency of Mr. H. M. Platnauer.

THE President of the Board of Education has appointed Mr. H. H. Thomas to succeed Dr. J. S. Flett as petrographer to the Geological Survey of Great Britain.

PROF. JOHANNES HARTMANN, professor of astronomy at Göttingen and director of the University observatory there, has been appointed, says *Science*, director of the Argentine Observatory at La Plata.

MR. A. J. WILMOTT, late scholar and Hutchinson student of St. John's College, Cambridge, has been appointed an assistant in the department of botany of the British Museum (Natural History). Mr. Wilmott will devote himself especially to the European and British collections.

DR. IRVING has found the remains of another horse at Bishop's Stortford. As the bones were lying under some 6 feet of peat along with those of a small ox of the *Bos longifrons* type, it may be provisionally assumed they belong to the Neolithic age.

AT the recent annual meeting of the Paris Society of Friends of Science, Prof. M. L. Joubin, the general secretary of the society, announced that during the preceding year 80,000 francs had been distributed to men of science and their families who were in need.

THERE will be a meeting of the Biochemical Club at the Rothamsted Experimental Station, Harpenden, Herts, on Saturday next, June 10. The director and staff of the station have kindly consented to conduct members round the various plots in the morning and in the afternoon. The honorary secretary of the club is Mr. R. H. Aders Plimmer, University College, Gower Street, W.C.

THE death is reported of Mr. Samuel Hubbard Scudder, the veteran American naturalist, in his seventy-fourth year. Nearly fifty years ago he was a museum assistant to Louis Agassiz. He subsequently held various posts in connection with the Boston Society of Natural History, the Harvard University Library, and the U.S. Geological Survey. He had a wide reputation as an entomologist, particularly on account of his numerous volumes on butterflies.

IN a recent letter to *The Times*, Prof. Marcus Hartog directs attention to the fact that there is no provision made in the new Copyright Bill in reference to reproduction on lantern-slides for teaching by recognised teachers. He points out that an actual researcher is usually gratified at the implied recognition of his work when it is utilised by others, and that permission to copy the figures in original papers is not, as a rule, asked for, save, perhaps, as a matter of form. But with reference to standard text-books there seems to be much doubt. Prof. Hartog asks, "Would it not be possible to insert a clause specifying that unless the right were expressly reserved, no prosecu-

tion would lie for the making, obtaining, and using of lantern-slides taken from a publication by or for a recognised teacher for class demonstration or the illustration of a paper before a learned society?"

An appeal against the use of the New Forest for military manœuvres, signed by a large number of distinguished zoologists, botanists, ornithologists, entomologists, and other naturalists, appeared in *The Times* of June 2. The appeal, after referring to the use of the New Forest in this way in May, points out that May and June are exactly those months of the whole year in which non-disturbance is of vital importance to the birds, insects, and plants which give to the New Forest its unique interest, not only for men of science, but for all educated persons who take an interest in natural history. The damage done by bodies of troops during this period must inevitably result in a destruction of the wild life of this area that can never again be repaired. The signatories recognise that manœuvres must be held, but express the wish that wild tracts of country other than the New Forest might be utilised for the purpose; and, if this cannot be, that future manœuvres may at any rate be deferred until after July 15, when less harm would be done.

A spell of exceptionally bright and warm weather was experienced over the British Isles at the close of May and at the beginning of the present month, and some exceptionally high temperatures for the time of year have occurred. For thirteen consecutive days, from May 25 to June 6, the shade temperature at Greenwich exceeded 75°, and on June 5 the thermometer registered 84°, which is 1° warmer than any previous reading on the corresponding day since 1841. A heavy thunderstorm occurred in and around the metropolis on May 31, when the rainfall at Greenwich measured 1·0 inch and at Epsom 2·86 inches, of which 2·44 inches fell between 5.20 p.m. and 6.10 p.m. The summary of the weather for the week ending June 3 issued by the Meteorological Office shows that extreme temperatures of 80° and above occurred during the period in nearly all parts of Great Britain, whilst the mean temperature for the week was largely in excess of the average over the entire kingdom, the excess amounting to 9·9° in the west of Scotland to 8·4° in the north-west of England, and to 8·2° in the south-west of England. The bright sunshine exceeded 70 per cent. of the possible duration in nearly all districts. May was exceptionally bright and warm, and at Greenwich the mean temperature was 5° above the normal, whilst on fifteen days the shade thermometer exceeded 70°, and on five days towards the close of the month the thermometer in the sun's rays exceeded 140°. The aggregate rainfall for the month was 1·88 inches, of which 1 inch fell on May 31, and in all rain only fell on nine days. The duration of bright sunshine was 212 hours, which is twenty-five hours more than the average.

The death is announced of Dr. J. C. Oman, author of several books on Indian customs and beliefs, at seventy years of age. From *The Times* we learn that in 1877 Dr. Oman joined the staff of the Lahore Government College as professor of natural science. In the Punjab capital, where he remained for twenty years, he won the esteem and regard of a great number of Indians of all castes and creeds by his sympathetic interest in their doings. When he retired from the Government service he was appointed to the principalship of the Khalsa (Sikh) College at Amritsar, and held the position for two years. His first book, "Indian Life, Religious and Social" (1889), was also, in a much revised and enlarged form, his last, for three years ago it was again issued under the title of "The Cults, Customs, and Superstitions of India." Among his other works are "The Great Indian Epics," which was included in Bohn's Standard Library, "Mystics, Ascetics, and Saints of India," and "Brahmans, Theists, and Muslims of India." Dr. Oman was a Fellow of the Linnean Society; and in recognition of his contributions to Indian ethnology, the degree of D.Litt. was conferred upon him by the Punjab University.

In connection with the recent discovery of remains of Palæolithic man in Jersey, the elaborate monograph by MM. M. Boule and R. Anthony on the skull found at La Chapelle-aux-Saints, published in the March-April issue of *L'Anthropologie*, is of more than ordinary interest. The morphological characteristics of this specimen are very remarkable, and in its simian type it is intermediate between man and the anthropoids. The writers thus record the result of their examination:—"L'encéphale de l'Homme fossile de la Chapelle-aux-Saints est déjà un encéphale humain par l'abondance de sa matière cérébrale. Mais cette matière manque encore de l'organisation supérieure qui caractérise les Hommes actuels."

The question of the existence of that strange birth rite known as the Couvade among the Basque race has been again raised in correspondence in the March-April issue of *L'Anthropologie*. It is now denied that any word in the Basque language describes the practice, which is said to be opposed to the national family system. On the whole, while the extent of the area in which the practice has been alleged to prevail may have been overstated, its existence in certain districts seems to be certain. In view of the rapid modification of national customs now in progress, the writer with some force appeals for a complete re-examination of the question so far as it affects the Basque people.

The July-December (1910) issue of the Journal of the Royal Anthropological Institute, which has recently made a rather belated appearance, is full of interesting matter in connection with the problems of early man. Prof. Boyd Dawkins issues his Huxley lecture on the arrival of man in Britain in the Pleistocene age, in which he confirms his original theory, published in his book on "Early Man in Britain," issued in 1880. He still believes that the cave men have handed down their culture to the Eskimo by means of the post-Glacial hunters in northern Asia. He now so far modifies this theory as to suggest that the facts do not, as he originally supposed, imply identity of race; it may have been brought about by tribes of different race. This must, he imagines, remain an open question until we have more evidence than we now possess of the Palæolithic hunters of Siberia, as well as more evidence from the caves of Europe.

In the July-December (1910) issue of the Journal of the Royal Anthropological Institute Dr. J. H. Anderson, a promising recruit to the school of physical anthropology in Australia, subjects to a searching analysis the existing formulæ for the estimation of cubic capacity in the living, and gives the results of a series of experiments on the actual capacity as determined by the displacement method. This he follows up by a paper of more general interest on the proportionate contents of the skull as demonstrated from an examination of forty Caucasian crania received from the metropolitan hospitals and benevolent asylums of the City of Melbourne. The results are that the brain volume probably decreases with advancing age; that the variation in the volume of the brain is compensated by

an inverse variation in the amount of cerebro-spinal fluid present; and that the dura mater does not vary in proportionate volume with increasing age, but remains constant with a volume from about 4·5 to 5·5 per cent.

In *The Malaya Medical Journal* for April (vol. ix., part ii.) Mr. E. D. Whittle directs attention to what is undoubtedly a description of sleeping sickness published in 1721. It is by a surgeon of the Royal Navy named John Atkins, who in that year sailed to the Guinea coast, and subsequently published a book, "The Navy Surgeon," in 1732, which in an appendix contains a chapter on "the sleepy distemper." This is probably the earliest account of the disease that has yet been found.

In the Bulletin of the Johns Hopkins Hospital for April (xxii., No. 241), Drs. Margaret and Warren Lewis record experiments on the growth of embryonic chick tissues in artificial media. The medium which gave the best results consisted of a mixture of Ringer's saline solution with a little agar and bouillon. In this a fragment of liver from a nine-day-old chick embryo enlarged to four times the original size in forty-eight hours, and the cells of the tissue radiated and migrated into the media and showed all forms of mitotic figures.

In a lecture delivered to the Manchester Clinical Society on the life-history function and inflammation of the appendix (and now issued in book form), Mr. E. Comer points out that appendicitis first became frequent in America at a time more or less contemporaneous with the preparation of flour in steel roller mills; in England the disease approximately dates from the introduction of this milled American flour, and among the blacks in America it similarly appeared when the milled flour became so cheap that it was simpler for them to buy their bread than to take the trouble to prepare their own. It is a curious coincidence if nothing more.

In a circular (No. 110) issued by the United States Department of Agriculture on food customs and diet in American homes, the author, Dr. Langworthy, points out how frequently erroneous statements regarding food and diet are made. Thus it is commonly said that the Chinese and other Oriental races live on a few handfuls of rice a day. Actually, rice with them takes the place of wheat with us as the chief source of starchy food, and is largely supplemented with other food-stuffs. Likewise, if due allowance be made for difference of body-weight, the American professional and business men and Japanese of similar employment consume a diet very similar in amount of protein and number of calories of available energy.

In No. 1828 (vol. xl., pp. 429–33) of the Proceedings of U.S. National Museum Mr. R. L. Moodie describes a third specimen of a salamander (*Eumicrerpeton parvum*) from the Carboniferous of Illinois in which the intestinal tract is preserved. The new specimen is larger and more developed than either of the other two. All three appear to be females, and not one shows any traces of branchiae. In the new specimen the intestine is longer and more convoluted than in the others, lying in five longitudinal folds and ending in a cloaca, near which are impressions of two glands, provisionally regarded as the terminations of oviducts. Eumicrerpeton is a member of the Branchiosauria. Mr. Moodie also describes a microsaurian from the same formation, referred to the genus Amphibamus, as *A. thoracatus*.

A note on the flowering of *Davidia involucrata* in Messrs. J. Veitch's Coombe Wood nursery, communicated by Mr. W. J. Bean to *The Gardener's Chronicle* (May 27), supplies some details regarding this unique monotypic genus, which is placed in the same family with Nyssa, but is not very closely related. The solitary pendulous flower, produced terminally on the branch, has two showy white bracts which subtend a conical receptacle bearing numerous stamens; arising out of the centre of the receptacle is an egg-shaped ovary surmounted by a few apparently barren stamens and several stigmas. The tree now flowering was raised from seed ten years ago, and has meantime reached a height of 14 feet; root pruning in the winter of 1909 may have induced premature flowering.

A memorandum compiled by Mr. F. Booth-Tucker with the object of promoting the more extensive planting of Eucalyptus trees in India has been issued as Bulletin No. 21 of the Agricultural Research Institute, Pusa. Failure in the past being attributed to the selection of unsuitable species, the chief object is to provide a list of suitable species and to indicate the conditions required individually. The species *amygdalina* is strongly recommended, both on account of its hardy nature and also for its economic value; *globulus*, the blue gum, requires a tolerably even climate such as that of the Nilgiris; *marginata*, jarrah, is only suitable for humid regions near the coast; *goniocalyx* is recommended for general forest cultivation.

In connection with the dispersal of fruits and seeds by ocean currents, the example most commonly quoted is that of the coconut, and the coconut palms growing on Krakatau since the eruption are attributed to this agency. This opinion has been previously combated by Dr. O. F. Cook, and he returns to the same charge in a recent number of the Contributions from the United States National Herbarium (vol. xiv., part ii.). His evidence is first directed towards refuting de Candolle's views pointing to the original home of the plant in the Old World, and controverting arguments, amongst others, are taken from a manuscript published in 1625, and the description by Cieza de Leon in the sixteenth century. Then, proceeding from the fact that all other species of Cocos and all species of closely allied genera are natives of South America, the author submits the argument that the coconut palm is a native of inland temperate plateau regions in South America, for which contention notes and illustrations are supplied of coconut palms growing in inland districts in Guatemala.

Geographical distribution and morphological modifications developed in species of Pelargonium form the subject of a paper by Dr. R. Knuth published in Engler's *Botanische Jahrbücher* (Beiblatt No. 103). The genus, comprising about 250 species, is almost entirely confined to Africa, where the chief centre of distribution lies in the extreme south-west. Annuals are few in number and confined to one section; they are characterised by having a short spur. Modifications are most pronounced in the perennials, and are mostly of a xerophytic nature. A string of tuberous thickenings—starch storing—are occasionally formed on the underground stem, and in *Pelargonium moniliforme* several such nodosities lie one above the other. In *P. squamulosum* an apparent collar is produced by the shrinkage of the cortex. In other cases the thickening occurs on the lower aërial portion of the stem, as in the section Otidea, and serves for water storage. Woody development of the petioles becomes most evident when the blade falls away and the petiole persists as a spine, as in *P. spinosum*.

DR. MILBURN has recently issued his reports on field trials with oats, mangolds, and nitrogenous manures carried out at various centres in Lancashire. The work is still in progress, but it was thought advisable to publish the available information for the benefit of farmers during the coming season. Demonstrations of this kind have been found of considerable benefit to the farmer, as they deal with problems that he cannot solve by himself, but that affect his profits considerably.

THE South African Association for the Advancement of Science issues each month *The South African Journal of Science*, containing original papers by its members, and notes extracted from other sources. No. 5 of the Journal contains an account by Messrs. Lundie and Hallack of seaweeds as manure, illustrated by several analyses of South African seaweeds. A new Cape thermal chalybeate spring is described by Mr. Rose; it contains 1·7 grains of ferrous carbonate and 25·7 grains of sodium chloride per gallon, and has a temperature of 129° Fahr. It is being exploited for curative purposes. There is also an article by Profs. Gilchrist and Thompson on the Cape klip-fishes (Clinus).

THE value of nicotine as an insecticide has long been recognised. A wash containing one ounce in ten gallons of water kills many of the worst insect pests that trouble the fruit- and hop-grower, including the apple sucker (*Psylla mali*), all kinds of aphides (Aphididæ), thrips or thunder-flies (Thripidæ), the larvæ of the winter moth (*Cheimatobia brumata*), and most young caterpillars. But unfortunately nicotine is too expensive for common use at present, and its price seems likely to rise, since it is now in demand for sheep-washes; the only hope for a fall in price is the more extended cultivation of tobacco. Experiments by Mr. Garrad at the Wye Agricultural College indicate that coarse varieties of tobacco can be grown here to produce nicotine at a rate much below the present market price.

The Agricultural Ledger, No. 3, issued from the Indian Government printing office, contains an account of the soya bean in India, by Mr. David Hooper, of the Indian Museum, Calcutta. Although the crop is not indigenous to India (its home being the extreme east of Asia), it has long been cultivated by certain hill tribes, mostly of Mongolian origin. Only recently, however, have any attempts been made at cultivation on the large scale, and it is not yet clear how far it is likely to succeed. Mr. Hooper points out several advantages of the crop: it is highly nitrogenous, and is therefore a valuable article of human diet in rice-eating countries; it can be made into certain food preparations—the Japanese make a soy-bean milk, a soy-bean cheese, and the shoyu sauce—and it also constitutes excellent cattle food, either in the unripened state as hay or as an oil cake. Numerous analyses of samples of the beans grown in India are given.

AN insect pest known as the froghopper has for some years been a source of serious trouble to the West Indian sugar planters. Not only does it cause a reduction in the weight of cane per acre, but it also adversely affects the quantity of sugar per ton of cane and the purity of the juice. The insect has now been identified by Mr. F. W. Urich as *Tomaspis varia*, Fabr., and a complete account of present knowledge of its life-history, its effect on the cane, and methods of control is given by Dr. L. H. Gough in Bulletin 67 of the Department of Agriculture for Trinidad. In the same publication Mr. Urich describes the cacao thrips (*Heliothrips rubrocinctus*, Giard), and gives some well-drawn coloured illustrations of the insect and the damaged pods and leaves.

AMONG various useful items contained in the meteorological charts of the North Atlantic and Indian Oceans for the month of June, issued by the Meteorological Committee, there is an interesting article on the phenomenon known as St. Elmo's Fire or corposants (*corpus sanctum*), the harmless luminous electricity of low intensity seen sometimes at night on ships' masts, &c., during unsettled weather. Many examples of authenticated experiences in olden and modern times are quoted, *e.g.* one by Columbus in October, 1495, during a severe storm. It was then assumed that the light emanated from the saint's body, and was a sure sign that the gale was at its maximum. In Dampier's time, 1687, a display was also accepted as a favourable omen, but in this case proved to be misleading, as the force of the wind continued to increase. The phenomenon is not unfrequent on land; it was quoted by Cæsar and others. On the summit of Ben Nevis the observatory was at times ablaze with it; the observers were not in any way inconvenienced, except by a slight tickling sensation in head and hands. Its behaviour furnishes an illustration of the elementary principle relating to the action of points on electrified bodies.

As an abstract from the *Jahrbuch de Hamburgischen wissenschaftlichen Anstalten*, vol. xxvii., we have received a brochure in which Dr. B. Walter describes and discusses a number of photographs of lightning. These photographs were taken in pairs, simultaneously, one plate being exposed in a stationary camera, the other in a camera which was moved by clockwork at a known rate. In the case of a single discharge, both plates register, of course, the same form, but in the frequent event of several subsequent flashes travelling down the lane of air ionised by the first discharge, the several flashes are seen separately; knowing the rate of angular motion of the moving plate and the focal length of the objective, it becomes a simple matter to determine the intervals of time separating these several flashes. On the five plate reproductions accompanying Dr. Walter's paper, such multiple flashes, sometimes occurring with single discharges from the same cloud, are clearly shown. For one of the sets of multiple discharge shown Dr. Walter finds that the time-intervals between five flashes taking the same path were 0·038s., 0·110s., 0·163s., and 0·080s., making a total duration of 0·391s. for the whole discharge. Dr. Walter considers a number of such cases, and deduces valuable results concerning the nature, intensity, and duration of the various forms of discharge.

THE special facilities which Prof. Raoul Pictet possesses in his laboratory at Berlin for carrying out experiments on low temperatures justify the interest with which the account he gave of his work at the meeting of the Royal Society of Arts on May 17 has been received. The experiments cover a wide field, but they centre round the fact that chemical processes which take place with freedom at ordinary temperatures are completely stopped at low temperatures, and for each process a temperature can be found for which it is just possible for it to occur. The determination and tabulation of these temperatures would, in the opinion of Prof. Pictet, constitute an important advance towards a dynamical theory of chemical processes. Such a theory, he points out, was published by him in the *Archives des Sciences phys. et Nat.* thirty-two years ago. It is founded on the definition of temperature as the mean amplitude of the vibratory oscillations of the molecules of a body, and of specific heat as the mean attraction of the body on the molecule. By means of these definitions he arrives at the conclusion that all physical and chemical phenomena can be accounted for by the existence of two distances apart at which two attracting masses will be in

stable equilibrium, and a third intermediate distance at which they are in unstable equilibrium. As Prof. Pictet's definitions differ so materially from those generally accepted at the present time, and his method of deduction is not very conclusive, or even at times clear, the theoretical portion of his address falls far behind the experimental in point of interest and importance.

THE launch of the *Titanic* took place at Belfast on May 31, and forms the subject of an illustrated article in *The Engineer* for June 2. The arrangements for launching were similar to those of the *Olympic*, and the ship took sixty-two seconds from the first movement until she was afloat. The launching weight was 25,000 tons. The hydraulic rams fitted in order to start the ship were not requisitioned. We understand that the *Olympic* has completed most satisfactory trials, and has been handed over to her owners a month before her time.

Engineering for June 2 contains an illustrated description of the yacht *Progress*, fitted with 100 indicated horse-power gas engine and produced and owned by the Empire Oil Engine Syndicate, Ltd., of London. Owing to the cost of oil fuel in many parts of the world, it seems certain that marine internal-combustion engines must be capable of using gas derived from ordinary coal. The engines of this yacht are on the two-cycle double-action principle, driving the propeller direct without the interposition of any gearing. The gas supply is from a suction producer, which has been worked with anthracite, with coke, and with coalite. The patentees are convinced that their accumulated experience will enable them to supply a producer capable of working satisfactorily with ordinary steam coal. The engines are so arranged as to secure great ease in manipulation; as instancing the handiness of the engines, it may be stated that, on coming out of dock on one occasion, twenty-six different movements were made in the course of twenty-one minutes. The time taken to reverse has been found to be from three to four seconds after the order is given. It is intended to build a second engine to develop from 350 to 400 horse-power, and a corresponding gas plant, in both of which a number of improvements in detail will be embodied. This plant will be fitted on board a vessel of the commercial type.

A "GRAPH TEMPLATE," designed by Mr. J. T. Dufton, by means of which standard rectangular hyperbolas and parabolas of large size can be drawn readily on squared paper, has been put upon the market by Messrs. Macmillan and Co., Ltd. The price of the template in transparent celluloid, with instructions, is 6*d*. net, and in nickel-plated metal 3*d*. net.

By a printer's error, the inscriptions of the two illustrations from "Kearton's Nature Pictures" reproduced in last week's NATURE (p. 450) were unfortunately transposed.

OUR ASTRONOMICAL COLUMN.

NOVA SAGITTARII NO. 4.—Circular 164 of the Harvard College Observatory announces the discovery of yet another nova in the constellation Sagittarius. This object was found by Miss Cannon during a rapid comparison of various photographs of the Harvard Map of the Sky on Map 43. It appears on eleven photographs taken between May 22 and July 9, 1901, but no trace of it can be found on 148 other plates taken in 1892, 3, 5, 6, 7, 8, and 9, and each year from 1900 to 1910 inclusive; each of these shows the C.D.M. star $-27°12411$, of magnitude 9·7, with which the nova at its maximum was equal in photographic magnitude. The exact date of the nova's appearance cannot be fixed, but the greatest observed brightness was 10·3 on May 22, 1901, and it is not shown on a plate taken on April 10, 1901, although this plate shows a fourteenth-magnitude star 0·3′ south of the nova. The fluctuations of brightness appear to be somewhat similar to those of Nova Persei (2). It is of interest to note that seven novæ are now known to have appeared in the region covered by Map 43.

THE MECHANICAL PRODUCTION OF THE STREAMERS SEEN IN THE SOLAR CORONA.—In order to test the theory that the shapes of observed coronal streams may be accounted for on the assumption that they are the natural production of certain defined mechanical forces, Prof. J. A. Miller examined the excellent series of corona photographs now available at the Lick Observatory, and he publishes the results of his discussion in No. 4, vol. xxxiii., of *The Astrophysical Journal*.

If the streamers are formed of particles ejected from the sun under the influence of the solar rotation, of the attraction and of the radiant pressure of the sun, certain shapes should theoretically ensue, and the velocity and direction at any point of the stream can be calculated. Prof. Miller has done this, and finds that not only do the observed streamers largely conform with his theoretical results, but he is able to compute and draw theoretical streamers, for the conditions obtaining at any one eclipse, which agree with those actually observed. Various modifications occur, but may be accounted for by reasonable assumptions of modified conditions; for example, the particles at the end of a stream are probably finer than those at the base, and therefore the sun's radiant pressure would act more strongly on them, or it may be that the particles of a stream are moving in a resisting medium which is denser in the inner than in the outer corona, and each of these causes would produce the differences observed between the computed and the observed results.

THE GENERAL PERTURBATIONS OF EROS.—A lengthy discussion of the general perturbations of the planet Eros is published by Herr H. Samter in No. 4498 of the *Astronomische Nachrichten*. The author tabulates his results for the combined perturbations by Jupiter, Saturn, and Venus, which were easily determined by Hansen's method, and in further tables gives the results of the earth's perturbations and those of Mars.

DETERMINATION OF THE APEX.—From the study of 620 stars having large proper motions, Dr. A. Wilkens has made a new study of the position of the apex. The stars are given in the Wilkens catalogue of 620 stars between 29° 50′ and 35° 10′ N., for 1875, and the Leyden A.G. catalogue, and include 267 having proper motions of 0″–5″; 173, 5″–10″; 76, 10″–15″; 35, 15″–20″; and 69 greater than 20″ per century. They also include 233 stars brighter than 8·5, but mostly fainter than 7·5, mag., 282 between 8·5 and 9·0 mag., and 105 fainter than the ninth magnitude. The resulting value for the position of the apex is $A=286°$, $D=+37°$, which is in good agreement with most modern estimations (*Astronomische Nachrichten*, No. 4499).

THE SPECTRA OF COMETS.—Visual observations of the spectra of comets 1908 III. (Morehouse), 1909*c* (Halley), and 1910*a*, are recorded by Herr von Konkoly in No. 4499 of the *Astronomische Nachrichten*. Bands were measured at 561·0 $\mu\mu$, 544·0 $\mu\mu$, and 515 $\mu\mu$ in the spectrum of 1908 III. on September 18, 1908, their respective intensities being 0·4, 0·6, and 1·0; the same bands were seen on September 22, but the wave-length in each of the last two was 1 $\mu\mu$ less. The red end of the spectrum was much brighter than the violet, and of the band at 470 $\mu\mu$ there was no trace.

Halley's comet on February 12 and May 26, 1910, gave a faint spectrum in which the same bands, with slightly varying wave-lengths, were seen. With a larger instrument, two other bands at 586·0 $\mu\mu$ and 472 $\mu\mu$ were seen, and possibly a third at 482 $\mu\mu$. The bands were very bright while the continuous spectrum was abnormally faint. From nineteen separate observations, the wave-lengths of the bands in Halley's comet were found to be 586·0, 561·5, 543·7, 514·7, and 472·0 $\mu\mu$.

The spectrum of comet 1910*a* gave bands at 556·0, 537·0, 512·0, and 481·0 $\mu\mu$.

THE BRITISH SOLAR ECLIPSE EXPEDITION.[1]

Aboard H.M.S. "Encounter."

April 12, 1911.

MY last letter was concluded when the Tonga Islands came in sight, for I knew that as soon as we dropped anchor my time would be fully occupied. We have now been here ten days, so there is much eclipse matter to report. The approach to our destined spot, namely, Neiafu, was beautiful in the extreme. The numerous islands of various sizes which form this large group opened out one by one. Some amounted only to rocks sticking up out of the water, whilst others extended over several acres, and were densely covered with trees, the useful cocoanut palms towering above them. Every island was so luxuriant with this thick verdure that I began to think we should have to utilise some of the ground at the Neiafu village itself.

Hunga on our port side and Nua Papu on the starboard were the first two large islands we passed, and then we took a more easterly course and came to the large island of Vavau, with the conspicuous hill called Moungalafa ahead. We entered a narrow channel separating the island of Pangai Motu from Vavau. Passing up this channel, it looked as if further progress would be impossible. Right ahead were two pyramid-shaped landmarks at the foot of Kilikili, a hill 220 feet high, and here was the gate to the chief town Neiafu; the channel became still more narrow, until it looked as if the good ship *Encounter* would be too large to swing round to go through the small entrance. In fact, it was a case of turning a sharp corner to keep in the middle of the fairway. The manœuvre was splendidly made, and we slipped into this nearly land-locked harbour; looking back, one began to wonder how it had been accomplished, so invisible was the entrance.

Well, here we were at Neiafu at last. Our anchor was dropped at 3.40 p.m. on April 2, and before us lay a picturesque-looking island town, with numerous flags flying over the houses.

It was not long before the health officer, Dr. Anderson, pushed off from the shore, for he had heard the gun which is always fired as soon as a ship is seen coming into the harbour. He was pulled out to the ship by a crew of finely built Tongaus. It was noticeable that all, even the doctor, were covered with hundreds of flies, and these (including mosquitoes) I later found to be the most populous inhabitants ashore.

Dr. Anderson told us that "measles" had been passing through Vavau, and that there were still a few cases, one of them being a European who was in hospital. This news suggested that it would be policy to find a site for our eclipse camp somewhere out of the town. Dr. Anderson kindly placed the ground about his house at my disposal for a site for the instruments, but when I inspected it later in the afternoon I found that it was not large enough, and unsuitable for so large a party. In fact, when I was ashore I could see no site that was at once a favourable spot. Mr. Worthington and Mr. Cruickshank, who had preceded us from England to observe the eclipse, had already been on the island some three weeks, and we visited their living tents and eclipse site, which were in the heart of the village.

Before reaching Vavau I had carefully studied the chart of the region, and came to the conclusion that it was well worth while visiting the spot, marked as an Admiralty coaling station, about a mile from Neiafu. Here I thought we should be free from all the disadvantages of a native town. The same evening I dined alone with the captain, and we determined that this site should be inspected.

[1] Continued from p. 463.

Accordingly, next morning, April 3, the captain, Mr. McClean, Fathers Cortie and Pigot, and myself set off in the steamboat and landed up the boat passage near the coaling ground called Umuna. We found that part of the ground was fairly level, high up, and partially cleared, and that by cutting down only about six cocoanut trees and doing a small amount of scrub clearing we should have a first-rate observing station. It did not seem difficult either to find a place where our instruments could be landed, so while Captain Colomb returned to the ship to meet the Governor, Mr. McClean, Father Pigot, and I remained and explored the seashore for possible landing places. In most places there was a steep coral front, but at Bai bai we found an admirable spot, and very close to the site. Fortunately, the captain returned to the ground with the Governor while we were still making investigations. The Governor, who is a native, and communicated with us by means of a native interpreter, told us that the ground was Admiralty property, and that the native who used it as a garden was only a kind of caretaker. This made things easy, for we were then entitled to cut down the necessary trees and make any clearing that was required. Most suitable and

FIG. 1.—The position taken up by H.M.S. *Encounter* close to the Eclipse Station. The photograph was taken from the Hill Muikilekila, 180 feet high.

picturesque places for the guards' camp, the living tents for the shore astronomical party, and other spots for the captain's wife and the officers' wives, who were coming from Australia, could be seen at a glance. In fact, the site could not really have been a better one, and the soil on which the instruments were to be placed was sufficiently rigid and dried very hard. The result of this inspection was so eminently satisfactory to the captain, Father Cortie, and myself that the first-named decided to move the ship right up the harbour and lay her off the observatory site.

The same afternoon anchor was weighed, and we steamed slowly up this beautiful inland sea, dropping it again at the mooring mark, which had been placed in position by the navigating officer, Lieut. Hurst, as a result of his survey in the morning. A shore party, including officers, then went off to the site to get a general idea of the nature of the selected spot.

Tuesday, April 4, was a very busy day. Clearing the ground was at once taken in hand, and a path was cut straight down to the spot selected for landing the cases. Numerous natives came on the scene to clear away the yams, a kind of bread fruit, which were growing on the site. A party from the ship set to work to erect the living tents. The site for Captain and Mrs. Colomb's quarters, selected by the Governor, had been previously

cleared by the local authorities. Great signs of activity were being shown, for the Union Steamship *Atua* was due to arrive in the afternoon with the officers' wives and three members of my party, namely, Messrs. Brooks, Raymond, and Winklemann. Owing to the living accommodation on shore not being quite ready, Captain Colomb kindly permitted the latter three to remain on the ship that night. The *Atua* brought also a portion of the Australian party, namely, Messrs. Moors, Merfield, Holloway, Paradice, and Burne, the site of whose camp had been settled near the Catholic Mission Church at Neiafu.

Since we arrived it has been very hot. On shore it is comparatively cool up to about 7 a.m. The temperature, however, quickly rises after, and between two and four o'clock in the afternoon it is extremely hot, the thermometer being at a maximum about 3.30 p.m. The two self-recording instruments which I set up in the camp tell us the temperature and the humidity of the shade air. The daily curves of these are the reverse of each other, the temperature rising when the humidity is falling. This is very fortunate, for the humidity is always high and the shade temperature at a daily maximum of about 86°. The self-recording barograph I still keep in my cabin on board, and this is daily marking out the two small diurnal oscillations with a long secular wave extending over many days.

FIG. 2.—The shore party's tents on the east side of the hill on which is situated the observatory station. The marks from left to right when looking at the photograph indicate :—1. Brother McKeon, 2. Dr. W. J. S. Lockyer. 3. Mr. Raymond. 4. Mr. Brooks. 5. Lieut. Clover. 6. Mr. F. K. McClean.

Wednesday, April 5, was occupied mainly in bringing all the instrumental gear from the ship to the instrument tents ashore. A most effective method was adopted to obviate the difficulty of the rise and fall of the tide: a landing stage jutting out several yards was improvised, and the boats came alongside and discharged their cargo. Block and tackle and a stout tree at the top of the 20-foot sharp rise at the shore, coupled with the strength of several hale and hearty bluejackets, quickly settled the question of hauling the cases up the inclined spars. If the cases were not too heavy, two men with one case slung over a spar carried it to the camp, whilst if it were rather heavy the limber from the gun (which had been previously landed) and a team of bluejackets made short work of it all. Working from 8.30 a.m. to 11.30 a.m., and from 2.30 p.m. to 4.30 p.m., both Father Cortie's cases and mine were all transferred from the ship to the instrument tents. In this way eclipsing is made very easy.

Up to this time no cocoanut trees had been cut down, as it was desired to preserve as many as possible, for each tree brings in an annual income of four shillings a year and takes six years to grow to a bearing condition. However, four trees had to come down as a first approximation, and these were felled the same afternoon; it has only been found necessary at the time of writing to cut down five altogether. On Wednesday a record, so far as I am aware, has been broken in eclipse expeditions with a man-of-war, for the guards' camp ashore and the ship have been connected by telephone, most of the cable being under water; on previous occasions a signal station and flag waving was the procedure adopted. Until to-day, Messrs. Brooks, Raymond, and Winklemann of my party have been sleeping ashore, as the three tents were fully prepared. To-day two more tents were completed, so Mr. McClean and Mr. Anderson joined them, and I still remained on board at night. The row of seven tents and the large mess tent dotted among the cocoanut trees, and situated on the trade-wind side of the hill, forms a very pretty picture and a cool spot when one has been on the eclipse site for some time. Flies and mosquitoes are there, however, in abundance, and spiders, large and small, galore.

The dark-room lies in a cool shady corner near the living camp. This position was chosen as all water has to come from the ship, and most of it daily goes to the living quarters, so labour is saved. To-day the positions of all the large instruments were carefully pegged out, and parties were sent to skirmish for sand and deal coral for the pillars, which will be erected immediately. Mr. Brooks has been busy with his theodolite, laying out the north and south lines for the siderostats and the correct azimuths for the cœlostats. To-day a crow's-nest has been erected on a tall cocoanut tree overlooking the ground, so that our hard-working photographer, Mr. Winklemann, and his two assistants can secure a good view of the whole eclipse camp as it progresses daily.

After consultation with my party, I have decided to sleep on board at night, so as to be a link between the ship and the shore party. This I consider to be advisable, as we require so much material and help each day. To-night three sharks were swimming about the ship, and many lines with hooks and pork were over the sides to tempt these hated brutes. Although almost daily sharks are present, no catch has been successful yet. According to the statements made by the Europeans here, the Tongaus can call the sharks by uttering native words. We have not seen this put into practice, but there is yet time.

Daily we have quite a lot of small fracto-cumuli clouds moving slowly across us, but the weather is thoroughly hot and tropical. Those living here inform us that we are having rather abnormally fine weather, as was the case in Australia. The weather, therefore, seems to be abnormal in this portion of the southern hemisphere, and we are hoping that the fates will be kind to us when we come to eclipse day.

Every day the camp shows great signs of progress. Levelling, making concrete pillars, covering small huts with willerden canvas, and similar operations being in progress. On April 7 several parties who could be freed from the eclipse camp went off collecting for the "'ologies" specimens of coral, flowers, butterflies, fossils, shells, &c. This specimen collecting is taken up very keenly, and I hope to have a good selection to bring back. The navigating officer is leaving the ship next week with a diving staff for Nukualofa to help salvage the ss. *Bouveric*, which has piled up on a coral reef. The captain was asked whether the *Encounter* could assist, but in reply to his message to the Admiralty for instructions he was informed that he could only render assistance if it did not affect the eclipse parties. At our present site we are now entirely dependent on the ship, and most especially for water, so Captain Colomb has decided that Lieut. Hurst, the navigator, should go by mail steamer and do what he can with divers and

explosives. Lieut. Hurst was a volunteer for the time determination as observed by the cusps, so he has now been replaced by Lieut. Clover.

On the evening of April 7 Commander Mellor, Father Cortie, and I went ashore after dinner to Neiafu to inquire about Prof. Moor, one of the Australian party, who had an accident yesterday. It seems that after a hard day's work he went to bathe, and while undressing fell from the bathing platform into very shallow water on to coral. He not only cut the back of his head badly, but his back, and he was in bed suffering from concussion. He is now (April 12) progressing, but he is suffering with his sight, and may have to return to Australia by the next steamer.

FIG. 3.—Preparing concrete for the pillars. Sand, cement, and dead coral (the last-mentioned quarried from the top of the hill) were used.

After another hard day's work on Saturday, when good progress was made in all directions, Sunday was considered a day of rest. Mr. McClean and Mr. Brooks preferred to stay ashore, Mr. Raymond and Mr. Winklemann went to Neiafu photographing, while Mr. Anderson and I went off for a sailing picnic with some of the officers. We visited the famous "Swallows'" Cave; hundreds of swallows flew out as we rowed in. The cave is of considerable dimensions, and its upper portion is a mass of stalactites. One projects vertically upwards from a ledge on the side, and when hit with a boat-hook it gives out a beautiful low tone like a large bell. The water in this cave is very deep and clear, and when it was thought no sharks were about some of the party indulged in a bathe. Lunch was partaken on a small sandy beach a mile or so away in the presence of thousands of flies, and there I made a collection of several shells and seeds. On our return in the evening we again entered "Swallows'" Cave, as the sun was well round and shining nearly in it. The colours of the water were superb, but the heat and the innumerable mosquitoes and flies made our stay shorter than we intended.

On Monday (April 10) at 2 a.m. very heavy rain fell, but as there was little wind and my bunk was placed well in the middle of the quarter-deck, I did not wake. Every night many of us sleep on the quarter-deck or after-bridge, and we dine on the former also. The ward-room gets very hot after the day's sunning, and the ship is so kedged that the wind strikes the starboard side; the port side is therefore the sunny and leeward side. The temperature in my cabin, with scuttle open and electric fan working, varies during the day time from about 84° to 90° F.

Unfortunately, on Monday Mr. Brooks, while chopping a piece of wood with an axe, cut his left-hand thumb badly. Staff-Surgeon Milln soon stitched it up for him when he got on board.

In the evening, during dinner, clouds appeared in the east, indicative of vertical currents, very tall cumuli clouds with flat bottoms. The wind began gradually to increase from a slight zephyr to a cooling breeze, and became fairly strong about 9.30 p.m., and the rain came down in torrents. While thinking of those living ashore and the instruments, we had to rush to remove our bunks from the deck, for the awning was of no apparent use.

This shower gave one some idea of how it can rain here, although up to now we have experienced very little of it. I made up my mind, therefore, to prepare for all eventualities. Thus Tuesday morning was chiefly spent in digging trenches. Fortunately, the dark-room had previously been dealt with in this manner, and could not be washed out. That afternoon was the climax. Down the rain came again in torrents. Mr. McClean and I went round the camp to see that all was in order, and at the same time obtained a good idea of what to do in the future. Although these rain squalls may not be numerous, they are tremendously heavy when they do come, and one thickness of canvas barely keeps the rain out. Fortunately, the ship can supply a great number of small waterproof coverings, and I expect we shall indent for most of them. Even to-day (April 12) rain has been frequent, and prevented much opening up of instruments. The sky was completely overcast in the early morning, and all day blue sky has been rarely seen. Later in the afternoon we had another deluge; but now we are well prepared, and do not mind so much. The humidity here is very high, and everything exposed to the air quickly rusts, even keys in one's pockets.

FIG. 4.—The 6-in. prismatic camera in course of erection.

Nevertheless, we are all a very cheerful party, and the assistance from the ship is magnificent. This evening the *Tofua* is expected to arrive, bringing more of the

Australian party, namely, Messrs. Baracchi, Cooke, Dodwell, Kenney, and Beattie, and Mr. Short for Worthington's party. This is the last post until after the eclipse. We will do our best to keep the flag flying on that eventful day, but we must have a clear sky.

W. J. S. LOCKYER.

N.B.—The photographs accompanying this letter were all taken (with one exception) by Mr. Winklemann. They were printed by a bluejacket on board H.M.S. *Encounter*, as conditions were not favourable for the process ashore. This bluejacket is a volunteer for our photographic department, and a very valuable one. W. J. S. L.

PHYSIOGRAPHIC STUDIES IN THE FRENCH ALPS.

THE former of the two memoirs included in the publication before us is a report by MM. Flusin and Bernard upon an apparatus for boring into a glacier, devised by MM. Hess and Blümcke, the working of which they had studied on the Hintereisferner in the Austrian Tirol. As the scientific interest of this is at present more indirect than direct, we may pass on to the second memoir, "Etudes Glaciaires Géographiques et Botaniques dans le Massif des Grandes Rousses," by MM. Flusin, Jacob, and Offner.

The Grandes Rousses is a rather lofty and insulated range in the French Alps, which rises on the right bank of the Romanche, roughly north-east of Bourg d'Oisans. On its jagged crest, which runs approximately from N.N.E. to S.S.W., two peaks, though some distance apart, attain the same altitude—11,395 feet. Its western side descends more abruptly than the eastern, so the glaciers on the former are shorter and steeper than on the other. It is an island ridge of crystalline rock—granites more or less gneissoid, and schists—rising from a hilly district of Lower Mesozoic (chiefly Liassic) rocks, mainly, no doubt, a result of the second of the two great folding processes which have given birth to the Alpine chain.

First in order, to the west of the watershed between France and Italy, is the great mass of crystalline peaks which rise around the headwaters of the Vénéon—two of them, the Ecrins and Meije, exceeding 13,000 feet in height—and are linked by the Col du Lautaret to the mountains south of the Arc. Farther west is the range of the Grandes Rousses, and still farther in that direction, separated by another syncline of Mesozoic rock, comes that of the Belledonne, the highest peak on which attains 9781 feet. The Ecrins *massif* is probably an extension (though perhaps not a simple one) of the Mont Blanc axis; the Grandes Rousses and the Belledonne, a prolongation of that of the Arguilles Rouges, which has either bifurcated or raised up another earth-wave in front. But the Grandes Rousses *massif* affords evidence of a much more ancient system of disturbances, for two strips of Carboniferous rocks (as may be seen in the valley of the Romanche) are sharply infolded in the crystalline series—just as occurs in the valley of the Rhone and on the way from Vernayaz to the Tête Noire. The author attributes this folding to the Hercynian movements, though its strike is much more nearly north and south than east and west. It was, at any rate, succeeded by enormous denudation, for in this part of the Alps the base of the Mesozoic series may be seen resting on the denuded edges of these huge folds.

The report includes a study of the Alpine plants in the three regions or stages into which the range may be divided, and a very full account of the snowfields and glaciers. The snow-line, of course, varies in different localities, but the authors take 8720 feet as an average, which very nearly coincides with the limit of the *névé*, that is, where ablation balances accumulation, or expenditure just exhausts income in the matter of snow. This limit, they point out, rises as the altitude of a group increases, being about 650 feet higher in the Grandes Rousses than in the Belledonne, while in the eastern *massif* it overtops the former by 400 or 500 feet, a result which seems to call for explanation. Particulars also of the retreat of the glaciers are given, with maps and some interesting photographs; in short, the memoir is a most elaborate one, though we cannot forbear remarking that if a similar exhaustive treatment is applied to other parts of the Alps—and the practice seems to be growing—conscientious students will before long often have to choose between hours in a library and work in the field.

THE MOVEMENT OF SUBSOIL WATER.[1]

IN all densely populated areas the water supply is a matter of primary importance, especially where the rainfall is scanty, and where a large proportion of the supply is derived from shallow wells. Dr. W. F. Smeeth, of the Geological Department of Mysore, has prepared a report dealing with this subject, which is based upon observations made during the year 1909, so that it provides rather a basis for further study than a complete discussion of the subject. The Mysore plateau extends over some 29,400 square miles, and is composed almost entirely of gneisses, granites, and crystalline schists, which are more or less decomposed to a depth of from 50 to in some places as much as 100 feet; the upper 50 feet of this forms a reservoir which is fed by the rainfall, and will hold a quantity of water varying with the porosity of the materials, and from it the wells derive their supply. On account of the seasonal character of the rainfall the level of the water-table varies considerably, and from various considerations the author takes a zone of intermittent saturation having a mean depth of 10 feet, and an average porosity of 12 per cent., as representing the average conditions which occur.

The rainfall varies greatly, from 73·21 inches in the west to 21·27 inches in the east of the area, and from the average variation of the water-level in wells, compared with a ground water supply which is taken as equal to 10 per cent. of the variation in the water level in each district, a "percolation factor" is obtained. No river discharges are included, nor is evaporation determined in order to obtain an independent value of the amount accounted for by percolation, which by the method employed is given as from 19·9 to 66·7 per cent. of the average rainfall. The rainfall also differs considerably in type in different portions of the area, having a strongly marked maximum in July due to the south-west monsoon in the west, while in the east the rainfall of the north-east monsoon in September and October is more important.

Observations were collected so far as possible from all villages, and 2563 wells were recorded from which fairly representative deductions for the year under investigation were possible. The mean depth of the water from the surface varied from about 38 to 4 feet, the mean values for maximum and minimum depths being 30 and 18, while the mean variation in the course of the year was 12·4 feet, and 27·5 per cent. of the wells were reported as drying up during the year. The variations of level ranged from an average of 15·3 feet for shallow wells in which the minimum depth to water-level was under 10 feet, to 8·2 feet in those where it was over 40 feet. Details of the water met with in the Mysore mines is included, but not much is deducible from such information at present. A series of diagrams show the position of the maximum and minimum water-levels in the village wells observed, and it is clear that a large number of them do not reach the depressed water-table of the dry season, since the conditions are not realised by the well owners. Deeper and fewer wells are recommended with pumping where necessary, and a systematic distribution of the permanent supply so obtained. Further investigation is recommended for the seasonal variation of water-level in different districts has not been considered. While diagrams are abundant, maps of the region, whether topographical, orographical, or showing the distribution of the rainfall, are conspicuous by their absence, and render a satisfactory study of the report difficult.

Although the Nile and its system of canals provide most

[1] "Notes on the Underground Water Resources in Mysoer." By Dr. W. F. Smeeth. Pp. 69, plates 1–69. (Government Press, 1911.)

of the water needed by the population of Egypt, nevertheless many questions connected with the increase of population in towns and with intensive cultivation have lately directed attention to the position and the movements of the water-table in the alluvial plain of the Lower Nile. After some preliminary work in previous years, a more systematic investigation was started in Upper Egypt from Aswan to Cairo, in 1907–8, to obtain definite information. This has now been published in the form of a departmental paper by Mr. H. T. Ferrar, of the Geological Survey of Egypt.[1] Observations were made at 239 wells which were visited, and the water-level recorded an average of eight times during the twelve months from one flood of the river to the next; since no rainfall occurs to complicate the conditions, these data were sufficient to define with adequate accuracy the range and movement of the water-table in that year. The rock trough in which the Nile flows is largely filled by pleistocene sands and gravels, over which the alluvial deposits have been laid down, and into these the wells from which water-wheels lift water are usually dug down through the alluvium and into the underlying sands; from these wells most of the observations were taken. At many points the Nile itself has cut into these sandy diluvial deposits, or flows against them at the margin of the valley, so that the river water is in communication with both deposits. A series of diagrams show the variation of the water-level in each well throughout the year, and also the position of the water-table for each month at fifteen different points of the river. Slight differences due to variations in porosity, &c., are to be seen, but the whole gives a very clear picture of the movement of subsoil water. The lines for September and October show its rapid rise, after which the fall commences, being greatest between December and January and afterwards decreasing. In these later months there is often a slope towards the river, and an appreciable amount of stored water is then returned from the flood plain to the river. It would have been preferable if the observed values had been indicated on the diagrams and the depths of the wells drawn, as the curves do not show to what extent they are controlled by data without reference to the printed tables.

In subsequent chapters an attempt is made to compute the quantity of water which the alluvial plain can hold, 60 per cent. by volume being taken as the water absorbed by the soil, but measured discharges of the river and canals are not utilised, and the values obtained cannot be regarded as more than rough approximations. Data for determining the direction of movement are scanty; near the river, results vary greatly within short distances, and in villages any use of colouring matter in such investigations would arouse much hostility. A large amount of valuable data has been collected, which greatly increases our knowledge of the water in the Nile valley, and must be of the greatest value for agriculture and for public health. The wells of the flood-plain are grouped into those of the river margin which are immediately affected by its changes of level, those of the plain which have an annual rise and fall about a month and a half after that of the river, and those close to the desert margin where the range is comparatively small. Further investigation on the same lines has been carried on since in the delta, which will be published in due course, forming a study of much value which, it is to be hoped, will be continued in the future.

[1] "The Movements of the Subsoil Water in Upper Egypt." By H. T. Ferrar. (Cairo: Survey Dept. Paper No. 19, 1911.)

THE ROYAL OBSERVATORY, GREENWICH.

MR. DYSON'S first report—as Astronomer Royal—was read at the annual meeting of the Board of Visitors held at Greenwich on June 2, and covers the year ended May 10. Below we give a brief summary.

The transit circle was employed for the usual observations and for the observation of stars of magnitude 9·0 and brighter between +24° and +32° north declination. The latter research, commenced in 1906 with the intention of securing five observations of each star, includes some 12,000 stars, and about 48 per cent. of the observations were completed at the date of report.

From the transit-circle and altazimuth observations of the moon's limb and Mösting A, made during 1909, the mean error of the moon's tabular place was found to be −0·423s. in R.A. and −0·53″ in N.P.D.; from ninety-eight observations with the transit-circle, the mean error in R.A., for 1910, was found to be −0·543s.

A new mercury trough has been added to the altazimuth. It is carried on iron rails quite isolated from the floor, and the steadiness of the star images has become greatly improved.

Values for the moon's parallax have been obtained from the Cape-Greenwich observations of Mosting A, made during 1905–10, and the probable error of the result, so far as it is independent of the earth's ellipticity, is ±0·06″. For values of $1/e$ ranging from 293 to 300, the correction to Hansen's value of the parallax ranges from +0·53″ to +0·12″; the combined results give +0·44″ as the correction and 294·5 as the value of $1/e$.

Bimonthly investigations of the R–D discordance revealed a nearly constant discordance, amounting to 1·14″, in the yearly mean, which changes sign when the instrument is reversed, and although the object-glass has been remounted, the cause of this has not yet been discovered.

The mean error in R.A. of the moon's tabular place for 1910 is −0·59s. from meridian observations of the limb and −0·55s. from those of Mösting A.

The reflex zenith tube observations for 1906–9, discussed by Mr. Eddington, give results in fair accordance, on the whole, with those published by Dr. Albrecht for the International Latitude Service.

About 600 double-star observations were made with the 28-inch refractor, including observations of 110 pairs under 0·5″ separation and 153 pairs between 0·5″ and 1·0″.

In the 30-inch Thompson equatorial the mirror, last silvered in February, 1910, is still in good condition owing to the cover having been made air-tight by a band of pure rubber. This instrument was employed in photographing Saturn and its ninth satellite, comets 1909*c* and 1910*b* and *e*, and some of Herschel's nebulæ, the latter for identification and position determination.

The 26-inch refractor was chiefly employed in the photographic determination of the parallaxes of stars in the Greenwich astrographic zone, Kapteyn's method of exposures on the same plate at intervals of six months being followed.

As the southern declination of Jupiter made observations at Greenwich impossible, the director of the Helwan Observatory undertook to continue the observations of J viii, and eight photographs, taken on eight nights, have already been received at Greenwich for measurement. Approximate measures of the first two photographs of the satellite indicate that the Cowell-Crommelin ephemeris is only 20″ in error.

Since November, the Greenwich astrographic telescope has been employed in the photographic determination of the magnitudes of stars given in the two published volumes of the Greenwich zones, Pickering's plan of polar sequences being employed.

An interesting investigation now being carried out at the observatory is the enumeration of the stars of different magnitudes on the photographs of the whole sky taken by Mr. Franklin-Adams, who is bearing the cost. Twenty-six plates, covering the sky between the North Pole and +53°, have been dealt with, and 42,284 stars counted. The greatest number counted on any one plate (in twenty-five 20′ squares) was 5138, the least 301.

The Dallmeyer photoheliograph is now housed in the dome of the old altazimuth, where one quarter of the original dome was cut away and a corresponding sector fixed permanently in the north, so that the large dome-aperture thus secured is easily closed by bringing it under the fixed sector. For 1910 the solar photograph record is complete, the ninety gaps in the combined Greenwich and Cape series having been filled by photographs received from the Dehra Dûn and Kodaikánal observatories in India. Since the beginning of May, one of the photoheliograph observers has attended from 7 to 9 a.m., thus adding two hours to the period of observation, and also securing better results.

The mean daily spotted area of the sun's disc in 1910 was less than half that of 1909, and during the five months ended March 31, 1911, the disc was free from spots on sixty-seven days. During the rapidly approaching minimum the direction of the sun's axis is to be determined

from the thirty-seven years' observations now available.

The principal results for the magnetic elements in 1910 were:—

Mean declination	15° 41·2″ West.
Mean horizontal force	0·18532 (C.G.S. units.)
Mean dip (with 3-inch needles) ...	66° 52′ 37″.

There were no days of "great," and only six of "lesser," magnetic disturbances.

The mean temperature for 1910, 49·7°, was 0·1° above the 1841–95 average, but the sunshine recorder showed a deficiency; July provided only about half the average number of hours of bright sunshine, and May was the only month when the amount was appreciably above the average. The rainfall, 25·93 inches, was 1·81 inches in excess of the 1841–95 average, and the number of "rainy days" was 175.

In the time department, the performance of chronometers is reported as satisfactory, and that of chronometer watches as exceptionally good. The increase of electrical devices on board ships having made the question of the magnetic disturbance of chronometers an urgent one, special experiments are being carried out with strong magnetic fields at the observatory.

THE HARD AND SOFT STATE OF METALS.

DR. G. T. BEILBY, F.R.S., delivered the second annual May lecture of the Institute of Metals on Friday, May 12, taking for his subject "The Hard and Soft States in Metals."

In the course of his lecture Dr. Beilby said that the hardening effect of cold working on ductile metals, and the softening effect of reheating, must have been known to the earliest workers in metals. To the general mind, the phenomena were sufficiently explained as being due to the "compacting" effect of hammering and the "opening up" effect of heat. The advent of scientific methods of inquiry led to the exposure of this fallacy, and to the discovery of new points of difference in a metal in the two states. The discovery that the polishing of all substances, even of those so hard or brittle as antimony or calespar, involves the transient liquefaction of a thin layer on the surface, led to the study of this subject from an entirely new point of view. In a pure ductile metal which has been slowly cooled from the molten state, the structure of the solid is completely crystalline, and the metal is in its softest condition. Any permanent deformation of the mass, whether by hammering, by rolling, or by wire drawing, hardens and stiffens it. The microscopic examination of the hardened metal shows that its original crystalline structure has been broken up and replaced by a new type of structure. If the hardened metal is raised to a sufficient temperature, the softness is completely restored *and the crystalline structure is also restored.* In the ductile metals the greatest degree of softness is always associated with well-developed crystallisation.

The composite character of the hardened structure, which in some cases resembles a bed of broken and distorted strata concreted or cemented together by a matrix, can only be explained by the presence of two constituents, namely, the broken-down remains of crystals and an amorphous or glass-like form of the metal by which the mass is so firmly cemented together that it has become vastly more rigid and mechanically stable than the crystalline structure. This amorphous or vitreous form of the metal stands in the same relation to the crystalline form as glass does to the crystalline silicates of which it is composed, or as the clear, vitreous "barley sugar" does to the ordinary crystals of the breakfast table.

The pure ductile metals cannot be obtained in the vitreous state by cooling, because their molecules retain sufficient mobility to enable them to marshal themselves in crystalline formation for a range of about 800° below the solidifying point. All the facts show, however, that when liquefaction is produced by mechanically induced flow the solidification is so rapid that the solid which results is in the vitreous condition.

Microscopic analysis of the surface skin produced by polishing a plate of calcite shows that the disturbance due to polishing has penetrated to a depth of one thousandth of a millimetre, and that the subsequent healing over of the disturbance has been so perfect that it can only be explained by the assumption that the transient liquefaction of a layer some thousands of molecules in thickness has occurred. It is evident that the conditions necessary to bring about liquefaction and solidification at the outer surface must equally exist within the substance at all surfaces of slip or shear, and the microstructure of the hardened metal confirms this view.

The direct bearing of these researches on the obscure subject of molecular structure in solids was pointed out, and a "pulsation cell" hypothesis of the three states of matter was outlined.

Prof. Quincke's "foam-cell" theory of solidification was referred to, and was applied to the explanation of certain observations made by Prof. Carpenter some years ago. In view of the possible bearing of this theory on questions of foundry practice, it was suggested that the Institute of Metals might offer a prize for the best research on the subject.

HYDRO-ELECTRIC PLANTS IN NORWAY AND THEIR APPLICATION TO ELECTROCHEMICAL INDUSTRY.[1]

THE physical configuration of Norway is remarkably favourable for the utilisation of the large number of waterfalls to be found on the seaboard of the mountain chains which almost cover the country, and through the valleys of which the enormous quantity of water precipitated from the western and south-eastern sea breezes finds its way as rivers flowing down to the sea. In the winter the rainfall takes the form of snow, so that the volume of water brought down by the rivers is at its greatest from May to July, when the snows melt on the mountains. To make use of the water-power, storage is therefore necessary, and for this the nature of the country is peculiarly adapted, being covered with lakes that have very contracted outlets, and which can be easily converted by damming into storage reservoirs. Thus in the watershed of Skien the natural water-power of 50,000 horse-power has been increased to an available horse-power of 375,000, while the Mösvand reservoir has increased the water-power of the Rjukan factories from 30,000 to 250,000 horse-power, with a capital outlay of only some 85,000*l.*

The total water-power in Norway has been estimated at from five to seven million horse-power, but as much of the country has not been hydrographically surveyed, this is probably too low an estimate. The power stations can supply power at from 22*s.* to 44*s.* per e.h.p.-year, and in some cases even for less; and as the quantities available are as high as from 50,000 to 100,000 horse-power for a single fall, the conditions are ideal for the development of electrochemical and electrometallurgical industries. Many such industries have already reached an advanced stage of development. Thus nearly 180,000 horse-power will be utilised this year in the manufacture of nitrates of lime, soda, and ammonia from the air by the Birkeland-Eyde process and the Badische Analin und Sodafabrik Company's process; about 60,000 horse-power are employed in the manufacture of calcium carbide, and other electrochemical and electrometallurgical industries absorb at present some 20,000 horse-power. Now that a suitable electric furnace—the Grönwall—has been designed for the smelting of iron ore, a furnace that has yielded excellent results on a practical scale, electric iron and steel smelting is likely to develop largely in the near future, for Norway possesses extensive deposits of iron ore. Three plants, aggregating 16,000 horse-power, with provision for increasing to nearly 60,000, are now being erected at Hardanger, Arendal, and Tinfoss. Other ores, notably copper, nickel, zinc, will also possibly be electrically smelted at no distant date.

The second portion of the paper describes in some detail the various hydro-electric schemes now being developed in

[1] Summary of a paper read before the Faraday Society on May 2, by Mr. A. Scott-Hansen, of Christiania.

Norway. On the Glommen River, in the east, three falls are utilised. The uppermost, Kykkelsrud, yields about 40,000 horse-power, of which 10,000 kilowatts is transmitted at 60,000 volts (3-phase 50 periods) to Christiania, thirty-one miles away, and the remainder to Sarpsborg. At Sarpsborg occurs the lowest fall of the Glommen, and here there are two power stations—Hafslund, supplying 24,000 horse-power to calcium carbide works and for zinc smelting, and Borregaard, the output of 26,000 horse-power of which is utilised by the Kellner Partington Paper Pulp Company, Ltd., owning the largest works in Norway. The intermediate fall on the Glommen is at Vamma, where a dam is now in course of construction under considerable difficulties. This dam will have a height of 90 feet, and will be one of the largest in Europe. The power station will be in the centre of the river bed below the dam, and will yield some 70,000 to 80,000 horse-power.

A large number of the minor power stations in the south supply the towns with light and power. Among the smaller electrochemical works are the electro-iron and steel works at Arendal, the experimental nitrate works of the Badische Company at Christianssand, and nickel and aluminium factories near the same town. The nickel works refine nickel matte, and turn out about 400 tons of the pure metal per annum. At Gjössingfjord is Mr. Albert Hiorth's small experimental electro-steel works. At Vadheim, on the west coast, is a sodium factory, and at Trondhjem, in the north, carbide, ferro-chrome, and ferro-silicon are manufactured.

Another great power centre is in the Telemarken district n the south-east of Norway. The Svaelgfoss power station supplies 40,000 horse-power to the nitrate factory at Notodden at a voltage of 10,000, delivered without transformation. The four 10,000-horse-power machines—capable of developing 13,000 horse-power—are among the largest in the world. A power station now being constructed at Lienfoss will be able to furnish Notodden with a further 20,000 horse-power. The Tinfoss Works, also at Notodden, are intended to generate 15,000 horse-power, to be used mainly for iron and steel smelting.

The third of the great Norwegian falls is the celebrated Rjukanfoss waterfall on the Maaneely River. The Mösvand dam, above this fall, provides a reservoir of about 840 million cubic metres (tons) of water, and five miles below is another dam, forming the intake for the power station, situated 1000 feet below. A lower fall of about 1000 feet provides the power for a second station. Both of these power stations—the largest in Europe—will yield 140,000 horse-power, there being in each 10 units of 14,000 horse-power. The turbines, on account of the great height of the falls, are Pelton wheels. The construction of the dams, flumes, and power stations at Rjukanfoss was attended with great engineering difficulties, which are described in the paper. The power from these stations is transmitted through sixty copper and aluminium cables to Saaheim, where factories for the manufacture of nitrogenous products to employ from 2000 to 3000 persons are in course of erection.

The paper concludes with a description of the power plant at the Tysse falls, which consists of seven units, each of 4500 horse-power, and from which electric energy is transmitted at 12,000 volts to Odda, where it is used for the manufacture of calcium carbide and of cyanamide. Here again, on account of the steep, mountainous character of the country, great difficulties presented themselves, particularly in the drilling of tunnels 1320 feet above the fjord, and in fixing the flumes, some against a smooth precipice, with an inclination of 60°. The Tysse power station will eventually yield some 100,000 horse-power.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—At the last meeting of the council the following resolution was passed:—"The council of the University has heard with great regret of the death of Prof. Whitcombe, who for twenty-three years was professor of mental diseases at Queen's College, Mason College, and the University, and desires to place on record its appreciation of the valuable services he has rendered to the University."

Dr. Helen M. Wodehouse has resigned her appointment as lecturer in philosophy on being elected to the principalship of the West Riding of Yorkshire Training College.

At the forthcoming degree congregation, official degrees are to be conferred on Prof. C. E. Martineau (M. Com.), professor of accounting, and on Miss S. M. Fry (M.A.), the warden of the Hall of Residence for Women Students.

Bristol.—Mr. Herbert Bolton, curator of the Bristol Museum of Natural History, has been appointed reader in palæontology in the University.

The thanks of the council have been accorded to the Local Committee on Agricultural Development for passing the following resolution:—"In view of the valuable research work now being done in the University of Bristol in the interests of the cheese industry, and also in the investigation of plant diseases, this meeting urges that a substantial grant for a given period of time be provided by the Development Commission, to enable the investigations to be proceeded with until practical results are arrived at."

Cambridge.—An offer to contribute 200*l.* a year for the next five years to the Geographical Education Fund has been made by the council of the Royal Geographical Society, which has further granted an additional 100*l.* for the year ending Michaelmas, 1912. A private benefactor has also offered 100*l.* for the ensuing academic year. It is proposed that these offers be gratefully accepted by the University.

A lecturer in historical and economic geography, a lecturer in regional and physical geography, and a lecturer in surveying and cartography, will be appointed by the General Board for five years from Michaelmas. The two latter will be known as the Royal Geographical Society's lecturers.

It is proposed to confer the degree of Doctor of Letters, *honoris causa*, upon Prof. Wilhelm Dorpfeld, principal secretary of the Imperial German Archæological Institute in Athens; and the degree of Master of Arts, *honoris causa*, upon Mr. John Watson.

Oxford.—The following is the text of the speech delivered by Prof. Love in introducing Prof. H. L. Bergson for the degree of D.Sc. *honoris causa* on May 27:—"Adest Henricus Ludovicus Bergson, inter huius aetatis philosophos insignis, vir multis nominibus laudandus, doctrinae novae et singularis suasor, eiusdem variis in rebus probator, rationis sibi constantis et late patentis inventor, orationis vi lumine venustate pollens. Qui cum non solum mathematicam et scientiam naturalem, sed etiam litteras et philosophiam penitus hausisset, id consecutus est ut, si quis alius, ipsius scientiae rationes corrigere et quasi terminos statuere posset. Nova profecto eius est sententia, esse quaedam, velut durandi notionem, sine qua vita et libertas esse non possint, quae in scientiam physicam mathematicis fundamentis exstructam non cadant: nova etiam eius doctrina, esse quoddam cognitionis genus ipsi scientiae non obnoxium, quo usa mens ipsam veritatem capiat, et durandi, vivendi, mutationis, motuum naturam comprehendat. Hanc ad sententiam, cum multa alia, tum rationem Darwinianam exegit, qua de re magna controversia exorta est, cum multi multis in terris huic suffragentur, ii qui adhuc dissident eius acumen admirentur.

Sheffield.—Mr. Llewellyn Lloyd, assistant curator of the Museum of Zoology, has been appointed entomologist to the Sleeping Sickness Commission of the British South Africa Company, and is leaving England at once for northern Rhodesia.

The fourth holiday course and second nine months' training course in physical instruction for men and women at Silkeborg, Denmark, sanctioned by the Danish Board of Education, will commence respectively on July 31 and September 2. Particulars can be obtained from the principal, H. G. Junker, Silkeborg, Denmark.

A course of three lectures on "The Evolution of Coasts" will be given by Prof. Albrecht Penck, director of the "Institut für Meereskunde," Berlin, at Burlington House, Piccadilly, London, W., at 5.30 p.m. on June 27, 28, and 29. The following is an outline syllabus:—development of English coastal scenery; formation of

Romney Marsh, Chesil Beach, Plymouth Sound. The lectures are addressed to advanced students of geology of the University of London and to others interested in the subject. Admission is free, without ticket.

WE learn from *Science* that a Bill has been signed by which the Massachusetts Institute of Technology will receive 20,000*l.* annually from the State for ten years. By the terms of the measure, the institute will maintain eighty free scholarships to be apportioned among the forty senatorial districts of the State. The California legislature has passed a Bill, which has been recently signed, appropriating 5000*l.* for a soils laboratory building, equipment, and other improvements at the Citrus Experiment Station. The work of the laboratory is to be confined to the study of citrus soils. The legislature of Hawaii has voted 15,000*l.* for a new building for the College of Hawaii and 4000*l.* for maintenance expenses.

THE report has been issued (Cd. 5662) of the Departmental Committee appointed to inquire into the administration of (*a*) endowments the income of which is applicable, or is applied to or in connection with, elementary education, and (*b*) small educational endowments other than the above, in rural areas, the application of which to their proper purposes presents special difficulties; and to consider how far under the existing law it is possible to utilise them to the best advantage; and whether any, and, if so, what, changes in the law are desirable in the direction of conferring upon county and other local authorities some powers in respect of such educational endowments or otherwise. The committee makes a number of recommendations, which are summarised in the report under twenty-two headings. Especially important is the proposal that, subject to certain exceptions and modifications, county councils in their capacity as local education authorities under the Education Act, 1902, should perform the functions at present performed by the Board of Education with regard to the administration of the endowments within the terms of reference, that there should be an appeal to the Board of Education from any scheme made by a local education authority, and that the range of educational objects to which trustees may apply their funds should be widely extended. It is also recommended that the local education authority should have the same powers of demanding accounts and investigating the administration of charities as are at present exercised by the Board of Education, but that the Board of Education should have a concurrent power of demanding accounts, though trustees will no longer be under any obligation to render accounts to the Board. Certain of the suggestions are not made unanimously, and memoranda at the end of the report provide particulars of the points on which some few members of committee do not agree with the main recommendations.

ATTENTION has recently been directed to a somewhat anomalous situation which had come into existence during the last few years in connection with medical education. The General Medical Council exercises a supervising control over the standard of the tests required by the various qualifying authorities in this country. In the regulations published by the Council, students are required to study the preliminary sciences at an institution recognised by the council, and *after* passing an examination in general education when above sixteen years of age. The council requires no elementary science at all in the general education. These regulations, which are obviously designed to make sure that students shall not scamp their literary, for the sake of their scientific, education, and that they shall study elementary science under generous conditions, probably achieve their purpose satisfactorily for a certain class of student. But, since public schools are not recognised by the council as places where elementary science can be studied, they evidently do not meet the case of the very large number of boys who enter the medical profession from the public schools. The difficulty has been met in the past by the fact that those qualifying authorities most used by public-school boys have not conformed to the regulations of the council. For though termed "regulations," they are not legal requirements, but more in the nature of recommendations. Thus the Conjoint Board of London and the Universities of Oxford, Cambridge, and London, the professional tests of which are beyond suspicion, allow students to pursue the study of the preliminary sciences at the public schools. Hence a boy following the usual school curriculum, and working at elementary science as part of his general education, has been able to offer himself for examination in these subjects on leaving school at eighteen or nineteen years of age. Recently, however, an increasing number of boys have gone from public schools to the newer universities and other authorities where they have to conform to the requirements of the Council. To observe the regulations, these boys have had to study again the elementary science which they have already, in many cases, satisfactorily done at school. Representations have been made to the council by the public schools directing attention to the difficulty thus raised; and on May 29 last at the meeting of the General Medical Council a resolution was proposed by Sir Henry Morris to remove the disabilities from which public-school boys suffer by "recognising" the schools under certain conditions. This resolution was adopted by 24 votes to 5.

THE fifth annual Conference of the Association of Teachers in Technical Institutions was held at Southport on June 5. Mr. Barker North, of the Bradford Technical College, in his presidential address, said that during the year the membership of the association increased by more than 20 per cent., and branches were formed in Ireland and Wales. More than 50 per cent. of the full-time technical teachers of England and a large percentage of the part-time teachers are now in the association, which is the only organisation representing all grades of the profession. Many technical institutions, he said later, suffer from the unsatisfactory nature of the constitution of education committees, and he urged the co-option of experts to remedy the present lack of special knowledge. Mr. North gave a tabular statement from the recently published census of production which shows that the net output in the nine leading industries of the country rose with an increase in the percentage of salaried persons. This suggests that, within certain limits, the employment of a large number of skilled technologists would develop the industry into higher forms and increase productivity. The state of the chemical industries shows how fatal is the system of limiting the employment of research chemists. Referring to the reforms necessary in education, he argued for the closer affiliation of continuation schools with the higher institutions; the work of the former should be a real continuation of that of the primary schools, and in technical institutes and universities provision must be made alike for the rank and file of the industrial army and for their officers—the second type being evolved from the first by means of natural selection. The defects of the present system would be remedied by drafting the best of the evening students systematically into day courses and by concentrating them for the highest class of work in specialised institutions. Such institutions should be affiliated to form technical universities. On these lines, he thought, the development of the Imperial College should be carried out. The time is ripe, said the president, for the appointment of another Royal Commission, with broader terms of reference than those assigned to the present, so that the whole question of the organisation of higher technical education in this country may be subjected to an exhaustive inquiry. Papers were read by Prof. W. W. Haldane Gee and Mr. T. J. Burnett, and resolutions were adopted urging the formation of an Advisory Council on Technical Education, consultative committees of teachers, the representation of teachers on education committees, and advisory committees for juvenile employment.

SOCIETIES AND ACADEMIES.

LONDON.

Faraday Society, May 2.—Mr. James Swinburne, F.R.S., president, in the chair.—A. **Scott-Hanson**: Hydro-electric plants in Norway and their application to electrochemical industry (see p. 501).—Edgar **Stansfield**: Two simple forms of gas-pressure regulators. The two regulators described give a steady pressure, easily adjusted, not influenced by the rate of flow of the gas. They consist merely of an outer containing vessel into which water is

poured, and an inner cylinder open top and bottom containing a floating beaker to which a valve is connected. When gas is passed into the inner cylinder through the valve, the position of the floating beaker adjusts itself so that the pressure of gas rises until the valve just closes. —Dr. W. C. McC. **Lewis**: Internal, molecular, or intrinsic pressure—a survey of the various expressions proposed for its determination. If we consider an imaginary plane of unit area placed in any direction well inside a liquid mass, equilibrium across this plane is maintained by the balanced attractive and repulsive molecular forces, which we have reason to believe are of very great magnitude, amounting to hundreds, or even thousands, of atmospheres. The attractive force per unit area is defined as the molecular, internal, or intrinsic pressure of the liquid, and is usually denoted by the symbol K. The present paper is a survey of the various attempts which have been made to estimate the value of K for various liquids.

May 23.—Dr. R. T. Glazebrook, C.B., F.R.S., vice-president, in the chair.—Dr. Arthur L. **Day**: Recent advances in high-temperature gas thermometry. The paper reviews the work done in recent years to increase the range and accuracy of the temperature scale upon which the various methods of measuring high temperatures depend for their calibration.—Dr. J. A. **Harker**: The high-temperature equipment of the National Physical Laboratory. The paper dealt with the methods of construction and the use of the various forms of apparatus for the attainment of temperatures above 100° C. which have been designed at the laboratory during the past ten years.—H. C. **Greenwood**: The boiling points of metals. In view of the scanty and uncertain nature of our knowledge of these important constants, a general investigation of the question was greatly needed. The present experiments may be divided into three sections:—(1) A study at atmospheric pressure of the boiling points of a number of metals which are unaffected by carbon at high temperatures (antimony, 1440° C.; bismuth, 1420° C.; copper, 2310° C.; lead, 1525° C.; magnesium, 1120° C.; silver, 1955° C.; tin, 2275° C.). (2) A study at atmospheric pressure of the boiling points of some metals which readily combine with carbon (aluminium, 1800° C.; chromium, 2200° C.; iron, 2450° C.; manganese, 1900° C.). (3) The influence of pressures varying from 10 cm. of mercury to 50 atmospheres on the boiling points of bismuth, copper, lead, silver, tin, and zinc.—A. **Blackie**: The behaviour of silica at high temperatures. This communication gives an account of some experiments made to determine the effect of heat on the strength and devitrification of the opaque and transparent varieties of fused silica. A determination was also made of their relative coefficients of expansion at high temperatures.—Prof. Max **Bodenstein**: Methods of maintaining constant high temperatures. Three general methods are in use:—(1) By means of a vapour in equilibrium with its liquid. Suitable substances are only available for a moderate range of temperature, but a uniform temperature over a large volume is easily maintained. On the other hand, constancy of temperature over a long period cannot be relied upon. (2) A liquid heating bath controlled by a thermostat. For high temperatures the method is restricted by the difficulty in obtaining a suitable substance, although for moderate temperatures oil or paraffin in a suitably constructed bath are fairly satisfactory, and temperatures up to 350° can be maintained within 0·05° for several months if a sensitive gas regulator be employed. (3) For high temperatures air baths only can be employed. Tube furnaces heated electrically, either directly or by means of coils, are now exclusively used, but although a constant temperature is easily maintained, uniformity of temperature is more difficult of attainment. —M. Charles **Féry**: Stellar pyrometry. The temperatures of incandescent terrestrial bodies can be measured by reference to the laws of radiation, either the law of Stefan or the law of monochromatic radiations, but these cannot be applied in the case of stars, owing to the small amount of radiation. The author has therefore devised an instrument, based on Weiss's displacement law, according to which temperature is measured by an appreciation of the colour tint of the star. In the instrument described, the colour of an image of the star is compared with that of a standard lamp the tint of which can be varied. The pyrometer is standardised by reference to an electric furnace, an arc (3500° C.), and the sun (6500° C.).

Royal Microscopical Society, May 17.—Mr. H. G. Plimmer, F.R.S., president, in the chair.—J. E. **Barnard**: A method of disintegrating bacteria and other organic cells. The author first mentioned that bacterial toxins were of two kinds, extracellular and intracellular. The former were excreted into the medium, *e.g.* beef broth, on which the organism was cultivated, so that by a process of filtration the organisms could be removed and the toxin was obtained in the filtrate, but the majority of pathogenic micro-organisms did not excrete their toxins, at least to any extent, and the toxins were retained within and formed integral parts of the cells of the organisms. One method of obtaining these toxins was mechanically to disintegrate the bacterial cell, so that the cell contents were expressed, and the apparatus described accomplished this. It consisted essentially of a containing vessel in which, by a suitable rotation of steel balls, the organisms were crushed. The principal conditions to be filled in such an appliance were:—(1) approximately every cell should be brought under the grinding action; (2) little or no rise of temperature should take place; (3) the disintegration should be carried out in a vessel which was sealed so that, when dealing with pathogenic organisms, none could escape at any stage of the process. These conditions were, in the main, complied with in the apparatus described. Experiments indicated that by this method the cell-juices were obtained unaltered, and so were suitable for investigation on the chemical composition and properties of the bacterial proteins and other cell constituents. Also that, after the grinding process had been carried on for a sufficient time, practically no cells remained which could be stained properly by any recognised bacteriological method, and which, therefore, could be regarded as whole cells containing a normal quantity of cell-juice.—James **Murray**: Third portion of a Report on the rotifera observed by the Shackleton Polar Expedition of 1909. This portion of the report dealt with the new species, &c., from the Pacific Islands, in which the author said that in Fiji fifteen bdelloid rotifera were collected, in Hawaii twenty-four. Ten species were common to the two groups. In Fiji two new species were distinguished, *Callidina pacifica* and *Habrotrocha nodosa*, the latter previously known as a variety in India and elsewhere. In Hawaii there were no peculiar species, but some very distinct varieties. In the various Pacific islands there have been recorded thirty-one species of bdelloids.

Zoological Society, May 23.—Dr. A. Smith Woodward, F.R.S., vice-president, in the chair.—Dr. J. Stuart **Thomson**: Alcyonaria of the Cape of Good Hope and Natal. The author dealt exclusively with the order Gorgonacea, and recorded nineteen species, of which six were described as new.—Dr. A. Hopewell **Smith** and Dr. H. W. Marett **Tims**: Tooth-germs in the wallaby (*Macropus billardieri*). The material upon which their observations were based had been kindly sent to the authors by Mr. Brooke Nicholls, of Melbourne. It consisted of three embryos of *M. billardieri*. The smallest specimen (allowing for the difference in size of the adults of different species) was considerably younger than that of any other Diprotodont previously examined. In the upper jaw they had identified six incisors, thus confirming M. F. Woodward's original statement. The functional incisors of the adult appeared to be the second, fourth, and sixth of the series. There were four premolars, of which the first, third, and fourth persisted. There was also one molar tooth. In the lower jaw, owing to the difficulty of interpreting the conditions, it was not certain whether there were representatives of five or six teeth in front of the premolars. Presuming there were five, the large functional incisor of the adult was the fourth of the series. As in the upper jaw, there were four premolars and one molar, the second premolar not fully developing. There were evidences of vestigial predecessors to the large lower incisor and to pm^4. The following points of histological interest were noted:—(1) The heaping up of the epithelium along the alveolar margins, a character often supposed to be peculiar to the ungulates. (2) The precocious development of the enamel. (3) The compactness of the stellate

reticulum of the enamel-organ. (4) The abundant evidence of blood-vessels within the enamel-organ, thus confirming the observations of Poulton and Howes in the rodents. The opposite opinion is usually held. (5) Some slight evidence in support of the fusion of enamel-organs. Such fusion has been recorded in the fishes and reptiles, but not hitherto in mammals.—Rev. A. Miles **Moss**: The Sphingidæ of Peru, based on studies of Lepidoptera, with special reference to the larvæ, made during a three years' residence at Lima.—Dr. R. **Broom**: The structure of the skull of cynodont reptiles. The author, after a study of all the available material contained in the British and South African museums, gave a detailed comparative account, illustrated by a series of figures, of the morphology of the skull in the chief genera of the Cynodontia, including Bauria, Nythosaurus, Cynognathus, Trirachodon, Gomphognathus, Diademodon, Sesamodon, and Melinodon. He also discussed in some detail certain peculiarities of the mammalian skull, apparently derived from a cynodont ancestor.—Dr. C. W. **Andrews**: A new species of Dinotherium from British East Africa (see p. 457).

Geological Society, May 24.—Prof. W. W. Watts, F.R.S., president, in the chair.—R. J. Lechmere **Guppy**: The geology of Antigua and other West Indian islands, with reference to the physical history of the Caribbean region. After noticing the work of former observers on the geology of Antigua, the author gives a brief description of the formations of that island, showing that it is divided into three principal regions:—(1) the volcanic (or igneous) region; (2) the central plain; and (3) the calcareous formation, the first-named being, according to previous authors, the oldest, as it is pre-Tertiary, and the others following in succession. The calcareous formation, hitherto considered the newest, contains fossils, of which the most remarkable is a species of Orbitoides. After a discussion of these formations, and especially of the evidence for the so-called "Oligocene" age of the calcareous formation, the conclusion is reached that this formation is the oldest, not the youngest, and is probably Eocene or older. The island was raised above sea-level by the development of the great Antillian dislocation, which is described, and divides each of the islands of Guadeloupe and Antigua into two parts, of which the eastern is calcareous and the western volcanic. In Antigua the central plain intervenes between the two parts, while in Guadeloupe they are only separated by a narrow channel. In support of this proposition, the physical features of Antigua are discussed, and it is shown that the island has not been submerged since the volcanic period.

Institution of Mining and Metallurgy, May 31.—Mr. H. Livingstone Sulman, president, in the chair.—C. O. **Schmitt**: Future economies in Rand reduction plants. The main idea permeating this paper is a defence of the stamp tube-mill combination, against which arguments have been adduced by other authorities, with the further argument that, if either component of this combination is abandoned in the future, it will be the gravity stamp rather than the tube-mill that will be replaced by a machine capable of producing a finer product at a reduced cost. Naturally, a chief point of this paper is to promote discussion on a matter concerning which there are two distinct schools of thought. The author points out in introduction that, if working costs remain at their present figure, the limit of profitable mining will be reached approximately at a vertical depth of 5000 feet in a period of time that can be readily estimated. To increase the depth at which profits may be obtained, and consequently the period of life of a mine, it will be necessary to reduce working costs and capital charges, the former being the factor as regards which most improvement can be effected. What is known as the "big mill" policy was introduced on the Rand with the view of reducing working costs, and gave satisfactory results within proper limits. The author proceeds to analyse the work accomplished respectively by the sorting and breaking plant, and the milling or crushing plant, and he urges that, in view of recent developments and exhaustive experiments made on a sufficiently large scale, the efficiency of the tube-mill when dealing with material of a fineness suitable to produce the best results will be an important factor in the lowering of reduction costs to meet increased expenditure necessitated by seeking ore at depth. A considerable amount of data has been collected for this purpose, much of it in the form of tabular matter and diagrams of typical flow sheets in modern practice, with the view of showing that double-stage crushing is a certain means of effecting marked economies in operating costs and securing better extraction.—A. C. **Hoare**: The roasting of complex ores in gold assaying. Opinion is divided as to the advisability of roasting before fusion when assaying complex gold ores, and though in consequence of experiments it is now established that there is no loss of gold by volatilisation when telluride gold ores are roasted, the volatilisation losses, if any, met with in roasting other complex ores have not been definitely established. The author therefore undertook this investigation with respect to sulphide ores containing iron pyrites, which after careful assay had a base sulphide, such as zinc blende, stibnite, cinnabar, or mispickel, added to them, so that the influence of the sulphide on the roasting could be determined by subsequent assay. The results of these experiments showed that there was no loss of gold in roasting low-grade ores containing zinc blende or antimony, but that there is a loss when the ores contain arsenic, cinnabar, or mispickel.—G. M. **Austin**: A prospector's method of gold assay. In this paper the author details the outfit necessary for carrying out assays in a remote district without the need of taking an elaborate equipment, and he furthermore gives the results of a number of tests made with the view of determining the degree of accuracy attainable by means of a comparatively simple outfit, using one of two methods of assay of which he gives full particulars.

Manchester.

Literary and Philosophical Society, May 9.—Prof. F. E. Weiss, president, in the chair.—Ernest F. **Lange**: Some remarkable steel crystals, coupled with some notes on the crystallisation of the iron-carbon alloys. The crystals were discovered by Colonel T. E. Vickers, C.B., in the cavity of the rising head of a large steel casting, and were preserved by him in view of the known rarity of the occurrence of such a mass of perfectly developed steel "pine-tree" crystals, as the crystalline structures of steel are usually allotrimorphic instead of idiomorphic, that is to say, their geometrical forms do not, except in very unusual circumstances, correspond with their internal crystalline symmetry. A photograph of the cavity was exhibited which showed the walls covered with pyramidal apices of the crystals formed in the liquid metal, and masses of crystals up to 14 or 15 inches in length pendant from the upper portion of the cavity, where they had slowly formed and elongated with the sinking metal with remarkably little interference and in exceptional circumstances of size of casting and casting head and slowness of cooling. Reference was made to the columnar structure of steel castings and ingots as cast, and to the fact that although steel ingots show such a strongly defined columnar structure, the experiments of Müller in Germany had shown that the interior of "bled" ingots was invariably smooth, and that ordinarily solidification proceeded in smooth parallel layers without intrusion of any crystal growths towards the interior. These steel "pine-tree" crystals had never been reproducible in a laboratory experiment, and the problems of the crystallisation of steel had been worked out by experiments upon the allotropic forms of the iron and iron-carbon alloys, the work of Stead and Osmond and Cartaud being specially mentioned for its laboriousness and ingenuity. The author illustrated the internal symmetry of the crystalline structures of various steels by lantern-slides showing the structures that had been obtained in some of his own experiments in the heat treatment of steel, some of which had led to the scientific control of certain metallurgical operations formerly guided by rule-of-thumb practice only.—Prof. S. J. **Hickson**, F.R.S.: *Osteocella septentrionalis*. Some pieces of a very fine pennatulid well preserved in spirit were sent to Prof. Bell by the Rev. J. H. Keen from 30 fathoms off Lucy Island, British Columbia. They were sent by Prof. Bell to the author for examination and report. The specimen was, when caught, about 2 metres in length, and possessed a long, hard calcareous axis reaching a diameter of 7 mm. in its thickest region. On comparing the axis with that

of the type-specimen of *Osteocella septentrionalis* from Burrard's Inlet, British Columbia, preserved in the British Museum, no doubt could be entertained that the specimen from Lucy Island belongs to the same species. Large pennatulids from the same waters similar to this in structure have been described by different authors under the names Verillia, Halipteris, Pavonaria, and Ballicina. There can be no doubt that most of these specimens belong to the same species, and the proper name for it by the rules of nomenclature is *Osteocella septentrionalis*. The paper contains some general account of the structure of Osteocella, but, apart from the characters of the axis, the most important character is the great development of fleshy substance on the ventral side of the rachis and the presence of ventral radial canals.

DUBLIN.

Royal Irish Academy, May 8.—Rev. Dr. J. P. Mahaffy, president, in the chair.—K. T. **Wang**: The differentiation of quaternion functions. Quaternion functions are considered which involve only one quaternion, the constants being scalars. The formula

$$dfq = f'q\,dq + (f'q.\mathrm{V}q - \mathrm{V}fq)\mathrm{V}(\mathrm{V}dq : \mathrm{V}q)$$

is obtained, where $f'(q)$ is the differential coefficient of $f(q)$ formed as if q was a scalar. Several examples are given, and also application to the operator $\lhd$ (defined by $d = -Sdq\lhd$).—I. **Arwidsson**: Some Irish Maldanidæ. The paper dealt with a small collection of polychaet worms belonging to the family Maldanidæ, collected in Irish waters. One new genus, Cæsicirrus, and two new species, *C. neglectus* and *Nichomache maculata*, were described. Both species had been found previously by various naturalists, but were erroneously identified.—G. A. J. **Cole**: Glacial features in Spitsbergen in relation to Irish geology. The paper arises out of the excursion made in connection with the International Geological Congress of 1910. The comparison of Spitsbergen with Ireland towards the close of the Ice age is rendered an apt one, both on account of the scale of the surface features and the proximity of the open oceanic waters through a large part of the year. The effect of frost action, and especially of "nivation-hollows," is pointed out as originating the recesses, which are ultimately converted into cirques. It is urged that in plateau areas, like those of the eastern part of the Ice Fjord and around Killary Harbour in Ireland, cirques arise by the notching of the plateau edges below the snow-line. The Irish cirques, it is argued, belong to a late stay in the glaciation of the country. The possibility is discussed of the retention of lowland ice in the central areas of Ireland after regions to the east had become free. Interglacial phenomena may thus be traceable only on the margin of the Irish "ice-island," though pronounced in other areas.

May 22.—Rev. Dr. Mahaffy, president, in the chair.—James **Murray**: *Rotatoria bdelloida* (Clare Island Survey). No fewer than sixty-five species of bdelloid rotifers have been collected on Clare Island and the neighbouring mainland by Mr. Murray and his helpers, among them one species (*Habrotrocha hibernica*) new to science. The Irish bdelloids correspond closely with those of Scotland, only two species being, so far, unknown from that country.

Royal Dublin Society, May 23.—Prof. T. Johnson in the chair.—Prof. James **Wilson**: The inheritance of milk-yield in cattle. This investigation involved considerable preliminary inquiry, especially on the following points:—(*a*) the corrections to be made in short and prolonged lactations in order to bring them to the normal; (*b*) the allowances to be made for age; (*c*) in determining how far a cow's total normal yield might be estimated from her yield early in a lactation. These points having been determined, it was found that in full-sized breeds there are three grades of cows, a low grade giving from 450 to 600 gallons, a high grade giving from 1000 to 1200 gallons, and an intermediate grade giving from 750 to 950 gallons, and it was found, also, that the high and low grades are approximately "pure" strains, while the intermediate grade is a "Mendelian" hybrid between them.—Prof. T. **Carroll**: Experiments carried out at the Albert Agricultural Institution, Glasnevin, Dublin: an inquiry into the potato disease *Phytophthora infestans*. The experiments consisted of (*a*) placing in a field of potatoes a case protected by cotton-wool from the entrance of disease spores. The potatoes planted in the case belonged to a variety liable to disease; but the haulms and tubers of these protected potatoes were not attacked, whilst the surrounding unprotected crop was badly affected. (*b*) A portion of ground in which potatoes were growing was completely covered with cotton-wool immediately after the plants had made their appearance, when it was found that the tubers of the crop were completely free from disease, although the surrounding crop was much diseased, as were the haulms of the protected potatoes. (*c*) Between the drills (*anglice* ridges) holes were made 12 inches, 6 inches, and 3 inches deep, into which immature potato tubers were put, the haulms of the potatoes being placed over them. The potatoes from the 12-inch hole were free from disease; those from the 6-inch and 3-inch holes were one-third and two-thirds diseased respectively. Experiments with diseased tubers were also undertaken. (*a*) These were planted in a cool conservatory; disease did not appear in the plants nor in their tubers, although crops in the neighbourhood were badly diseased. (*b*) One of the tubers of this experiment planted in the conservatory showed no sign of disease up to September of the following year. The haulms of this plant were removed, and, the soil having been carefully removed from the tuber, diseased haulms from a plant grown outside were shaken over the exposed tubers after they had been sprayed with pure spring water. Almost all the tubers contracted the disease on their exposed surfaces. These and other experiments were undertaken in order to test whether the disease *Phytophthora infestans* is carried to the tubers of potato plants from the leaves through the stems, and with the object of proving the value of preventive spraying and suggesting its *raison d'être*.

PARIS.

Academy of Sciences, May 29.—M. Armand Gautier in the chair.—H. **Deslandres**: A simple explanation of the solar protuberances and other phenomena by very weak magnetic fields. By assuming the existence of a solar magnetic field analogous to that of the earth and also the ionisation of the gas of the black filaments and protuberances with the predominance of ions of the same sign. The consequences of this assumption are developed and compared with various experimental data.—Ch. **Lallemand**: A project for an international map and aëronautical fixed points. Proposals for a map for the use of aëronauts, enabling the position to be readily determined. The necessity for an international agreement is pointed out.—A. **Haller** and Ed. **Bauer**: The oximes and phenylalkylisoxazolones obtained with ethyl, methyl, and dimethylbenzoylacetic esters. The oxime of benzoylethylacetic acid described by MM. Hantzch and Miolati does not exist, and is, in fact, phenylethylisoxazolone. The esters of monomethyl, monoethyl, and dimethylbenzoylacetic acids, whatever their mode of preparation, give rise to substituted phenylisoxazolones when treated with hydroxylamine hydrochloride and alcoholic potash. The oximes, however, can be obtained by treating these esters in alcoholic solution with the chlorzincate of hydroxylamine (Crismer's salt).—Ch. Ed. **Guillaume**: The coefficient of the quadratic term in the formula of the expansion of nickel steels. The value of the coefficient of the quadratic term in the expansion is plotted against the percentage of nickel, the data from eighty-four alloys being utilised. The disturbing effects of chromium and manganese are discussed.—S. **Arloing**, M. **Fern**, and J. **Chattot**: The influence of the anæmia of the organs on the incidence of tuberculous lesions. Tubercle bacilli, varying in virulence, do not produce lesions in an organ deprived of circulation by aseptic means.—M. Godlewski was elected a correspondant for the section of rural economy in the place of the late M. Fliche.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the first quarter of 1911. The results of observations on fifty-nine days are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—Jules **Drach**: The determination of the asymptotic lines to the general surfaces of the third degree.—Lucien **Godeaux**: Linear congruences of

conics.—G. **Kœnigs**: The law of the curvatures of conjugated superficial profiles.—M. **Lemeray**: The principle of relativity and the forces exerted between bodies in motion.—H. **Larose**: The propagation of a discontinuity along a telegraph line with uniform loss.—G. A. **Hemsalech**: The air spectrum given by the initial discharge of the self-induction spark. It has been shown in a previous note that the spectrum of the initial discharge of a self-induction spark differs from that emitted by the oscillations, the spectrum having a large proportion of lines. A further study of these spectra of the initial discharge shows that the intensity varies inversely as the capacity of the condenser and directly as the self-induction of the discharge circuit. An increase in the capacity of the electrodes produces a strengthening in the line spectrum and a weakening of the bands.—André **Léauté**: The irregularities of the disruptive potential.—H. **Lioret**, F. **Ducretet**, and E. **Roger**: A self-recording telephone. A combination of a loud-speaking telephone and phonograph is described.—Pierre **Sève**: The measurement of magnetic fields in absolute value. The simultaneous use of the Cotton balance and the induction method described allows fields up to 15,000 Gauss to be measured with an accuracy of 1 in 1000.—E. **Baud**: The molecular heat of fusion.—A. **Tian**: The radiations causing the decomposition of water and the extreme ultra-violet spectrum of the mercury arc. The radiations decomposing water, forming hydrogen and hydrogen peroxide, are localised in the extreme ultra-violet at about 1900 Angström's. The light from a quartz mercury arc lamp determines this decomposition, owing to the presence of rays 1846, 1848, and 1851.—Georges **Dupont**: The catalytic isomerisation of acetylene pinacone. The synthesis of tetramethylketohydrofurane. The pinacone

$$(CH_3)_2.C(OH).C \quad C.C(OH).(CH_3)_2,$$

treated with an aqueous solution of mercuric sulphate gave, not the expected dioxyketone, but its internal anhydride, tetramethylketohydrofurane. The latter gives both ketonic and enolic reactions.—Emile **André**: A new method of preparing β-diketones. Ketones of the type $C_6H_5.C \quad C.CO.R.$ combine with amines forming compounds $C_6H_5.C(NR'R'').CH.CO.R.$ The latter, under the influence of acids, readily hydrolyse, forming the salt of the amine and the β-diketone $C_6H_5.CO.CH_2.CO.R.$ Examples are given proving the generality of the method.—P. L. **Viguier**: Tetrolic aldehyde.—V. **Grignard** and Ch. **Courtot**: The magnesium derivative of fluorene. In xylene solution at 135° C. fluorene reacts with ethylmagnesium-bromide, the magnesium compound

$$\begin{array}{l} C_6H_4 \\ | \\ C_6H_4 \end{array}\!\!\!>\!CH.Mg.Br.$$

being formed, several reactions of which are described.—M. **Battandier**: Experiments on the germination of an aquatic plant, *Damasonium Bourgaei*.—P. **Vuillemin**: Remarks on a disease of the Weymouth pine (*Pinus Strobus*). Reasons are given for supposing that this disease is not really a new one in France.—Pierre **Bonnier**: The monostatic capacity in aviators.—A. **Marie** and Léon **MacAuliffe**: The influence of the social medium on the development of height in women. The average female height increases with the social position.—L. **Le Nouëne**: The addition of a microphone apparatus to the ear trumpet for the relief of deafness.—Charles **Nicolle**, A. **Cuénod**, and L. **Blaisot**: Some experiments on trachoma (granular conjunctivitis). An account of attempts to transmit trachoma from human subjects to monkeys.—A. **Magnan**: The influence of the nature of the food upon the large intestine and cæcum of birds.—N. **Lehmann** and C. **Vaney**: The relations between the climatic conditions and frequency of the larvæ in the Hypoderma of the ox.—M. **Maisonneuve**: The fecundity of Cochylis.—Adrien **Lucet**: The influence of agitation upon the development of *Bacillus anthracis* cultivated in liquid media. If the liquid cultures of anthrax are kept agitated, the bacilli tend to assume the same form as in blood, and the yield in a given time is increased.—A. **Marie**: The development of a neutralising substance in the brain of mammals.—Eloy de **Stœcklin**: The oxydase properties of oxyhæmoglobin.—Gabriel **Bertrand** and Arthur **Compton**: The action of heat upon emulsin.—Stanislas **Meunier**: The *rôle* of biological force in the evolution of the terrestrial surface.—G. **Vasseur**: Western France during the Stampian epoch.—M. **Deprat**: The importance of recent epirogenic movements in south-eastern Asia.—L. **Cayeux**: Dislocations in the islands of Delos, Rhenee, and Mykonos (Cyclades).—Francis **Rey**: The presence of the Gothlandian in the plain of Tamlet, on the Algeria-Morocco border.—Charles **Moureu** and Adolphe **Lepape**: The ratio of argon to nitrogen in natural gaseous mixtures and its signification. This ratio has been determined for fifty-two natural gases from springs, and varies between 0·76 and 3·37, with an average of 1·15.—M. **Boudry**: A new method of utilising thermal waters at a distance from the spring.

CALCUTTA.

Asiatic Society of Bengal, May 3.—I. H. **Burkill**: Swertiæ chinenses quatuor novæ ex herbario G. Bonati. Four new Swertias from Yunnan are described, viz. *S. Bonatiana*, *S. Duclouxii*, *S. rosea*, *S. patens*; *S. patens* is a very marked species.—W. W. **Smith**: Note on *Sterculia alata*, Roxb., var. *irregularis*, a remarkable instance of leaf variation. The author directs attention to the wide range of variation in the leaf of this peculiar variety as represented on a tree in cultivation at the Royal Botanic Garden, Calcutta. Seedlings from the tree may vary like the parent.—W. W. **Smith**: A new Gentian and two new Swertias from the E. Himalaya. Descriptions of a small Gentian and two Swertias from Sikkim, *Gentiana pluviarum*, *Swertia ramosa*, and *S. Burkilliana*.—W. W. **Smith**: Plantarum novarum in Herbario Horti Botanici Calcuttensis cognitarum Decas. Descriptions of *Oritrephes septentrionalis*, *Senecio biligulatus*, *S. Lagotis*, *S. Kingianus*, *S. Chola*, *Saussurea fibrosa*, *S. Pantlingiana*, *S. Nimborum*, *S. Laneana*, and *Veratum shanense*. The first and last are from Burma; the others are from the Sikkim Himalaya.—Lieut. F. H. **Malyon**: Some current Pushtu folk-stories.—D. **Hooper**: The composition of Indian yams. Proximate analyses are given of forty samples of the tubers of identified species and varieties of Dioscorea, grown wild or cultivated in India. The food value of the best kinds is shown to agree with that of the potato. The poisonous principle, dioscorine, is described, and its presence or absence is recorded in the samples examined. The chemical changes that take place when the poisonous roots are treated with water to render them edible is shown by comparative analysis of the raw and prepared tubers.—D. **Hooper**: Some Asiatic milk-products. Peculiar forms of dried cheese, called *Karut* in Baluchistan and Afghanistan, and *Chema* in Tibet and Mongolia, are described, and the analysis of samples from Nepal and Quetta are recorded. They consist largely of casein, with more or less free lactic acid. Examinations are also made of Bengal curds, called *chhana* and *dahi*, the first being a rich cream containing more casein than ordinary cream, and the second being buttermilk undergoing lactic fermentation. *Karut* is prepared from fermented skimmed milk by pressing and drying the coagulated proteids.—Kashi P. **Jayaswal**: Elucidation of certain passages in I'tsing.—Biman Behari **Dey** and Hemendra Kumar **Sen**: Interaction of hydrazine sulphate with nitrites, and a new method for the determination of "nitritic" nitrogen. On attempting to prepare hydrazine nitrite by the double decomposition of barium nitrite and hydrazine sulphate, barium sulphate is precipitated, and the new salt appears to be formed at low temperatures, but readily decomposes. A systematic examination was made of the gases evolved, and it was found that by collecting the gases in an endiometer, nitrous oxide and nitrogen existed in the proportion of two to one. By calculating the weight of the gases evolved, the formation of monacid hydrazine nitrite is demonstrated according to theoretical equations. Nitrites of the alkalis, the alkaline earths, the heavy metals, and, in fact, nitrites in general, were decomposed in a similar manner, and the estimation of the volumes of residual gases indicated the amount of nitritic nitrogen formed in the reactions.—Prof. W. **West**, with notes by Dr. N. **Annandale**: Descriptions of three new species of Algæ associated with Indian fresh-water polyzoa. The algæ described are from the Western Ghats and Orissa, and represent the genera Tolypothrix, Dactylococcopsis, and Microcystis.

DIARY OF SOCIETIES.

THURSDAY, JUNE 8.

ROYAL INSTITUTION, at 3.—Practical Progress in Wireless Telegraphy: T. Thorne Baker.

MATHEMATICAL SOCIETY, at 5.30.—On the Multiplication of Dirichlet's Series: G. H. Hardy.—On the Range of Borel's Method for the Summation of Series: G. H. Hardy and J. E. Littlewood.—On the Convergence of Fourier Series and of the Allied Series: Dr. W. H. Young.—On some Two-dimensional Problems in Electrostatics and Hydrodynamics: W. M. Page.—On Groups of Linear Substitutions of Finite Order with Rational Coefficients: Prof. W. Burnside.

FRIDAY, JUNE 9.

ROYAL INSTITUTION, at 9.—Applications of Physical Chemistry to the Doctrine of Immunity: Prof. S. Arrhenius.

ROYAL ASTRONOMICAL SOCIETY, at 5.—(1) The Transformation of the Moon's Latitude; (2) On the Progress of the New Tables of the Moon's Motion: Ernest W. Brown.—Measures of the Proper Motion Star Sh. 190: S. W. Burnham.—Further considerations relating to the Systematic Motions of the Stars: J. Halm.—Observations of Saturn's Ninth Satellite (Phœbe): Royal Observatory, Greenwich.—On the Detection of a New Element (Dysprosium) in the Solar Chromosphere: Alex. D. Ross.—*Probable Papers*: On the Law which Governs the Variations of SS Cygni: E. T. Whittaker.—Preliminary Results of the Photographic Method of obtaining Differential Places of Reference Stars: H. H. Turner.—The Hartmann-Cornu Formula: F. J. M. Stratton.—The Galactic Distribution of Gaseous Nebulæ: A. R. Hinks.

PHYSICAL SOCIETY, at 8.—The Lüders Lines on Mild Steel: W. Mason.—Exhibition of a Model illustrating the Passage of a Light Wave through Quartz: Dr. H. S. Allen.—Tables of Circular and Hyperbolic Functions for Complex Values of the Argument: A. Johnstone.—On the Measurement of Contact Differences of Potential: Prof. Anderson and J. G. Bowen.—Exhibition of some Gyroscopic Apparatus: Sir G. Greenhill.—A New Method of Approximate Harmonic Analysis by Selected Ordinates: Prof. S. P. Thompson, F.R.S.

MALACOLOGICAL SOCIETY, at 8.—Description of a New Species of Acmæa from Bombay and Notes on other Forms from that locality: E. A. Smith.—Description of Three New Species of Operculate Land Shells from Grand Cayman Island: H. B. Preston.—Further note on Preoccupied Molluscan Generic Names and Proposed New Names: G. K. Gude.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology of the District of the Bergen Arches: Dr. C. F. Kolderup.—The Rock Formation of the Bergen District: Horace W. Monckton.

SATURDAY, JUNE 10.

ROYAL INSTITUTION, at 3.—Types of Greek Women: Dr. W. L. Courtney.

ARISTOTELIAN SOCIETY (at Corpus Christi College, Oxford), at 9.—Real Being and the Object of Thought: G. F. Stout.

MONDAY, JUNE 12.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Observations on Cotton and Nitrated Cotton. Part III.: H. de Mosenthal.—Methods of Testing Inflammable Gas and Vapour Detectors: A. Philip and T. Stenhouse.—A New Form of Automatic Detector of Inflammable Gases and Vapours: A. Philip and L. G. Steele.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Some Explorations in the Himalayas: Dr. Arthur Neve.

INSTITUTE OF ACTUARIES, at 5.—Annual General Meeting.

TUESDAY, JUNE 13.

ZOOLOGICAL SOCIETY, at 8.30.—On Antelopes of the Genera Madoqua and Rhynchotragus from Somaliland: Dr. R. E. Drake-Brockman.—On an Amphipod from the Transvaal: Hon. Paul A. Methuen.—The Somali Rhinoceros and the Nigerian Klipspringer: R. Lydekker.—A Contribution to the Ornithology of Western Colombia: C. E. Hellmayr.—The Subspecies of the Spanish Ibex: Prof. Angel Cabrera.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—The Saints of the Indus Valley: Major A. J. O'Brien.

ROYAL STATISTICAL SOCIETY, at 5.30.—Under the Crown: Sir J. Athelstane Baines.

MINERALOGICAL SOCIETY, at 5.30.—On Zirkelite from Ceylon: G. S. Blake; with Notes on the Crystallography of the Mineral: Dr. G. F. H. Smith; and on the Chemical Composition: Dr. G. T. Prior.—Note on some Crystals of Artificial Gypsum: Rev. Mark Fletcher.—The larger Diamonds of South Africa: L. J. Spencer.—Brecciation in Mineral Veins: F. H. Butler.—On a New Mineral from the Binnenthal: R. H. Solly.—Prehnite from the Lizard District: Arthur Russell.

FARADAY SOCIETY, at 8.—Allotropic Forms of Metals: Prof. Ernst Cohen.

WEDNESDAY, JUNE 14.

GEOLOGICAL SOCIETY, at 8.—On a Monchiquite Intrusion in the Old Red Sandstone of Monmouthshire: Prof. W. S. Boulton.—Notes on the Culm of South Devon. Part I., Exeter District: F. G Collins; with a Report on the Plant Remains: E. A. Newell Arber; and Notes on the Cephalopoda: G. C. Crick.

ROYAL METEOROLOGICAL SOCIETY, at 4.30.—The Diurnal Inequality of Barometric Pressure at Castle O'er, Dumfriesshire: Dr. C. Chree, F.R.S.—Rain Drop Experiments: S. C. Russell.—Investigation of the Electrical State of the Upper Atmosphere, August, 1910: A. J. Makower, Dr. W. Makower, W. M. Gregory, and H. Robinson.

THURSDAY, JUNE 15.

ROYAL SOCIETY, at 4.30.—Croonian Lecture: A New Conception of the Glomerular Activity: Prof. T. G. Brodie, F.R.S.

LINNEAN SOCIETY, at 8.

ROYAL GEOGRAPHICAL SOCIETY, at 5.—Research Meeting. Report on River Investigation: Dr. A. Strahan.

FORTHCOMING CONGRESSES.

JUNE 28, 29.—Conference on Education and Training of Engineers. London. President: Mr. Alexander Siemens, President of the Institution of Civil Engineers. General Secretary: Dr. J. H. T. Tudsbery.

JULY 18-22.—International Association of Seismology. Manchester. President: Prof. Arthur Schuster, F.R.S.

JULY 25-28.—British Medical Association. Birmingham. President: Dr. H. T. Butlin, Pres.R.C.S.

JULY 26-29.—First Universal Races Congress. University of London. President: Lord Weardale. General Secretary: G. Spiller, 63 South Hill Park, Hampstead, London.

JULY 29-AUGUST 5.—Congress of French Geographical Societies. Roubaix. President: Prince Roland Bonaparte.

JULY 30-AUGUST 2.—Annual Meeting of the Swiss Society of Natural Sciences. Soleure. President: Dr. A. Pfaehler. Inquiries to Secretaries: Dr. Küng (German) and Prof. Brönnimann (French).

AUGUST.—Centenary of the Foundation of the University of Breslau.

AUGUST 12-18.—First International Congress of Pedology. Brussels. President: M. Alexis Sluys. Secretary: M. Vital Plas, 35 Avenue Paul de Jaer, Brussels.

AUGUST 13-20.—Prehistoric Society of France. Nîmes.

AUGUST 31-SEPTEMBER 6.—British Association. Portsmouth. President: Sir William Ramsay, K.C.B., F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

SEPTEMBER 4-6.—Centenary of the University of Christiania. President of Festival Committee: Prof. Brögger.

SEPTEMBER 9-20.—International Congress of the Applications of Electricity. Turin. President of the Committee of Honour: H.R.H. the Duke of the Abruzzi. Honorary Secretary of the Committee: Signor Guido Semenza, Via S. Paolo 10, Milano International Secretary: Col. R. E. Crompton, C.B., R.E., Crompton Laboratory, Kensington Court, W.

SEPTEMBER 24-30.—International Congress on Tuberculosis. Rome. Address for inquiries: Honorary Secretary of the National Association for the Prevention of Consumption, 20, Hanover Square, W.

OCTOBER 2-7.—Third International Congress of Hygiene. Dresden. General Secretary: Dr. Hopf, Reichsstrasse 4, Dresden.

OCTOBER 15-22.—Tenth International Geographical Congress. Rome. President: Marquis Raffaele Cappelli. General Secretary: Commander Giovanni Roncagli, Italian Geographical Society, Rome.

DECEMBER 27.—American Association for the Advancement of Science. President: Dr. C. E. Bessey, University of Nebraska. Permanent Secretary: Dr. L. O. Howard, Smithsonian Institution, Washington, D.C.

CONTENTS.

THURSDAY, JUNE 15, 1911.

RURAL DENMARK.

Rural Denmark and its Lessons. By H. Rider Haggard. Pp. xi+335. (London: Longmans, Green and Co., 1911.) Price 6*s*. 6*d*. net.

MR. RIDER HAGGARD'S book is the outcome of a recent visit to Denmark, made in order to inquire into the actual conditions of farming prevailing there, and particularly into the success of the small holders, who form so marked a feature of Danish agriculture. Mr. Rider Haggard's further object was to gather information as to whether such small holdings are likely to succeed better on the leasehold system that has been established in this country by the recent Act, or whether, as advocated by the other party in the State, it is essential for success that small holdings should be owned by their occupiers. Mr. Rider Haggard also wished to ascertain the working of the various forms of credit banks and State loans to farmers to enable them either to purchase their holdings or to provide working capital when they were already in occupation. For the last generation Denmark has been the standard example to all agricultural reformers of how the farming of a country can be made efficient by taking thought, either through the medium of cooperation or more directly by State aid. Denmark has to live by its agriculture alone, and it is well known that the productivity of the country, the wealth of its population, and the value of its exports have been raised to an astonishing degree during the forty years or more that have elapsed since the war with Germany; so that, despite many natural disadvantages, Denmark has been able to maintain its position as a free-trade country in face of the unprecedented competition from America, which has so severely shaken the status of agriculture in other European countries.

Mr. Rider Haggard went provided with the best introductions, and he reports, with the clearness and the power of description for which he is so well known, the impressions which he formed as he passed from one agricultural enterprise to another. For example, he tells us of the operations of a cooperative dairy, of a milk supply company, and of an egg export association; he visited one of the great capitalist farms worked by its owner, carrying more than 1000 cows, and earning a net profit estimated at 20,000*l*. a year. As a contrast, he also describes in detail the mode of working some of the State-created small holdings of about six acres each, and compares them later with other privately acquired peasant properties of from five to thirty acres.

In his survey education also bulks largely; the elementary schools, the high schools which take young men and women between seventeen and twenty-five for three months in the winter, the agricultural school proper, and the great central college at Copenhagen were all visited, and one cannot fail to be impressed throughout the whole of the book by the manner in which the success of the Danish farmer seems to depend upon the high standard of education he has reached, and his attitude towards the things of the mind.

Finally, Mr. Rider Haggard reports the substance of his discussions with various authorities on the particular questions about which he was making inquiries. For example, he shows that even in Denmark men are not agreed as to the value of small farms as compared with large, still less so as to the desirability of the State making loans and subventions in order to create a community of small farmers. After a general discussion of the present position of Danish agriculture, he emphasises the fact that the success of the small farmers, even the possibility of their existence, is dependent upon the way they have learned to work together, and the almost universal adoption of the form of cooperation in both buying and selling. Not only is cooperation necessary to enable the small man to buy somewhere near prime cost and to realise a due return for his produce, but the cooperative societies form the great medium for the technical education of the farmer. For unless men in a district have learned to act together it is impossible to deal properly with such questions as the improvement of stock and crops, the eradication of disease, &c.

Mr. Rider Haggard's book is extremely interesting reading, and though at times we may feel a little inclined to doubt whether his working knowledge of agriculture was quite sufficient to enable him to appreciate the real bearing on the situation before him, his book is most valuable because it is free from that indiscriminate laudation of the Danish farmer and his methods, which has been preached somewhat *ad nauseam* to the English agricultural community.

Mr. Rider Haggard has been too wise to suppose that an economic revolution can be effected in the English countryside by merely copying Danish methods, and he sees that any attempt to impose Danish organisation upon our farmers at the present time would only end in disaster. Organisations, methods, institutions, really count for little except in so far as they are the outcome of the spirit of the men and women who are working through them, and agriculture on a Danish model will be impossible here until we have a community possessing the same mental outlook. Mr. Rider Haggard rightly lays stress in almost every section of his book on the high pitch of education to which many of even the smallest occupiers of land in Denmark have reached, and again and again it comes out that this education is general and not merely technical. The Danish small farmers, even the Danish peasant or milkmaid, seek for education in order to become free and effective men and women, and it is almost incidentally that they learn certain other things which they can turn to direct pecuniary account. It is through education, and through an education founded on a respect of things of the mind, that cooperation has become possible there, and it has made so little headway in this country just because its immediate returns are but a small inducement to men who live in an atmosphere of distrust of the unknown and suspicion of all joint actions.

If for this reason alone, his insistence that the success of small holdings depends upon cooperation, and that cooperation ultimately depends upon education, we can most cordially recommend Mr. Rider Haggard's book to everyone who is interested, either directly or indirectly, in the welfare of the rural population.

THE SEWAGE PROBLEM.

Sewage Disposal. By Prof. L. P. Kinnicutt, Prof. C. E. A. Winslow, and R. W. Pratt. Pp. xxvi+436. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1910.) Price 12*s.* 6*d.* net.

THE economic solution of the important problem of sewage purification depends for its success on the careful application of engineering principles to the numerous physical, chemical, and biological changes involved. It is therefore with pleasure we find a volume devoted to the subject which is the result of collaboration between distinguished American representatives of chemistry, biology, and engineering, particularly so when each of the individual authors has had wide experience in the practice of sewage purification and disposal.

It is stated in the preface that this work was in progress before several of the recent publications on sewage purification had appeared; the authors, however, claim that there is still room for a general survey of the subjects with particular reference to the conditions of American practice. This claim is certainly justified by the careful way in which world-wide information in regard to the various methods of sewage purification has been collected, and by the admirable manner in which the subject-matter is presented.

From the point of view of American practice it is not surprising to find that separate chapters are devoted to the consideration of the questions of sewage purification or disposal by dilution, and of intermittent sand filtration. The former question receives thorough treatment, and the conditions necessary for the adequate purification of sewage discharged into waterways are discussed at length. Interesting examples are given of the self-purification of rivers receiving sewage. While this method of disposal is rendered possible in many cases in America by reason of the relatively large volume of the rivers, it is, of course, for obvious reasons, scarcely practicable in the case of inland towns in England.

The question of the preliminary treatment of sewage by the various tank processes, and also that of the disposal of sludge, is thoroughly dealt with in chapters iv. to vii., inclusive. Under the head of the septic process, the Hampton hydrolytic tank is described in detail, and the Emscher tank of Imhoff receives notice. The Hampton doctrine on the theory of sewage purification is given careful attention, and the authors' conclusion in regard to the relative value of this theory as compared with the views advanced by Dunbar will probably meet with general approval by those actually engaged in the work of sewage purification.

It is interesting to note that when discussing the bacteriology of intermittent filtration, no reference is made to the theory recently promulgated of direct nitrification of organic nitrogen, the authors evidently being in agreement with the generally accepted view of the preliminary formation of ammonium compounds.

In subsequent chapters is given a comprehensive survey of the question of the purification of sewage on contact beds and percolating filters respectively, illustrated by numerous examples of purification works in England, America, and on the Continent. The authors' review of the relative merits of the two systems of filtration may, in general, be commended. It is to be feared, however, that the quantities of sewage actually dealt with by percolating filters will be found on investigation to be considerably lower than those given in table lxxxv., especially when the time the filters are out of operation is taken into consideration.

Exception must also be taken to the authors' statements that the results obtained at Croydon, which are quoted on p. 372, afford an excellent idea of the comparative efficiency of contact beds and percolating filters.

These results give an entirely erroneous impression as to the possibility of contact beds, inasmuch as the purification mentioned of from 40 to 47 per cent., is certainly much below the results generally obtained when working at so low a rate as 46 gallons per cubic yard per day.

The concluding chapters are concerned with the disinfection of sewage and sewage effluents, and the methods of analysis.

In view of the present tendency amongst certain English sanitarians, it is important to observe that in the opinion of the authors, it has not yet been demonstrated that any electrolytic process for making chlorine at the sewage plant, unless free power is available, is as economical as the purchase of the ordinary commercial product.

This work can be thoroughly recommended to all interested in sewage purification, more particularly as the authors themselves do not dogmatise on the subject, but are successful in presenting in a lucid manner both the principles involved in the problem of sewage treatment, and the various views and theories which have been advanced by leading investigators. A clear statement of the present position of the subject is thus afforded. The value of the book is enhanced by the excellent list of references, which will be found of considerable use to those engaged in sanitary work.

EDWARD ARDERN.

FACT AND HYPOTHESIS IN BIOLOGY.

Lectures on Biology. By Dr. Curt Thesing. Translated from the second edition by W. R. Boelter. Pp. viii+334. (London: J. Bale, Sons, and Danielsson, Ltd., 1910.) Price 10*s.* 6*d.* net.

THIS book could be heartily recommended to readers who wish for a modern presentation of general biological discovery were it not for the pseudo-philosophical limitations which the author imposes upon each and every hypothesis that has been advanced to account for the facts. The arguments that

go to prove the truth of evolution are skilfully and attractively marshalled, but that is not the author's chief object. What he aims at is to show that the selection-hypothesis only applies to a limited field, that use-inheritance has its restricted place, and so on; in short, that all our explanations are partial, and that in none of them can we have complete confidence.

When we come to ask on what grounds this want of confidence is asserted, we find the old objections answered fifty years ago by Huxley put forward as if they were discovered yesterday. "Darwinism yields no information concerning the causes of variability" (p. 210); "the theory of natural selection is the doctrine of chance"; "the theory of mutation plays with chance even more than selection." What is Darwinism but a method? The author uses this word as if it implied a corpus of knowledge which could not be extended, and was to be judged by its expression in the writings of casual essayists. In only a single place does he refer either to the "Origin" or to "Variation under Domestication," though he quotes extensively from modern critics. It is idle talk to say that Darwin did this, but not that as though one man could do all, or as if Darwin claimed a complete supremacy for his selection hypothesis. Are we to have no confidence in the theory of natural selection because its discoverer was not able to give a complete treatment of variation? One would really conclude from this book that variation was a subject to which Darwin gave no serious consideration. The old goddess "chance" is once more used as a stick to beat the dog "selection" with, and we become rather tired at the iteration of arguments urged and rebutted any time these thirty years. Even the old crude presentation of the Miltonian "creation" is made to stand up in order to receive fresh blows.

The book is sadly in need of competent revision. The number of misprints is really irritating. Amongst the animals of the tropics we are told there is the leopard and the *gepard*, a creature the nature of which is wholly problematical. The choristers at Rome have well developed "mammals" (p. 148); "*Omni* vivum e vivo" (p. 97); "like all other infusorians, no bell-animalcule is able to reproduce by simple fission" (p. 230); the vermiform appendix "has no function whatever, its object being rather apparently to create suffering." On p. 129 Balanoglossus is classed with Vermes, and the larvæ of Crinoids are termed Bipinnaria, whilst on p. 130 the larvæ of starfish are correctly called by that name, but the figure refers to an Auricularia or Holothurian larva. In his condemnation of sexual selection the author entirely overlooks the careful observations by Mr. and Mrs. Peckham on the spiders of the family Attidæ, and as these support the Darwinian position the whole criticism falls to the ground.

Apart from critical matters, the book is full of interest, and its summary of recent work on heredity is but one example of the wide reading and careful exposition which the author exhibits. Read with due caution the book can only do good.

AN AMERICAN COLLOQUIUM.

The New Haven Mathematical Colloquium. By E. H. Moore, E. J. Wilczynski, and Max Mason. Pp. x+222. (New Haven: Yale University Press; Oxford: University Press, 1910.) Price 13s. 6d. net.

IN the autumn of 1906, at the meeting of the American Mathematical Society, three short courses of lectures were delivered to the assembled experts, and are here published for the benefit of the world at large, or at any rate for that of such persons as are interested in the most recent aspects of pure mathematics. The authors assume that their hearers have a good knowledge of analysis, and the reviewer must do the same, in order to keep within due limits.

Prof. Moore's discourse is an introduction to general analysis, which may be described as an essay on the "functional theory" of Fréchet and others. A free use is made of the Peano stenography, and this is one more sign of a fact which some of us will admit with regret, namely, that students of the logical side of mathematics must become proficient in Peanese.

Two important ideas play a leading part in Prof. Moore's discussion. The first is the dominance of one function by another; μ_1 is dominated by μ_2 if, for every argument p, the absolute value of $\mu_2(p)$ is not less than the absolute value of $\mu_1(p)$. The other, which appears to be both new and important, is that of uniform convergence relatively to a function σ. Thus we have a notation

$$\mathrm{Lt}_n\, \mu_n = \mu\ (\mathrm{R}\ ;\ \sigma),$$

meaning that when R is the range of the variable x, and $(\mu_1, \mu_2, \ldots)$ is a sequence of functions of x, this sequence converges in such a way that, by taking n large enough, and for all greater values of n, $|\mu-\mu_n|<e|\sigma(x)|$, where e is any assigned positive number; and if n can be determined by means of e alone (without x), we have uniform convergence relative to σ. When σ is constant, we come back to the usual definition of uniform convergence. The second part of the essay is on composition of classes, which may be described as a generalisation of the theory of the composition of moduli and ideals in the theory of numbers.

In connection with a certain notation, the author remarks that "the intention is to discriminate sharply between function and functional value." With this we confess we are in sympathy, though, of course, we shall be told that a function is merely an enumeration of values, either actually or potentially complete. In the abstract, of course, this is undeniable; but consider the function $\sin x$, for example. Its property of being periodic is intrinsic, and was actually realised before there existed a table of its values, or rather it was made part of a generalised definition of $\sin x$. Again, the class of algebraic numbers, or that of algebraic functions, surely has a significance apart and beyond the aggregate of values associated with it.

The next essay is upon projective differential geometry, especially in connection with ruled surfaces. Various results of great interest and generality are obtained by the author; for instance, it appears that

an arbitrary space curve being given, it can be considered as one branch of the flecnode curve of an infinity of ruled surfaces, into the general expression of which there enters an arbitrary function. On the other hand, two curves taken at random cannot be connected, point to point, so as to be the complete flecnode curve on the ruled surface thus generated. As the author remarks, there is no doubt that the field thus opened promises valuable results. So far as the analysis goes, it follows the lines of the known theory of differential invariants, constructed by Halphen, Lie, and others.

Finally, Prof. Mason gives an interesting summary of various boundary-value problems of differential equations. Perhaps one of the most elegant things in this essay is the construction of a doubly periodic Green's function G, which satisfies the equation $\Delta u=0$ within the period rectangle, except at two points where it is logarithmically discontinuous. This is followed by a remarkable application to the equation $\Delta u=f(x, y)$, where f is periodic in x, y independently, with periods a, b equal to the lengths of the sides of the period rectangle of G.

It is noteworthy to find the United States maintaining so many distinguished mathematicians, both native, and, if we may be excused the term, imported. When will the English nation wake up to the fact that it is not waste of money, or at best a concession to dilettante ideals, to provide a living for a first-rate mathematician, even if he proposes to devote his life to varieties in n dimensions, or the theory of aggregates, or the distribution of primes? Surely, and at an accelerating rate, the dominion over nature and over their fellow-men is coming into the hands of the star-gazers, the speculators, the originals, who have been lampooned and pilloried from the age of Aristophanes to that of Swift, and from his days to our own. Or rather, the material profit, the worldly dominion, will come to those nations that have the sense to see that by attracting these creators of new ideas they are encouraging every kind of higher invention, and buying in the cheapest market the best of goods—brains.

G. B. M.

IMPRESSIONIST ASTRONOMY.

The Night-Skies of a Year: Being the Journal of a Star-gazer. By J. H. Elgie. Pp. xii+247. (London and Leeds: Chorley and Pickersgill, Ltd., 1910.) Price 6*s.* net.

TAKING sections for each month of the year as basis, the varying aspects of the constellations are presented in a series of discursive notes purporting to describe the impressions of the writer on the occasions when he observed the various objects. The author takes as his aim the task of teaching the geography of the sky by means of a journal showing how the constellations alter in their relative aspects from night to night, and at different times on any night. So far this is commendable. It is evident, however, that the desire to produce a volume of impressive magnitude has induced the decision to inflict a superfluity of purely personal impressions; if these were in the main likely to be experienced by other observers, they might be helpful, but from the nature of many of them it is very questionable if they can be. Take as an example the following:—

"Ten o'clock! Ugh! How drear and dismal is the night, a night unrelieved by star or moon. Rain is beginning to fall. The tempting gleam of a brightly burning fire comes out to me through my window, so I will indoors and try to think that this really is the opening of the 'merrie month.' Then, to round off the evening presently, I will study anew an appropriate article on the old, old question of 'Is the climate changing?' If matters do not mend soon I shall alter my opinion on that subject and persist that the climate is changing."

This quotation is a fair sample of the style of the whole, though here and there one finds an oasis of more acceptable material.

The book is illustrated by numerous rough sketches of constellation groups, and if these were not specially intended for instruction they might be passed over. The author specially directs attention to these sketches, and says:—

"I am convinced from the letters of numerous correspondents that the difficulty of recognising the main outlines of the constellations at any hour from the charts accessible to them has damped the enthusiasm of thousands of beginners in the study of astronomy."

Our opinion is, however, that the star alignment diagrams are perhaps the most unsatisfactory feature of the book. Taking any one constellation, even such a well-known one as Orion, for instance, it is shown with the component stars, in different relative grouping on consecutive pages, due, it must be assumed, to defective drawing. We would advise the "numerous correspondents" to purchase a trustworthy star atlas, and endeavour to commandeer the help of a capable friend for about five minutes each week. This would do away with all the damping of their enthusiasm.

SNAKES OF CEYLON.

The Snakes of Ceylon. By A. F. Abercromby. Pp. vi+89. (London: Murray and Co., 180 Brompton Road, S.W., 1910.) Price 2*s.* 6*d.* net.

THE author, being of opinion that the "many works and treatises" in which the snakes of Ceylon are described are "more suited to the scientist than the naturalist," and that "natural history books, on the other hand, seldom give sufficiently detailed information about snakes," has produced a volume which the discerning reader will see at once to be not in the roll of common art. The systematic part being an admitted compilation from well-known works on the fauna of India, we may restrict our inspection to those parts of the book which reveal the originality of the writer.

In dealing with the anatomy and physiology of snakes, the author laments that "the effect of, and antidotes for, snake poison is a subject which has been much written about and much discussed, but very little has been discovered about it." He has heard of permanganate of potash at least, but this, "although a very successful absorbent remedy, is

reported to have a poisonous effect upon the blood." His views on cures for snake-bite are those of a Rip Van Winkle; what we want is—

"not so much a remedy which will absorb and neutralise the poison, as a means by which this neutraliser may be enabled to reach the poison, or a treatment for keeping up the vitality of a patient until the poison becomes absorbed by the system."

In short, he makes the words "absorbed" and "absorbent" as odious as the word "occupy" was to Doll Tearsheet.

In the chapter on "hunting" snakes, our author is as coherent and profound as honest Dogberry himself. The "necessary point" in this hunting to be borne in mind is that "it is less important to go where there are a great many snakes than to go where the nature of the country facilitates seeing and catching of them." So also, "a cobra is best obtained by digging one out of an ant-heap or hole," but "the cobra must have been seen to enter the hole a short time before," for all is vanity. As to smoking a snake out, "it takes a lot of smoke to have any effect on a snake, owing to the latter's lung capacity." The snake has only one lung, but that, like the one eye of Mr. Midshipman Easy's friend, the master's mate, is of prodigious power. When the author tried smoke "it was so suffocating and so blinding that the capture of the snakes was extremely difficult and somewhat risky"; little wonder that he regards it as "an unsatisfactory proceeding." The way to comprehend vagrom pythons "can only be learnt by practice"; but if the python be asleep "it can often be captured without any trouble."

Touchstone and his shepherd could not improve the chapter on snakes in captivity.

"When feeding a tame python great care has to be exercised lest the snake should seize your hand in mistake for a rat, especially if your hand has just been in contact with the latter."

Truly it requires the careful experiments of a natural philosopher to discover

"that cold is not so injurious to these reptiles as is commonly believed, but that it is the infrequency of the sun's rays that renders a climate such as that of England unsuitable for serpents."

Finally, we would commend this weighty precept:

"Those who are desirous of keeping a serpentarium of live snakes should study as much as possible the conditions under which the various snakes live when in the wild state,"

otherwise they labour in vain on their "serpentarium."

THE METHODS OF ANTHROPOLOGY.

The Racial Anatomy of the Philippine Islanders. Introducing New Methods of Anthropology. By Prof. R. B. Bean. Pp. 236+25 photographs. (Philadelphia and London: J. B. Lippincott Company, 1910.)

THE most recent literature dealing with the study of man's physical characters reveals manifold signs of a widespread revolt against the domination of mere anthropometry in this field of research. It is often urged that no kind of investigation can claim the title "exact," or even be called "science," unless it deals with evidence that can be expressed in figures or mathematical symbols. But in all biological inquiries a primary sorting of the material is an indispensable preliminary to its mathematical treatment, and until the obviously heterogeneous elements in any series have been sifted, one species of material being separated from another, and males distinguished from females, any attempt to deal statistically with measurements of such unsorted material can produce only confusing and misleading conclusions.

The most urgent need in anthropology at the present time is the determination of those characters of the human body and its parts, which have definite significance as indications of race, and the investigation of the exact value and meaning of such traits, and of the bond of union between them and other distinctive characters, which are associated in groups in different individuals.

The comparative sterility of recent work in anthropology, so far as the determination of racial characters in series of skeletons is concerned, is due mainly to the common neglect of such preliminary studies and the immediate resort to blindly-made measurements as the sole means of investigation. It is the great merit of Sergi's work that he insisted on this return to the ordinary methods of zoological investigation in dealing with human remains, and by the use of such methods, crude and unsatisfactory as some of them undoubtedly are, he has been able to recover a great deal of true history of man's movements, and information concerning his affinities.

Prof. Bean's interesting book on the people of the Philippine Islands claims the consideration of the anthropologist, not so much for what he has accomplished, as from the fact that it is an attempt to direct the investigation of racial anatomy into its proper channel, for in it he has attempted to discriminate between the peculiarities of conformation of the external ear in the different racial elements in the Philippines, and use them as indices of race in precisely the same manner as the zoologist or "the man in the street" would distinguish a cat from a dog, even if these animals were of precisely the same size and quite irrespective of the measurements of their crania or other bones.

Dr. Bean has correlated the various types of ear with a large series of other physical characters, as well as with stature, proportion of limbs and trunk and head; and, like others who have undertaken similar investigations upon man or other living creatures, he finds that "the method of grouping reveals types that apparently represent *character-complexes* composed of unit characters," which "hang together in heredity or break up when crossed with other *character-complexes*."

Throughout the book the author is ever on the alert to detect Mendelian phenomena, and in chapter x. he builds up a scheme for the explanation of heredity in human mixtures.

The most unfortunate feature of Dr. Bean's sug-

gestive essay is his application to the peoples of this far-eastern island of terms such as "Alpine," "Adriatic," "Iberian," "Cro-Magnon," and others, which are not without objections even when applied to the population of Europe, but become doubly misleading when applied to Filipinos, who are partially hybridised with real Iberians.

G. ELLIOT SMITH.

PROF. GROTH'S CHEMICAL CRYSTALLOGRAPHY.

Chemische Krystallographie. By P. Groth. Dritter Teil, Aliphatische und hydroaromatische Kohlenstoffverbindungen. Pp. iv+804. (Leipzig: W. Engelmann, 1910.)

DESPITE the duties appertaining to a professorial chair and the unremitting labour attaching to the editorship of his flourishing *Zeitschrift für Krystallographie und Mineralogie,* Prof. von Groth proceeds steadily and rapidly to the completion of the great task he has set before him. The successive volumes have appeared at intervals of two years, and now, four years since the publication of the first, we welcome the issue of the third and penultimate volume. It includes the various aliphatic and aromatic compounds that have been obtained in crystallised form, and meets a widely and long-felt want. Putting aside a few oxalates which occur in nature, it has hitherto been impossible to turn up readily the crystal character of any of these substances; even the most comprehensive text-books on organic chemistry rarely define the forms more exactly than as being plates or needles.

The volume is composed of two parts, of which the first is by far the longer. In it the paraffins and the corresponding olefines are grouped together according to the number of carbon atoms in the molecule, the concluding chapter being devoted to the ureas and the derivatives of uric acid. In the second part the hydrobenzol derivatives and the terpenes and camphors are considered. For each substance the physical characters are stated tersely, but as completely as possible, the information including the melting point, the specific gravity, the morphological characters—the axial ratios, the indices of the observed forms, the values of the principal interfacial angles, and the directions of cleavage, if any, illustrations of crystals possessing features of exceptional interest being given—and the optical characters—the principal refractive indices for light of various standard wavelengths, the nature of the refraction, the relation of the optical indicatrix to the crystalline symmetry, and the optic axial angle; the authority for the data is recorded, and references to the original papers are given in footnotes. Each section is prefaced by a brief but interesting discussion of the substances dealt with and the relations subsisting between them. The book closes with two complete indices; in one the substances are arranged alphabetically by their names, and in the other by their formulæ in ascending order of the number of carbon atoms in the molecule. Little difficulty should therefore be experienced in tracing any particular compound. It is abundantly clear that every effort has been made to keep the book as free from errors as possible; in a work of this kind accuracy is everything.

The name of the publisher is sufficient guarantee for the excellence of the printing, which is, in fact, beyond criticism.

APPLICATIONS OF PHYSICAL CHEMISTRY.

(1) *Themen der physikalischen Chemie.* By Prof. E. Baur. Pp. iv+113. (Leipzig: Akademische Verlagsgesellschaft, m.b.H., 1910.) Price 4 marks.

(2) *Das chemische Gleichgewicht auf Grand mechanischer Vorstellungen.* By Prof. H. v. Jüptner. Pp. v+367. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 11 marks.

THE two volumes here noticed are not text-books of physical chemistry in the ordinary sense. They deal with selected parts of the subject, and are distinguished by the prominence given to its technical application.

Prof. Baur's book contains the substance of a series of vacation lectures delivered in the Brunswick Polytechnicum at the instance of the Society of German Engineers. The lectures are models of clear exposition, and are invariably terse and to the point. The experimental illustrations, directions for the repetition of which are included in the text, are well chosen, and calculated to stimulate inquiry. After a preliminary lecture on the principles of modern physical chemistry, the author proceeds to discuss such varied matters as voltaic cells, the blast-furnace, Deacon's process, the contact process for sulphuric acid, the production of atmospheric nitrate, catalysis, gas explosions, explosives in general, metallography, and colloidal chemistry. Students, both of industrial and of pure chemistry will find much to interest them in the little volume.

Prof. von Jüptner's work on chemical equilibrium is based on the following conceptions. The maximum external work which a chemical process is capable of performing is a measure of the chemical affinity of the process. This work can be measured by the gas pressures of the substances concerned. Hence chemical processes may be treated as mechanical, one substance being pumped into another (production of a compound) or being pumped out of another (decomposition of a compound). Thus dissociation phenomena may be considered as being at the root of all chemical processes. If the dissociation-pressure curves of all compounds are known, the behaviour of the compounds when they are brought together may be predicted; those with greater dissociation pressures will be decomposed, those with smaller dissociation pressures will be formed. The process will come to an end when the partial dissociation pressures of the common product (*e.g.* oxygen pressures of oxides) become equal.

Proceeding on these principles, the author considers the equilibrium conditions in systems with solid, liquid, and gaseous phases. As the book is intended in the first instance for practical men engaged in chemical industry, it is characterised by a wealth of

numerical data for dissociation pressures. The equations employed are often only approximate, but though subject to future correction, they cannot fail to be useful. In the study of iron and steel the author has achieved special eminence, so that the last chapter, which is devoted to the application of the above principles to the chemical reactions occurring in the blast furnace will be read with peculiar interest.

OUR BOOK SHELF.

The World of Dreams. By Havelock Ellis. Pp. xii+288. (London: Constable and Co., Ltd., 1911.) 7*s.* 6*d.* net.

MR. ELLIS very truly remarks that in the past the literature of dreaming has often been vitiated by bad observation and reckless theory. In the volume under review he gives a large number of carefully recorded dreams—chiefly his own—and is sparing of hypothesis. The drift of the book may be indicated as follows:—

The sleeping consciousness is weak in apperception and in will. It is, in fact, partly dissociated, as in insanity. But it can *reason;* and dreams are its serious and careful attempts to construct an adequate theory of the phenomena. These latter psychical facts may be sensations derived from external stimuli such as sounds—as when the drip of water from a burst pipe upon the floor near a dog's bed caused his owner to dream that the dog was being crushed in a mangle—or from visceral disturbances, as when indigestion causes dreams of terrifying situations. Stimuli of any kind are magnified by the sleeping consciousness, and the theory (the dream) is consequently out of proportion to their real importance, as when the singing of a canary caused a dream of the performance of Haydn's "Creation." Fear-dreams are often exaggerations of dimly-realised bodily discomfort, as when a lady had a horrible dream of murder after a supper of pheasant. The interesting point about this is that the dream is the result, and not the cause, of the emotion. Unpleasant feelings are really experienced, and the dream-consciousness invents a theory to account for them. This is in line with the James-Lange theory of emotion in general.

As to ultimate psychical origins, Mr. Ellis thinks that Freud presses his sexual-wish theory too far. The great Vienna psychologist has done brilliant work, but has become obsessed by his pet formula. His key will not fit all the locks. Probably most psychologists will now agree with Mr. Ellis on this point.

The chapter on dreams of flying and falling is particularly good. It can scarcely be doubted that the absence of pressure against the soles of the feet—a vague mass of sensation always present when standing or sitting—must have a great deal to do with these dreams. The other sensory nerves over the body being relaxed and inactive, the bed ceases to be felt; and the consequence is a dream of floating unsupported in the air. This suggests an explanation of the subjective feeling of levitation in the case of many saints. In ecstasy there is considerable anæsthesia, both of the soles of the feet and elsewhere.

The book is popular in style, but is thoroughly scientific in method, and Mr. Ellis has a wide acquaintance with the work of other investigators in this field. His contribution is a welcome one.

The Economy of Food: a Popular Treatise on Nutrition, Food, and Diet. By J. Alan Murray. Pp. xii+253. (London: Constable and Co., Ltd., 1911.) 3*s.* 6*d.* net.

THE subtitle of Mr. Alan Murray's book and the following extract from the preface will indicate its scope:—"The book is intended for students of domestic economy, cooks, caterers, housekeepers, and managers of institutions rather than for specialists in physiology, chemistry, and hygiene. The subject cannot be treated adequately without reference to the principles of these sciences; but the more difficult parts have been relegated to footnotes, and the use of technical terms in the text have been avoided as far as possible. The first section deals with the requirements of the body. The origin, properties, and composition of the commoner kinds of food are discussed in the second. In the third an attempt is made to combine these two branches in a form suitable for everyday use—to translate protein, carbohydrates, &c., into terms of bread and meat, *i.e.* of breakfast, dinner, and supper."

Mr. Murray has been very successful in his attempt; the scientific portions are accurate and up-to-date, the practical parts will fill a long-felt want, and the whole is presented in a clear and readable manner. In these days when so much rubbish is printed for popular consumption in the daily Press and elsewhere on the subject of food and diet, it is a godsend to have a really trustworthy and popular guide which it is a real pleasure to be able to recommend. Food, of all other subjects, is one which lends itself to the exploitation of fads. There is nothing of the sort in the present volume; we have no advocacy of any particular system, no hysterics on the subject of the Chittenden diet, or sour milk, or standard bread, but just plain, simple, sober, common sense. W. D. H.

A Text-Book of Botany. By J. M. Lowson. Seventh impression (fifth edition), revised and enlarged. Pp. viii+607. (London: W. B. Clive, University Tutorial Press, Ltd.; Cambridge: University Tutorial Press, 1910.) Price 6*s.* 6*d.*

ALTHOUGH there have been numerous and material alterations of the subject-matter for this edition, there is no change in the general arrangement, and the book still maintains its very apparent examination character—that is to say, the dominating idea is not to stimulate the observational and thinking faculties but to provide in the space as much information as possible, duly punctuated and diagrammatised. The general arrangement is not unsatisfactory, but it is not apparent why there should be such an early insertion of a chapter and various sections dealing with histology; also it may be suggested that the heading of chapter iv. would nowadays be more applicable to the chapter on ecology. The latter is a new introduction and requires revision, as the exposition is disjointed, and there is no mention of that important unit of classification, the formation. For the most part, however, the presentment of the information is essentially explicit and well ordered, and the trend of recent investigation and modern theories is carefully indicated. A useful series of physiological experiments is outlined, and the importance of combining practical work with reading is emphasised. The selection of cryptogamic types and the general scope of the book follow the requirements of the intermediate examinations at London University.

Le Chaos et l'Harmonie universelle. By Félix le Dantec. Pp. 195. (Paris: Félix Alcan, 1911.) Price 2.50 francs.

To a long list of previously published works, M. le Dantec has added a book dealing with a variety of subjects treated sometimes from a philosophical point of view, and at others from the mathematical side. To give the titles of a few of the sections is to indicate the range of the treatise. "Heredity and education," "the definition of chance," "living bodies," and "life," may be mentioned.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Breath Figures.

On reading Lord Rayleigh's short article on breath figures in NATURE of May 25 and finding he was not satisfied with the explanation I offered of them, I thought it would be as well to see if it was possible to get some further information on the subject. For this purpose I repeated the experiments with variations in the conditions. As the writer of the article seemed to think that the hot gases act in some way in cleaning the surface of the plate, the experiments were now made at lower temperatures. In place of the blow-pipe flame a Bunsen burner was used, and in order to protect part of the surface from the action of the hot gases, the plate was supported on two thick iron bars, so as to confine the action of the gases to the narrow space between them, and further, the glass plate was kept as cold as possible. It was intended to use ice for this purpose, but it was found that it kept the under surface always dewed, so that the gases could not come into contact with the plate. Wet blotting-paper placed on the upper surface was found to keep the plate cool enough, and yet not so cold as to cause the deposition of dew. It was found that it was not necessary to pass the plate through the flame to get the breath figures; it could be held some distance above it with a similar result, but, as might be expected, a longer time was necessary than when in the flame, not only on account of the lower temperature of the gases, but also on account of the plate getting heated by the longer exposure.

In these experiments it was noticed that it is not enough to allow the hot gases to travel along the space between the two bars, as the hot gases only produce the effect where they first strike the surface of the plate, and if it is dust that is the cause of the action, it will be deposited where the gases first touch the cold surface, the onward flowing gases near the plate being nearly free from dust, as well as being at a lower temperature. The plate should therefore be moved over the stream of hot gases in such a way that fresh gases come in contact with the different parts of the exposed surface. The plate should also be held at a considerable angle to allow of a free flow of the gases over it.

If the action of the hot gases is a cleansing one, then heat alone ought to produce the same effect as the flame, and cause the glass to take an even film of dew. To test this a cleaned plate was placed—clean side up—on a metal plate somewhat larger than itself, and the metal plate highly heated with a Bunsen burner. Some plates were heated slightly, others to a temperature far higher than those acted on directly by the flame, yet when cold these plates were unchanged. Part of the plate was freshly cleaned, when it was found that the deposit of moisture was the same all over the plate. Heat alone evidently has no effect. I may here mention that those breath figures are best developed by rubbing the back of the plate with a piece of ice. By this process the image remains longer in view, and gives time for inspection.

An examination, by means of a short-focussed lens and proper illumination, of the moisture condensed on the surface of a glass plate, reveals some interesting points. When the dew first begins to appear the water is seen to be deposited in the form of very small lenses nearly touching each other. On looking through the plate while the dew is still condensing, nothing can be seen through it. It acts very much like a piece of ordinary ground glass, a landscape being invisible; even the sky-line does not show. If the cooling be now stopped and the deposit allowed to evaporate it will be noticed that the spaces between the lenses widen, the lenses drawing in their edges and leaving clear glass. Objects can now be seen through the plate, the transparency increasing as the dew evaporates. If, however, in place of stopping the condensation at its early stages we keep the plate cooled so as to cause more moisture to be deposited, the lenses will be seen to grow into each other and coalesce, until at last the regular deposit of little lenses grows into irregularly shaped blotches of water of considerable size. If the condensation be stopped at this stage and the plate dried and again cooled, it will be found that the appearance of the condensation is not the same as it was the first time. The surface of the plate has been changed by the first condensation. On the dew making its appearance the second time the uniformity in the lenses is gone. In addition to a general ground of small lenses there now appears a number of much larger ones, and as these are distributed over the plate at about the same distance from each other as that occupied by the large evaporated blotches of water, they would appear to be produced by something left by the water on the glass. By observing a particular group of blotches near a mark on the plate, it was noted that each one of these reappeared on each successive dewing. The something which is left after evaporation has evidently a considerable affinity for water, as these large lenses condense more water than an equal area of small ones. They stand high, and are the last to evaporate.

But perhaps it will be asked, How can anything be left after the evaporation of pure distilled water? At first sight one might feel inclined to say that nothing could be left. It is, however, evident that something has been left—probably dust and gaseous impurities condensed along with the water—and I may point out that something similar happens when cloud particles of water are formed on ions in the presence of certain gases. In this case there are no solid nuclei, yet the drops do not thoroughly evaporate, but leave behind them something large enough to be nuclei of condensation in air only very slightly above saturation. These observations on the behaviour of glass plates show how delicate their surfaces are and how easily the condensation on them may be altered.

The something which produces these breath figures formed by flames is of such a nature that it acts more powerfully the higher the temperature of the gases, that is, the greater the difference in temperature is between the gases and the glass. Of course, it is possible that the effect may be due to some gas or gases condensed on the glass, and these gases having an affinity for water. On the other hand, it may be due to the gases depositing their fine dust; and while what we call clean glass repels water, dust, on the contrary, attracts it. The fact that this form of breath figure is easily washed off the plate seems to point rather to dust than absorbed gases as the cause.

The formation of these breath figures does not appear to be so much a question of cleanliness as of the nature of the foreign matter on the surface of the glass. If the impurity is of a water-repelling nature we get the lenticular deposit; if it has an affinity for water we get the uniform film. For instance, if the plate has been previously touched with paraffin oil, it will, even after a good deal of cleaning, give a very white obscure deposit, due to the great convexity of the lenses. On the other hand, if the surface has been previously treated with caustic soda, the lenses are flat and the plate more transparent.

As these experiments have generally been made with gas flames, and as the flame is an important factor, it was thought advisable to try other flames. Hydrogen when burned in filtered air, I have shown, gives rise to no fine dust, and, so far as I know, this is the only form of combustion which does not. It therefore ought to have been tested, but as the apparatus required would be somewhat complicated, it has not been done. Alcohol, however, was tried; with it I could only succeed in getting very slight indications of any action, though the plate was heated far more by it than what gave a marked effect with the Bunsen flame. This result is what we might expect if the figures are due to dust. A sulphur flame was also tried, and, as might be expected, gave very marked results with a very small flame. This might be given as a typical case of the effect of condensed vapour. Something of this kind may play a small part in the figures produced by gas flames.

It was thought it might be interesting to see how the fine dust on our windows acted towards condensed water. The fine dust in the air is deposited on our windows in the

same way as I imagine the dust of the flame to be deposited on the plates, namely, by difference of temperature, our rooms being warm and windows cold at night. The only difference is in the rate of deposit, due to there being less dust in the room air and to the smaller difference in temperature in the case of the window. Cleaning a small part of a window which had been clean ten days previously, a piece of ice was rubbed over the outer surface until dew began to deposit on the inside. The deposit on the ten-day-old surface was different from the newly cleaned one, but not greatly so. While the newly cleaned part was covered with the usual little lens-like discs, the older surface was covered with much larger and irregularly shaped blotches of film. As the nights had not been cold since the window was cleaned, we can hardly expect much dust to have collected in ten days; so another window was tried which had not been cleaned for some months. Repeating the cleaning and cooling on this window, it was found that while the newly cleaned part carried a ground-glass-like deposit, the uncleaned part was sufficiently clear for the landscape to be seen through it. These tests show that dust on glass does tend to cause water condensed on its surface to spread and take the film form in the same way as glass that has been exposed to flame or to hot gases.

Coming, now, to Quincke's experiment, referred to by Lord Rayleigh, in which sulphuric acid is shown to produce the same effect as the blow-pipe flame, this and the experiment with hydrofluoric acid seem to have inclined Lord Rayleigh to think that cleanliness was the cause of the breath figures. But does either sulphuric acid or hydrofluoric acid prove cleanliness? I have doubts. I know I am on dangerous ground in differing from Lord Rayleigh on anything connected with surface action, yet I have recently had my lesson on how some substances cling to glass in spite of efforts to get rid of them, and I think it is not improbable that some residual of both sulphuric and hydrofluoric acid may cling to the glass in spite of washing. Recently I was making an investigation in which was required a little iodine vapour, and for this purpose put a small crystal of iodine in a flask from which the vapour was drawn as required. Afterwards the investigation took another turn, and the flask was used for other purposes, but many days' work were lost owing to that flask. Results were obtained with it which were contrary to previous experience. As suspicion centred on the flask it was discarded, and not until a new flask had replaced it could satisfactory work be done. Yet all this loss of time was occasioned by a residual quantity of iodine, which the washings with alcohol, acids, soap water and a sponge, had not succeeded in removing. After that experience I confess to being sceptical of absolute cleanliness of glass after being touched with sulphuric or hydrofluoric acid. Any residual of these substances, as they have an affinity for water, would tend to form films and not little lens-like patches. Though breath figures may be formed by dust, yet there are evidently other ways of altering the surface of the glass and causing it to repel or attract water, and so making the surface capable of giving breath figures. John Aitken.

Ardenlea, Falkirk, June 5.

The "Vernal Phytoplankton Maximum."

In Nature for April 27 it was stated, in connection with the plankton statistics taken periodically in the Irish Sea from the Port Erin Biological Station, that (p. 289) "the outstanding fact in this season's work, so far, is that the diatoms are unusually scarce and late. The vernal phytoplankton maximum has not yet arrived."

That statement referred to the collections up to the middle of April. During the rest of April the catches remained small—for the most part 1, 2, or 3 cubic centimetres in a standard haul of the fine silk net. In May the approximate quantities (they have not yet been accurately measured), in the same net, run as follows:—

	c.c.		c.c.
May 1	2	May 22	35
,, 4	1	,, 25	10
,, 10	10	,, 29	15
,, 13	40	June 1	15
,, 16	60	,, 3	60
,, 19	50	,, 5	50

The large catches on May 13–22 were mainly composed of Chætoceras (*C. debile*, and a few other species of diatoms), while the sudden increase in the beginning of June is due almost wholly to Rhizosolenia (mainly *R. semispina*).

Last year we found that the vernal phytoplankton appeared as two well-marked maxima, one in April, caused by species of Chætoceras and Lauderia, and a second in June, composed of Rhizosolenia and Guinardia.

It is evident that the "vernal maximum" is really a complex made up of the maxima of several different species or groups of species which seem to occur in a definite sequence, but may be earlier or later, more spread out in one year or more telescoped together to form a single diatom maximum in another. Moreover, the individual species or groups of species may be more abundant one year than another.

In the present year, if we look at the three genera that usually bulk largest in our spring and early summer collections, we find that Biddulphia reached its climax in March (but continued throughout most of April in fair abundance), Chætoceras not until the latter part of May, and Rhizosolenia in early June. Rhizosolenia is usually as late as or later than this; Biddulphia is always one of the first forms to appear, sometimes causing a slight increase in the plankton as early as February, so it is really Chætoceras (some of the species of which are usually the most abundant of our April diatoms) that is this year unusually late.

I have just returned from Port Erin, where, during the first few days of this month, Rhizosolenia seemed to be unusually abundant. The water of the bay is visibly discoloured by it; when a tow-net at the end of a fifteen minutes' haul is raised from the sea it contains a column of thick soupy fluid, which runs out very slowly, as the meshes of the silk are largely clogged up with the diatoms; on a calm surface, with the sun shining, the peculiar iridescent glistening appearance characteristic of Rhizosolenia can be seen from the boat, and anything put into the water is at once covered by a slimy layer of the slender needles. It may be that Rhizosolenia has not even yet attained its climax, but a week ago the June increase in diatoms had certainly set in with unusual force. The "vernal maximum" has, then, this year been spread out and divided into three parts—a slighter increase in March (Biddulphia), a much greater one, later than usual, in May (Chætoceras), and another great increase (Rhizosolenia) early in June. W. A. Herdman.

Liverpool, June 10.

On the Action of the Latex of *Euphorbia peplus* on a Photographic Plate.

In August, 1909, our attention was directed to certain properties of surgical importance possessed by the milky juice of *Euphorbia peplus*, a spurge naturalised in this colony. During the examination of the milky juice or latex, we exposed during two days in the dark a highly sensitive photographic plate some millimetres above a sheet of glass on which we had dried a few drops of the juice. On development, a sharp image of the dried juice appeared on the plate. We propose to describe briefly a few results from the many experiments since made to determine the conditions and nature of the action on the photographic plate.

Thirty drops of the juice were spread on a sheet of glass as the letters EUPHORBIA, and the glass dried in an oven at 100° C. for two hours. A sharply defined image of the letters was produced on development of a photographic plate (speed 325) placed 5 mm. above the dried juice after an exposure of forty-eight hours or longer. The density of the images increased with greater length of exposure, with thicker films of dried juice, and with less distance between the plate and the film. The edges of the images were well defined, as if focussed on the photographic plate. No image appeared with short exposures of twenty-four to forty-eight hours unless the films were very thick. With long exposures, up to thirty days, the images were more dense, but showed a little diffusion at the edges of the letters. When a distance of 15 mm. separated the photographic plate from the film, the plate was unaffected. Action on the plate diminished

rapidly when the distance from the film exceeded 5 mm. The dried juice retained the action with undiminished effect for months. When the dried films were heated from 150° C. to 200° C. they charred, but did not lose their action on the plate. As the temperature was raised further the power of affecting the plates was diminished, as the ash of the juice became white. Even the white ash had a slight action on the plate (potassium salts).

The introduction of screens between the film and the photographic plate led to notable results. The interposition of tissue paper slightly delayed the action on the photographic plate. Thick black paper (0·13 mm.) employed by the makers to enclose photographic plates, and found by us impenetrable to the rays from phosphorescent salts, served only to delay the time in which an image of a definite intensity was formed. The effect was produced through a celluloid screen (0·07 mm.) and through paraffined paper (0·03 mm.). We were unable to obtain screens of glass or mica less than 0·02 mm. in thickness. These screens completely protected the plates from action by the film. Screens of aluminium foil 0·002 mm. thick made no alteration in the intensity of the image of the film. When eight layers of the aluminium foil were superimposed, the density of the image on the plate was increased.

Examination of the dried material with a zinc sulphide screen failed to show any scintillations due to the α particles.

When a rapid current of dried air was passed obliquely between the plate and the film at a rate of 300 c.c. per minute the image of the letters on the film was sharp and well defined. The distance between the plate and the film was 0·5 mm. Any gas or emanation would have been carried along by the current, especially any gas having such a slow action on a photographic plate.

Musical Sands of Eigg.

Since Hugh Miller's brief reference ("The Cruise of the *Betsey*") to the musical sands of the Bay of Laig, Isle of Eigg, much has been done with these, and sands of a similar character, to enable us to account for the cause of the phenomenon; and the interest taken by physicists in certain experiments which I conducted some years ago induces me to offer the results of some further observations for publication.

There is no musical sand in the Bay of Laig, and, so far as I can ascertain, its sands have never been musical within the memory of any inhabitant of the island. At the present time the psammological conditions are such as to preclude entirely the possibility of its existence there.

In a small bay—about a mile and a half along the shore to the north of Laig Bay—known as Camas Sgiotaig, musical sands occur. This bay is divided into two portions by a reef of calcareous sandstone jutting out from the cliffs seawards. In both portions, but especially close to the cliffs, a white quartzose sand has accumulated, and this is the only place where musical sands are found in Eigg.

The sands are derived from the waste of the calcareous sandstone referred to. In places the grains have accumulated in small rifts and cavities in the rocks, and in all such it was found to be equally musical, showing that long, flat stretches of sand are not essential conditions for the selective action of the winds and sea-waves.

The usual experiments with various vessels and plungers, &c., were carried out *in situ*, and the musical effects were in all cases much more pronounced than those produced by the Studland Bay sand.

An extraordinary volume of sound was obtained by dragging the convex part of a wooden bowl along the surface of the sand patches, one of which was only about 6 feet square. When the same bowl was partially filled, and the sand struck with a wooden plunger, it emitted a noise like the deep bark of a dog, and this could be heard for a considerable distance along the shore.

These musical sands are only found in calm weather; in the winter the huge waves carry away all fine matter, and only the rocks remain—for which reason we must regard it as a fine-weather phenomenon in this island.

Eigg, June 6. Cecil Carus-Wilson.

P.S.—Since the posting of my letter respecting the musical sands of Eigg, I have read the letter from Mr. Thomas which appeared in Nature of June 8.

Prof. Poynting, I think, informed me of the occurrence of these sands at Barmouth some time ago, and I have found them also at Penally, near Tenby, at Longland Bay, and in Swansea Bay.

I have frequently pointed out that the pitch of the note emitted from musical sands depends (*a*) upon the size of the grain, (*b*) the area of the plunger's striking surface, and (*c*) the form and composition of the vessel used. In some vessels of particular form I have succeeded in producing from the same mass of sand, and during the one thrust of the plunger, notes of both high and low pitch!

The vessel containing the sand is first well shaken in order that the smaller grains may settle at the bottom of the mass and the larger ones at the top. The plunger is then thrust sharply upon the surface, and coming first in contact with the larger grains, it produces a low note; this merges into a note of higher pitch as the plunger penetrates the mass and reaches the finer grains at the bottom of the vessel.

As a matter of fact, the notes from all natural musical sands appear to be a cumulative effect due to a combination of high and low pitch within a given range. The only sand which seems to emit a pure and definite note is that which I have produced artificially.

June 10. C. C.-W.

Botanical Research in Ceylon.

The letter from Cambridge with the above title, which appeared in your issue of May 25, has evidently been written without knowledge of the difficulties which have arisen at Peradeniya within the last few years and under a complete misapprehension of my views.

The letter reproduces, without the context, a single sentence from a memorandum of mine. In this memorandum special stress is laid on the importance of maintaining Peradeniya as a centre of botanical research, and it is suggested that Dr. Willis should remain as its director under such conditions as would allow of his conducting botanical investigations which in recent years he has found it impossible to undertake.

The letter seeks chiefly to justify Dr. Willis's position as a botanist, which has not been called in question. Neither have the services which Peradeniya has rendered to the botanical workers who have visited it been questioned.

The sentence quoted from my memorandum refers to the two principal members of the staff and the difficulties which admittedly have rendered botanical research impossible for them owing to the pressure of other work.

My suggestion, as a solution of the difficulties which have arisen, was to maintain Peradeniya "as a great reference garden and centre for botanical research in the tropics"—to reproduce my own words—distinct from, though cooperating with, the Agricultural Department which the Government of Ceylon, most wisely, now desires to establish. Whilst I should have preferred this solution, I am satisfied that the decision to incorporate the Royal Botanic Gardens at Peradeniya with the Agricultural Department will secure what the colony chiefly needs in the interests of tropical agriculture, for the advancement of which the whole community, European and native, is so deeply concerned.

Wyndham R. Dunstan.
June 3.

The Extinction of the Egret.

It will be remembered by those who are interested in the protection of the white heron that the feather dealers have urged that the breeding haunts, or garzeros, of these birds are guarded, and that the moulted feathers are picked up from the ground. From information which has been sent to me from the National Association of Audubon Societies, based on the sworn testimony of a man who

has been personally engaged in feather collecting in Venezuela, it appears that while a few moulted feathers, worth possibly a fifth of the value of those taken from living birds, are collected, there is not the slightest foundation for the statement that the breeding places are protected for the purpose.

Mr. A. H. Meyer, who has come forward, adds the following to his account:—"The natives of the country, who do virtually all the hunting for feathers, are not provident in their nature, and their practices are of a most cruel and brutal nature. I have seen them frequently pull the plumes from wounded birds, leaving the crippled birds to die of starvation, unable to respond to the cries of their young which were calling for food in the nests above. I have known these people to tie and prop up wounded egrets on the marsh, where they would attract the attention of other birds flying by. These decoys they keep in this position until they die of their wounds or from the attacks of insects. I have seen the terrible red ants of that country actually eating out the eyes of these wounded, helpless birds that were tied up by the plume hunters."

The story that the aigrettes used in the feather trade are picked up on the ground in Venezuela is stated by those interested to have been based on a letter written by Mayeul Grisol, naturalist and explorer of the Honorary Mission of the Museum of Natural History of Paris. Prof. Osborn, president of the American Museum of Natural History, recently sent the following cablegram to the Museum of Natural History of Paris:—

"Is Mayeul Grisol of scientific standing? Has he been an accredited explorer for your museum to South America?"

This is the answer:—"Mayeul Grisol unknown."

WILFRED MARK WEBB.

42 Bloomsbury Square, W.C.

THE NATIONAL EXPERIMENTAL TANK.

TO the present-day shipbuilder or shipowner there are probably no more important problems than those of getting the best or least wasteful form of hull with the limitations of dimensions imposed by its service or internal arrangements, and of obtaining a trustworthy forecast of the power required to propel a ship of that form at a given speed.

It is the exhaustive investigations of such problems as these which constitutes the primary object of an experiment tank. Such a tank is to the naval architect what the research laboratory is to the chemist, or the testing house to the engineer. Forty years ago model experiments were looked upon as "remote from practical use," and it was largely due to the fertile brain and the carefully conducted epoch-making experiments of the late Dr. William Froude that this impression has been removed, and replaced by a continually growing confidence in the application of the results of experiments with models to the full-sized ship.

FIG. 1.—National Physical Laboratory Experimental Tank. View looking North (empty).

Many early investigators, amongst whom may be numbered Bernouilli and Euler, attempted to solve the problem of least resistance mathematically.

Later on, in 1770, experiments on a small scale were made by D'Alembert, Abbé Bossut, and Condorcet, and an attempt was made to frame *formula* for forms of least resistance. These were followed by M. Romme, and later by Marc Beaufoy, who for five years (1793 to 1798) made experiments with various models in the Greenland Dock. Unfortunately, owing

to lack of financial support, Beaufoy's experiments were never extended to ship-shape forms, and although he insisted that such experiments would and did determine the relative merits of models, his results were neglected by the naval architects of his time, and only fitful attempts were made to revive interest in model experiments until the time of Froude and Rankine.

Rankine in 1862 read his paper on waves, &c., and in this and various papers published during succeeding years he developed the application of what is now known as the "stream-line theory" to all moving bodies.

Froude at this time, working on much the same lines, had produced his well-known "law of corresponding speeds"[1]—the true connecting link between ship and models—and had verified it by experiments on the river Dart with similar models varying in length from three to twelve feet; and in his "explanations" in the British Association Report of 1869 he insists on the trustworthiness of experiments with models of rational size. At the suggestion of Mr. E. Reed (afterwards Sir Edward Reed), a proposal and estimate was made for an experiment tank, and this was soon afterwards built at Torquay, and became the pattern on which all other tanks were modelled.

Shortly after this, in 1871, on the recommendation of the "Committee on Designs for Ships for War," Froude conducted for the Admiralty the towing experiments on the *Greyhound*, which, in conjunction with the experiments made on a small model one-sixteenth the dimensions of the ship, completely vindicated his theory, and led the Government to establish the experiment tank at Haslar, which was completed in 1879, where his son, R. E. Froude, has since superintended the work. The applicability of results of model experiments to full-sized ships has more recently been verified by some experiments conducted by Mr. Yarrow on a torpedo-boat, and published in 1883.

Such tanks are now possessed by every nation that has any pretence to marine power, and by several of our leading shipbuilding firms, and the national experiment tank, which is now approaching completion at Teddington, is the sixteenth to be built.

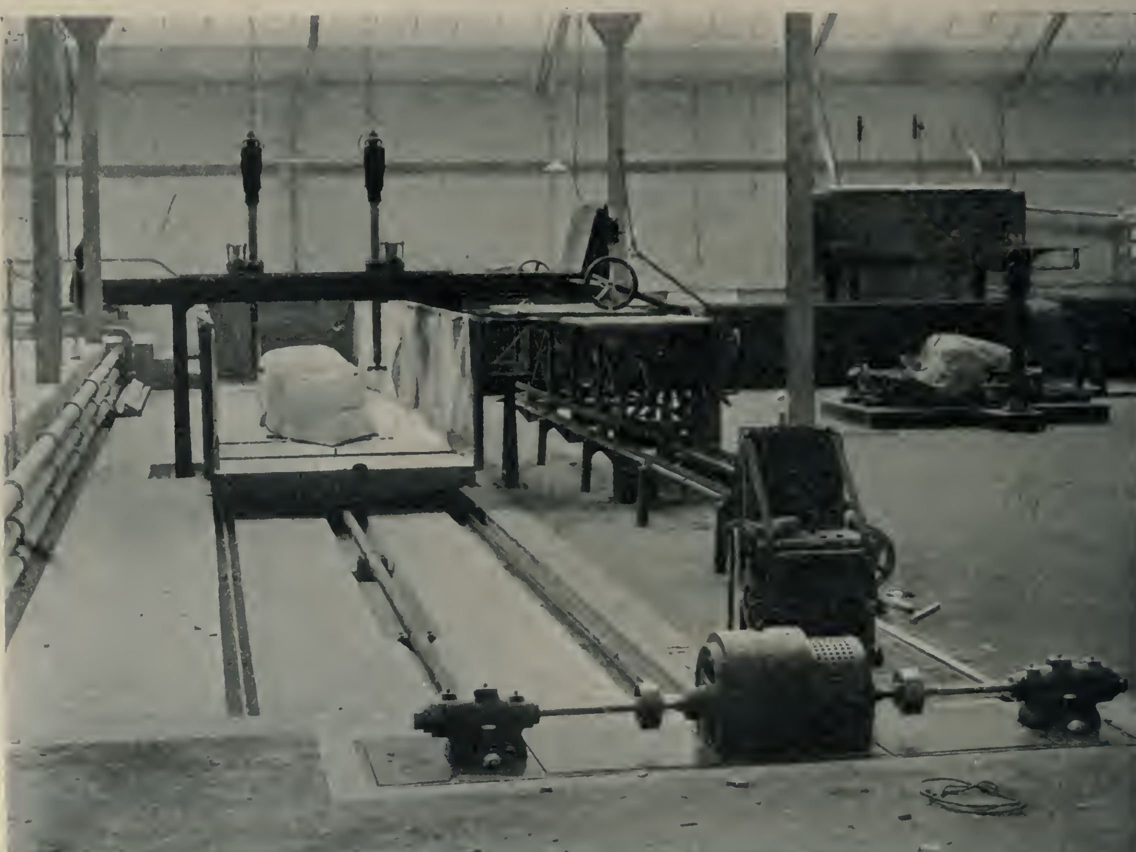

FIG. 2.—National Physical Laboratory Experimental Tank. Model-making Apparatus.

Suggestions for the establishment of a national experiment tank have been put forward from time to time by the council and various members of the Institution of Naval Architects, and among its chief advocates has been Sir William White. It is due to the munificence of Mr. A. F. Yarrow, a vice-president of this institution, that the proposal has become a reality, the whole of the first cost being defrayed by him. It will be largely supported by the leading shipowners and shipbuilders of the country, and will be open for the trials of any ship, but its chief purpose is to carry out research work in fluid resistance and ship propulsion. The site chosen for the tank is at Bushy Park, and it will be worked as a branch of the National Physical Laboratory.

[1] Dr. Froude's enunciation of this is as follows:—"If the ship be D times the 'dimension' (as it is termed) of the model, and if the speeds are V_1, V_2, V_3 . . . and the measured resistances are R_1, R_2, R_3 . . . then for speeds $\sqrt{D}V_1$, $\sqrt{D}V_2$, $\sqrt{D}V_3$ . . . of the ship, the resistances will be D^3R_1, D^3R_2, D^3R_3. . . . To the speed of model and ship thus related it is convenient to apply the term 'corresponding speed.'"

The chief features of the building are shown in Fig. 1. The main waterway is 30 feet wide, 12 feet 3 inches deep, and 500 feet long, clear of beach and docks, the latter being for storing models and for allowing access to them for ballasting and trimming purposes. The walls and floors are of concrete varying from 2 to 3 feet in thickness, except at the shallow docks, where the sides are 7 inches reinforced concrete.

A large steel carriage for towing the models has been erected across this waterway. It runs upon four wheels on rails which are bolted to continuous iron supports secured to the tops of the concrete walls. This carriage is driven by four motors—one over each wheel—the necessary power being obtained from conductors supported along the west wall of the building; these conductors are fed by a generator, which again is driven by a motor working on fifty-five cells. There are complete arrangements for controlling the voltage of the supply, so that the carriage may be brought to any speed up to fifteen miles per hour, and the speed be kept constant over the main portion of the run down the basin. This towing carriage will carry a dynamometer and other recording instruments for the measuring of the resistance, &c., of the models. These will be towed through the water in such a manner that though free to trim or move fore and aft to any extent necessary for equilibrium, no side motion will be possible, special guides being fixed under the carriage to ensure this.

The models will be made of hard paraffin wax of about 2 inches in thickness, the length being generally 20 feet, but varying according to the form. The paraffin wax is melted in a large tank through which hot water is circulated in pipes, and back through the surrounding casing, and the wax drawn off through pipes into a clay mould prepared to the shape of the model, but with an allowance of about a quarter of an inch for finishing.

The model when set is transferred to the shaping machine (Fig. 2). This machine works on the copying principle, and consists of two tables, each capable of being drawn longitudinally by a nut working on separate screws, which screws can be geared to revolve at any desired velocity. A plan of the ship is pinned on one table and the rough model secured keel up on the centre line of the second. Over this latter table there are two revolving cutters between which the model passes. Each of these is driven by a small electric motor attached directly to the upper end of its spindle. They can be set at any desired height, and their transverse motion be made to imitate (by means of a pantagraph mechanism), the lateral motion of a tracer, which the operator keeps in contact with the waterline on the plan corresponding to the height of the cutters on the model. By adjusting the fulcrum of this pantagraph, and the gearing between the driving screws, any proportion of length and breadth can be cut from the ship's drawing.

The model when it comes from the machine has upon it a series of horizontal guidance grooves, the wax between which is trimmed off with spokeshaves

FIG. 3.—National Physical Laboratory Experimental Tank. The small tank for still or flowing water experiments.

and a smooth surface obtained by the use of scrapers. This surface may be varnished or treated in any desired manner, and the model, after being ballasted and trimmed as necessary, is ready for an experimental run. A measuring table has also been installed, by means of which the lines of any model may be taken off, or the correct position for appendages may be marked on the model.

In addition to the main waterway already described, a smaller basin some 64 feet by 5 feet by $3\frac{1}{2}$ feet has been built (see Fig. 3). Experiments can be made in this with models up to 6 or 7 feet in length. These may be either propelled through the water the latter being at rest, or the model may be held at rest at the end of a dynamometer arm in the centre of the basin and the water caused to flow by it. A large power rotary pump has been fixed in this tank for this purpose.

The problems which remain to be solved by such a tank are many and wide. Chief amongst them are: the exploration of stream-line motion, frictional resistance on straight and curved bodies, the action and propulsive power of screws and the effect of form of hull, and size of waterway, on the resistance of a ship. Some of these fields have been partially explored already, but systematic research has not extended beyond the fringe of the remainder, and the rapid and continuous advance of naval science is ever bringing forward new problems.

That such a tank, though costly to establish and maintain, amply repays for its support, a single example will tell. It would not be a matter of much difficulty to effect an improvement of, say, 5 per cent. in the resistance or the propulsive efficiency of many ships of our mercantile navy. Such a saving in power would mean a reduction of 750 tons of coal on a yearly bill of 15,000 tons, and the whole cost of the upkeep of the tank now approaching completion at Teddington would be more than met by the consequent reduction in working expenses on some eight or ten ships.

UNIVERSITY EDUCATION IN LONDON.

THE second volume of evidence [Cd. 5528, price 3s. 8*d*.] has been issued by the Royal Commission on University Education in London, containing the minutes of evidence for the period June, 1910, to November, 1910, with numerous appendices. The first volume of evidence, published in April, 1910, contained the evidence from July, 1909, to the date of publication.

The appointment of this Commission, it may be recalled, originated indirectly from a letter reprinted in *The Times* of June 29, 1903, signed by Lord Rosebery, and addressed to Lord Monkswell, chairman of the London County Council, which directed attention to the failure to provide instruction and facilities for research in technology, and stated that Messrs. Wernher, Beit, and Co. had offered to place a large sum of money in the hands of trustees, to be applied as a contribution towards the cost of building and equipping an institution for advanced technology. The new institution, like the Royal College of Science and the Central Technical College, was to become a "school" of the University of London. Mr. (now Lord) Haldane conducted some negotiations on the subject with the London County Council, who undertook conditionally to support the new institution by an annual grant of £20,000.

At about that time the Board of Education was considering the future organisation and government of the Royal College of Science, and in April, 1904, the President of the Board, Lord Londonderry, appointed a Departmental Committee to consider and report on the question. The report of this committee, over which Sir Francis Mowatt, and later Mr. (now Lord) Haldane presided, recommended the establishment of a large college at South Kensington, to embrace the Royal College of Science, the Royal School of Mines, and the Central Technical College, and to take over, as it were, Lord Rosebery's scheme. On the question of the relation of the proposed college to the university, there was a division of opinion in the committee, for and against the incorporation of the college in the university. The senate of the university proposed certain changes in its own constitution in the direction of increasing the representation of technical interests, and at one time it appeared possible that the college would be incorporated in the university at its establishment. But in the result, the recommendation contained in the report of the Departmental Committee has been adopted; the college, known as the Imperial College of Science and Technology, was established by the Royal Charter in 1907 as a "school" of the university, and the question of its future relations to the university has been referred to a Royal Commission.

The Commission was appointed on February 24, 1909, with terms of reference of the widest character, corresponding to the title which it has taken, the Royal Commission on University Education in London. Lord Haldane is chairman, and the other members are Lord Milner, Sir Robert Romer, Sir Robert Morant, Mr. Laurence Currie, Mr. W. S. M'Cormick, Mr. E. B. Sargant, and Mrs. Louise Creighton. It is important to note the judicial character of the Commission—none of the members can be regarded as specially representative of any interest connected with university education in London. The evidence which is being published periodically acquires thereby an exceptional interest, for the findings of the Commission must be based, to an unusual degree, on the weight of the evidence tendered before it. The impartiality of the Commission is certainly reflected in the exceedingly able examination of witnesses by Lord Haldane and other members, which seldom suggests any bias for or against the contending opinions which have been expressed, though it may not always appear to show a friendly disposition to the existing organisation of the university in some of its aspects.

Within the limits of a short article, it is only possible to select a few of the more important questions on which evidence has been presented. The dominant issue is undoubtedly the constitution of the ultimate authority for the control of university education in London. Even such a simple statement as this assumes that, apart from the London County Council, whose statutory powers over higher education must not be ignored, there will be only one controlling authority, a matter on which opinion is by no means unanimous. The Commission has so far concentrated its efforts on this dominant issue, with its subsidiary questions of the constitution and powers of lower authorities, including faculties, board of studies, and committees.

Briefly stated, the main issue before the Commission in regard to the constitution of the ultimate governing body of the university relates to its principal characteristic, whether it should be representative or judicial. Evidence has been presented in favour of the creation of a large and representative court, with legislative functions, on the model of some of the northern universities, together with a small executive council, in the constitution of which no attempt would be made to represent all the interests existing in or related to the university. On the other hand, there is a large body of evidence which finds the solution of the present difficulties in a slight re-constitution of the present senate, including

the amendments proposed during the negotiations which followed the publication of the report of the Departmental Committee of the Board of Education. A special question, on which opinion is sharply divided, is whether the colleges incorporated in or affiliated to the university should be accorded direct representation on the senate. There appears to be fairly general agreement that the senate should have greater powers of delegation than are given by the existing statutes. The organisation of the faculties, composed of the teachers of the great groups of university studies in which degrees are granted, should, it is suggested, be made more effective, faculty boards being formed in the case of the larger faculties to exercise the administrative functions of the faculties. General approval has also been expressed of the existing organisation of the boards of studies for special subjects. The boards of studies, the faculty boards, and, lastly, an academic council, in which all the faculties would be represented, would form an administrative chain which would become largely responsible for the educational side of the work of the university, subject to the supreme control of the senate.

The existence of the external side of the university presents some difficulties in the way of such an organisation of the educational work of the university. Very little substantial evidence has so far been published in favour of the abolition of the system of external degrees, and a good deal of cogent reasoning has been adduced in its support. But it is admitted on all sides that the present statutory requirements for the equivalence of internal and external degrees have caused serious difficulties in practice, and that means should be found for averting these difficulties in the future. In this connection, the extension of the system of common examinations has been suggested, or, alternatively, the complete separation of the work of examination on the internal and external sides.

As already suggested, the Commission appears to be anxious to defer consideration of the future status of the Imperial College until some understanding is reached on other issues. Some interesting evidence has, however, been presented by Sir Alfred Keogh, on the actual working of the college. He states that it is the intention of the governing body to do nothing but post-graduate work eventually (Question 4521), and to get rid of the elementary students. As the evidence of the governing body has not yet been published, it will be wise to defer discussion of this policy for the present, except for the remark that its adoption will have far-reaching effects on the work at present carried on at South Kensington. Some valuable reports on the future work of the various departments of the college, prepared for the governing body, including a report on the organisation of a department of applied science, are printed in an appendix to the volume of evidence.

It should be mentioned, in conclusion, that the volume contains a large amount of information in regard to university work in London and elsewhere, both in its educational and financial aspects. Full statistics relating to the work of the University of London are printed in the reports of the various councils, faculties, and committees, which are included in the volume. Conditions in the United States and Canada are described in the evidence of President Murray Butler, of Columbia University, New York, and Principal Petersen, of the McGill University, Montreal.

BRITISH SHEPHERDS AND THEIR FLOCKS.[1]

IN this volume, which, as stated on the title-page, mainly consists of extracts from the writings of others, the author has succeeded in bringing together a large amount of valuable and interesting information concerning, not only the shepherds, but likewise the sheep, of the British Isles. In regard to the latter item, Miss Gosset has certainly not done herself justice in the title she has chosen, and it may perhaps be permissible to suggest that a better designation would have been the one standing at the head of this review. Neither, perhaps, has she conveyed an adequate idea on the title-page of her own contributions to the volume, at least one of which, namely, the article on sheep and shepherding in the Isle of Man, contains much interesting and little-known information.

Nor do shepherds and sheep by any means exhaust the contents of this fascinating volume, for we find a large collection of articles on sheepdogs, with others relating to shearing, to wool in connection with manufactures, and yet others on the arts, implements, crafts, and pastimes of shepherds, with a final series on pastoral folklore. There appears to be no mention in the index of black-horned sheep, which are stated

Mr. J. C. Bacon's Flock of Loughton Manx Sheep. From "Shepherds of Britain.

in the preface to include some of the oldest British breeds; but possibly the author intended to write black-faced in place of black-horned. With this exception there seems no fault to be found with the book.

Since sheep-farming has for several centuries been one of the most important industries in the British Islands, it is not a little curious that it has been reserved for the author—as she herself remarks—to treat of shepherds and their flocks in the full manner such an interesting subject undoubtedly demands. The charms of shepherd-life (with allusions here and there to its obvious discomforts and trials at certain seasons and on certain occasions), and the manners, customs, and nature-lore of the old-time shepherd—who, by the way, is fast disappearing from the face of the country, at least in our southern counties—are illustrated by a series of apposite extracts from a number of well-known writers on country life, among whom may be specially mentioned the late Mr. Richard Jefferies and Mr. W. H. Hudson. Several of these contain some delightful anecdotes, while others serve to bring out the accurate and comprehensive

[1] "Shepherds of Britain." Scenes from Shepherd Life, past and presen From the best authorities, by Adelaide L. J. Gosset. Pp. xxiv+331. (London: Constable and Co., Ltd., 1911.) Price 7s. 6d. net.

knowledge of climate, stars, plants, and nature generally possessed by the old-fashioned shepherd, who, as I have mentioned on a previous occasion, was, despite his frequent inability to write or read, thoroughly and completely educated and equipped for the purposes of his calling.

Much has been made in works on the Bible and in sermons, of the fact that Syrian shepherds lead, instead of driving, their flocks; but, as the author points out, and as everyone who has lived in the country ought to be aware, this is by no means a peculiarity of Eastern lands. Very interesting are the notes on sheep-bells, which are stated to date from a remote antiquity, and it is therefore the more remarkable to find that they are apparently unknown in the Isle of Man and Scotland. With this I must take leave of a delightful book. R. L.

DR. ALEXANDER BRUCE.

NEUROLOGY and medicine have sustained a heavy loss in the death of Dr. Alexander Bruce, of Edinburgh, physician and editor of *The Review of Neurology and Psychiatry*. It was known for some time that Dr. Bruce was in ill-health. The news of his death, however, came as a shock to many.

Born in Aberdeenshire in 1854, Dr. Bruce entered the arts faculty of Aberdeen University in 1870. He graduated in 1874 with first-class classical honours, being awarded the Town Council gold medal as the most distinguished graduate of his year. He had an equally brilliant career in medicine at Edinburgh University, and, on his graduation in 1879 as M.B., C.M., with first-class honours, he obtained the Ettles Scholarship as the best student of his year. During his tenure of the Leckie-Macteir Fellowship he studied at Vienna, Heidelberg, Frankfort, and Paris.

Returning to England, he commenced his professional career by being for a time assistant clinical clerk at the West Riding Asylum, Wakefield. In 1882 he took his M.D. degree, obtaining a gold medal for his thesis. Settling in Edinburgh, he gradually built up a large general practice. He became a lecturer on pathology at the Surgeons' Hall and pathologist to the Royal Infirmary, to the Royal Hospital for Sick Children, and to the Longmore Hospital for Incurables. He also lectured at the Surgeons' Hall on neurology, and later on the practice of medicine, while he was appointed a physician and lecturer on clinical medicine at the Royal Infirmary.

By this time he had acquired a considerable reputation as a consultant, especially in diseases of the nervous system. His contributions to the literature of this subject were very numerous, being marked especially by the care with which pathological lesions were investigated and described. The chief characteristic of his work was thoroughness, and in the preparation of these published reports of cases no labour, whether of bedside observation or of microscopic work, was spared. He did not restrict himself to neurological subjects, but published communications on general pathology and medicine. He also translated Thoma's "Lehrbuch der Pathologie."

It was characteristic of Dr. Bruce that he should undertake pioneer research into the minute anatomy of the brain and spinal cord. It is with this work that his name will perhaps be most associated. He began by publishing "Illustrations of the Mid and Hind Brain" and "Topographical Atlas of the Spinal Cord." Numerous researches on the nuclei of the cerebral and spinal nerves, on cranial nuclei, and on the nerve-fibre connections of these we owe to him. A notable example of this work is "Distribution of the Cells in the Intermedio-Lateral Tract of the Spinal Cord" (Trans. Roy. Soc., Edin., 1906), a research which must form the basis of all subsequent work on this subject. Feeling the need of a "Centralblatt" in English which should contain short, original communications and provide abstracts and a complete bibliography of recent work on neurological subjects, he founded in 1903 *The Review of Neurology and Psychiatry*. To the interests of this work he devoted a large part of his time, with what success only those who work on neurological subjects can adequately appreciate. Just before his last illness he had finished a translation into English of Oppenheim's great "Lehrbuch der Nervenkrankheiten," while he was busily engaged, along with Dr. Dawson, in an investigation on the lymphatics of the spinal cord.

Dr. Bruce was a strenuous worker. It was only by systematic economy of his time that he was able to keep abreast of his multifarious duties. His influence over the younger workers with whom he was associated was great. Among his *confrères* he was held in highest respect, as well for his uprightness and generosity as for his ability. As a mark of his distinction in neurology he was in 1899 made a corresponding member of the Neurological Society of Paris. In 1906 the Royal Society of Edinburgh awarded him the Keith prize for his work on the intermedio-lateral tract, and in 1909 the University of Aberdeen conferred on him the degree of LL.D. He is survived by a widow, two daughters, and three sons, one of whom has already made important contributions to neurological science.

NOTES.

THE council of the London Mathematical Society has awarded the De Morgan medal for 1911 to Prof. H. Lamb, F.R.S., in recognition of his researches in mathematical physics.

THE British Empire League and the British Science Guild are combining to entertain the Colonial Prime Ministers and other distinguished visitors at a banquet at the Savoy Hotel to-morrow, June 16. His Grace the Duke of Devonshire (president of the British Empire League and vice-president of the British Science Guild) will take the chair.

THE annual meeting of the Association of Economic Biologists is to be held at the rooms of the Linnean Society, Burlington House, London, on July 6.

ACCORDING to the June number of *The Selborne Magazine*, the annual conversazione of the Selborne Society held in London on May 5 was the most successful of the whole series. It was announced that the original MS. of Gilbert White's Nature Calendar is to be published shortly.

MR. FRANK A. PERRET, of Springfield, Mass., is proceeding to Hawaii to open and take charge of the volcanic observatory which has been established there through the combined efforts of the Massachusetts Institute of Technology, the Smithsonian Institution, and the Carnegie Institution of Washington.

A PROPOSAL will be laid before the members of the Aëronautical Society to reconstitute the society by the institution of the following five grades of membership, viz. ordinary members, associate members, fellows, associate fellows, and students, the last three categories being reserved for persons engaged in technical work connected with aëronautics, while the first two are open to all who are interested in the work of the society.

THE death is reported, in his seventy-fourth year, of Dr. Cyrus G. Pringle, botanical collector to Harvard University and curator of the herbarium of the University of Vermont. His best known work was done in connection with the exploration of the flora of Old Mexico, about fifty of the most important herbaria in the world having benefited by his researches in that country. Before his Harvard appointment he was a collector for the American Museum of Natural History in New York.

THE vessel carrying the collection of wild animals presented to H.M. the King by South Africa arrived in the Thames on June 1. The collection, which was brought home in charge of two keepers sent out by the Zoological Society, is stated to include about 200 animals. These are now housed in buildings specially erected for their reception in the Zoological Gardens, Regent's Park, and are exhibited to the public as the King's South African collection. They were inspected by the King on June 4.

REPRESENTATIVES of the Hessian Government, of the town of Darmstadt, and of numerous chemical works joined with many others on June 1 in congratulations to Dr. Willy Merck, of E. Merck, Darmstadt, upon the celebration of the twenty-fifth anniversary of his entry into the firm as a partner. In the name of the Grand Duke of Hesse, the representative of the Hessian Government handed to Dr. Merck the grand medal for art and science conferred upon him in recognition of his services, not only in promoting the advance of chemical research work and in developing this branch of the country's industry, but also as a distinguished patron of art.

MR. HARVIE BROWN writes to us suggesting that the great Scots pine trees on Auchnacarry are probably of much greater age than the two hundred or three hundred years at which they were recently estimated in our columns (June 1, p. 447). Mr. Harvie Brown is very probably in the right. But we are informed by the timber merchants, Messrs. Souness and Spiers, Edinburgh, that they will be at work in the forest within the next two or three weeks, and that plenty of trees and logs will then be available for ascertaining the actual age.

A BILL has been introduced in the House of Representatives of the United States of America "to establish in the District of Columbia a laboratory for the study of the criminal, pauper, and defective classes." We understand from Mr. Arthur MacDonald, of Washington, who has been prominent in advocating the establishment of such laboratories, that the Russian Government has already set aside a large sum of money for this purpose. The fundamental problem in such studies, it seems to us, is to determine which individuals among the criminal, pauper, and feeble-minded population occupy that position through accidental misfortune, and which are congenitally defective. It is useless, or worse, to spend money in the hope of curing the latter class. Permanent care and control is for them the only hope, and for society the most feasible way of preventing the ever-growing burden of their criminal or incompetent descendants.

A VIOLENT earthquake occurred in Mexico on June 7 at 4.35 a.m., and gave rise to unusually large disturbances in distant seismographs. In Mexico city many poorly-built houses were destroyed, and 172 persons were killed. The shock or shocks lasted there for about six minutes. The total number of deaths is estimated at 1300, of which 500 occurred at Zapotlan. The volcanoes of Colima and Popocatapetl are also said to be in active eruption. The position of the origin is still unknown. An earthquake capable of affecting European seismographs so strongly must have caused widespread destruction in the central area, and it is possible that this area may be isolated from the surrounding country, so that the full extent of the disaster may not be realised, or, for political reasons, detailed telegrams may be censored. It is clear, however, that the epicentre was at some distance from those of the Mexican earthquakes of 1905 and 1907. In those years the towns which suffered most were Chilpancingo and Acapulco, which lie from 200 to 250 miles south of Mexico city. Zapotlan is about 275 miles west of that city, and is situated in a well-known seismic district, having on several occasions been damaged or destroyed by earthquakes.

FOR the use of the members of the sixteenth annual Congress of the South-Eastern Union of Scientific Societies, held at St. Albans last week, the Hertfordshire Natural History Society and Field Club has issued an excellent guide to the topography, natural history, archæology, &c., of the city and the surrounding neighbourhood, the account forming part iii. of vol. xiv. of the society's Transactions. Mr. John Hopkinson has acted as editor, and has himself contributed the sections on topography, geology, hydrology, and climate, while the other sections have been written by various members of the society. The guide is illustrated by a map of the district, a plan of modern Verulamium, and several local views, and will be of permanent value to residents in and visitors to the neighbourhood. The congress lasted from June 7 to 10, and at the inaugural meeting a resolution was passed expressive of the hope that the negotiations between the Society of Antiquarians and the Earl of Verulam for the excavation of the site of Verulamium, which—owing in part to the death of King Edward—fell through last year, may be resumed and brought to a successful issue. Lieut.-Colonel D. Prain, F.R.S., was nominated president of next year's congress in succession to Sir David Gill, K.C.B., F.R.S.

THE Huxley lecture at the University of Birmingham was delivered this year, on May 29, by Prof. Henri Bergson. He chose "Life and Consciousness" as the subject of his lecture. He proposed the view that a world-wide antagonism exists between matter, which is essentially automatic and governed by necessity, and consciousness, which is characterised by the power of choice and creation. Consciousness, he believed, entered matter in order to entice it to organisation; but in thus binding itself to matter, consciousness lost much of its original liberty, and was continually being dogged and cramped by automatism. Prof. Bergson conceived consciousness as flowing through matter much as a stream of fluid flows through a tunnel; in digging galleries in this hard rock, consciousness found itself impeded at point after point. Thus it had repeatedly to make fresh starts in its ceaseless efforts to create, until finally, in the course of this crooked path of evolution, it created man. In man alone, the chains which elsewhere bound consciousness to matter were broken. Here, maintained the lecturer, every contracted habit could be opposed by another habit, every kind of automatism by another automatism. Consciousness thus acquired its liberty by setting one necessity to fight another. In this way it has expanded to such a state of freedom that in man, perhaps, it may be able to endure beyond his earthly life.

THE fine series of big-game and other sporting trophies arranged in a special building at the Festival of Empire and Imperial Exhibition at the Crystal Palace, and opened

to the public last week, is of interest from two points of view. It is, for instance, the first attempt to bring together in this country a collection of the big-game animals (exclusive of zebras, wild asses, and giraffes) to be found within the limits of the British Empire, while, in the second place, it includes many of the finest heads of animals of this nature which have fallen during the last thirty or forty years to the rifles of (mainly British) sportsmen. Although it was found impossible to render the series absolutely complete, the exhibition affords an excellent idea of the wonderful extent of the big-game fauna of Greater Britain, and how vastly it exceeds that of any other empire in the world. The specimens are arranged according to countries, and thereby afford an excellent object-lesson in geographical zoology, so far as it can be learnt from a few groups of mammals. Those who visit the Crystal Palace exhibit will at once realise how much is lost by the lack of a geographical section in the zoological department of the Natural History Museum. A considerable proportion of the specimens exhibited at the Crystal Palace were shown last year at Vienna, but, on the other hand, there are many new objects, a few of which are of more than ordinary interest. To particularise these on the present occasion is, however, out of the question, and we may conclude by offering congratulations to Lord Wolverton, the president, Mr. C. E. Fagan, the hon. organising secretary, and the other promoters of this extremely successful and instructive exhibition.

WE have received a booklet entitled "Vergiftungen durch Tiere und animalische Stoffe," by Dr. Kanngiesser (Jena: Gustav Fischer, 1911, price 1 mark), which gives a brief but simple and comprehensive survey of animal poisons, *e.g.* those of insects and arthropods, molluscs, fish and toads, snake venom, &c. Some of the subjects, however, being infections rather than intoxications, *e.g.* amœbic dysentery, coccidiosis, trypanosomiasis, and trichinosis, seem somewhat out of place.

IN a review on "Salvarsan" which appeared in NATURE of May 25 (p. 412), it was stated that Ehrlich had introduced trypan red for the treatment of piroplasmosis. Prof. Nuttall writes pointing out that this is an error; it was tried by Ehrlich for the treatment of trypanosomiasis. Trypan red was first used by Prof. Nuttall in conjunction with Dr. Hadwen for the treatment of canine piroplasmosis, but proved unsatisfactory, and trypan blue, a drug which emanated from Mesnil, has been used instead with considerable success in the treatment of piroplasmosis in different parts of the world.

NO. 42 of the Scientific Memoirs of the Government of India deals with the cultivation of the leprosy bacillus. The cultivation of this micro-organism has almost baffled investigators, only a few undoubted cultures having been obtained. Major Rost makes use of a culture medium prepared by steam distillation of rotten fish, and to this distillate some weak Lemco broth and milk are added. Inoculated with material from leprosy patients, masses of "acid-fast," leprosy-like bacilli develop in a few days. Captain Williams, using Major Rost's medium, or a somewhat similar one, in which distilled water replaced the fish distillate, has also obtained cultures of what he considers to be the leprosy organism. An interesting fact brought out by the work is the extreme variation of the leprosy organism; sometimes it has the ordinary bacillar form and is "acid-fast," at others it is non-acid-fast, while diphtheroid and streptothrix forms frequently appear, the streptothrix often breaking up into bacillar forms. Both these observers have prepared vaccines with which promising results, as regards the cure of the disease, have been obtained.

IN the report of the Horniman Museum and Library for 1910 attention is directed to the gift, by Mr. A. R. Brown, of a number of specimens illustrative of the ethnology of the Andaman Islands. During the year, the museum has lost the services of Mr. F. Slade, whose appointment as naturalist considerably antedates the transference of the institution to the County Council.

IN an article in the May number of *The Museums Journal*, Dr. Bather directs attention to the palæontological exhibit at the "White City," the leading idea of which is to display the scientific results attained by the study of palæontology, and more especially such as can be obtained only by means of this science. The restoration of extinct animals constitutes one section of the exhibit; a second is devoted to extinct faunas and floras in connection with their bearing upon the present distribution of animal and plant life upon the surface of the globe; while a third section illustrates contemporary individual variation in a species. The last-named feature leads on to the evolution of species and genera, which is also exemplified by actual examples.

The Scientific American of May 11 contains an illustrated account on the so-called "dinosaur-mummy"—that is to say, a skeleton of Trachodon still covered with the skin obtained in 1908 by Mr. C. H. Sternberg from the Cretaceous of Wyoming. One of the illustrations shows the finely tuberculated, or granulated, structure of the external surface of the skin, while a second reproduces the latest restoration of the entire animal. The tenuity of the skin suggests aquatic habits on the part of these dinosaurs, and this view is strengthened by the circumstance that the relatively small fore-legs terminated in a broad expansion of the skin, converting the toes into a kind of paddle, and projecting beyond their tips. The expansion of the extremity of the muzzle into an edentulous, duck-like beak seems likewise indicative of aquatic habits.

To *La Nature* of May 27 Dr. E. Trouessart contributes an account of a specimen of the New Guinea long-beaked Echidna (*Zaglossus*, or *Proechidna*, *bruyni*) now living in the Zoological Gardens at Amsterdam, which is probably the first example of its kind ever brought alive to Europe. It belongs to the race for which Mr. Rothschild proposed in 1892 the name *Z. b. nigro-aculeatus*. The communication is illustrated by two photographs, which show that the pose of the creature is quite different from the one given in pictures and mounted specimens. In these the animal is represented with the belly resting on the ground, and the claws of the hind-legs directed like those of a lizard. In reality, it stands up on its legs in elephant-fashion, with the hind-claws directed outwards and slightly forwards, this being a remarkable attitude for a burrowing animal. Unlike the ordinary echidna, which refuses to touch them, the long-beaked species exhibits a marked partiality to earth-worms.

A PALÆONTOLOGICAL communication by Mr. E. W. Berry, published in the Proceedings of the United States National Museum (No. 1821), presents a revision and reduction of species referable to fossil gymnospermous genera from the Potomac group. Of eight genera reviewed, Sequoia is represented at the present day, Arthrotaxopsis and Cephalotaxopsis indicate by their names their relationship to modern genera, Brachyphyllum and Sphenolepis are *sedis incertæ*; the two latter genera are

possibly composite. Cones and seeds of a pine, *Pinus vernonensis*, are abundant in the group.

The modification of plants induced by the extremely dry summer in West Australia furnishes the subject of a contribution by Dr. A. Morrison to the Journal of the Natural History and Science Society of Western Australia (vol. iii., No. 1). A thick development of woolly hairs on stem and leaves is shown by *Eragrostis eriopoda*; rolling back of the leaf margins is the device exhibited by *Grevillea oxystigma*; *Plagianthus Helmsii* furnishes an instance of extreme specialisation in an arrangement of closely set minute leaves. *Daviesia euphorbioides* is an interesting case of a leguminous plant which has developed a succulent cactus-like form, while *Calandrinia primuliflora* is provided with a water-storing tubercle.

The concluding portion of Dr. C. B. Robinson's article on Philippine Urticaceæ, published in *The Philippine Journal of Science* (Botany, vol. vi., No. 1), contains the diagnosis and illustration of a new generic type, Astrothalamus, segregated from Maoutia, and several new species, notably under the genus Leucosyke. In the same number Mr. O. Ames presents a list of new records and species of Orchidaceæ, with an introductory note summarising his conclusions regarding the orchid flora of the Philippines. Dendrochilum, Dendrobium, and Eria stand out as the most important genera. No genus is entirely confined to the islands, but the numerous species contained in one section of Dendrochilum are all endemic.

The current number of *The Gardener's Chronicle* (June 10) contains the first part of an article by Mr. H. N. Ridley, describing a botanical expedition to Lower Siam, undertaken with the object of demarcating the boundary between the two distinct floras of Malaya and Tenasserim. On the island of Alostar the northern element was already recognisable in the shape of a common species of Corypha palm and a yellow vetch, a species of Geissaspis, growing as a weed in the rice fields. *Crinum Northianum* and a Lepadanthus were notable discoveries, as also the growth of *Leea rubra* in the mud flats. Attention is also directed to a contribution by Mr. R. Farrer, presenting a systematic synopsis of European species of Primula, with the object of clearing up some of the confusion which exists owing to changes in nomenclature.

Various problems, mainly economic, are discussed by Mr. A. D. Blascheck in an article contributed to *Science Progress* (April) on the subject of afforestation in the United Kingdom. He proceeds to show that the climate is suitable, that land is available, and that Great Britain has a smaller proportion of land under forest than any other European country. But the crux of the situation lies in the financial aspect, with reference to which the opinion is expressed that forests, as a rule, yield less profit than Government securities, so that the benefits derivable are indirect, chiefly in the extra employment of workers required for the timber and allied industries. These arguments lead to the recommendation of measures that were proposed in the Development and Roads Improvement Funds Act, 1909, *i.e.* "the conducting of inquiries and research for the purpose of promoting forestry and the teaching of methods of afforestation," as also "for the purchase and planting of land found after inquiry to be suitable for afforestation."

Mr. F. Muir has recently published an account, in Bulletin No. 9 of the Experiment Station of the Hawaiian Sugar Planters' Association, of some new species of leaf-hopper (Perkinsiella) on the sugar-cane. The genus was investigated by Kirkaldy in 1903; it is particularly attached to the sugar-cane, and only occasionally goes on to other grasses. At present there are thirteen known species.

Mr. L. D. Larsen has recently collected his work on the diseases of the pineapple, and published it as Bulletin No. X. of the Hawaiian Sugar Planters' Association. The fungus *Thielaviopsis parodoxa* is by much the most destructive micro-organism involved, causing three distinct and important diseases, in addition to being responsible for a good deal of the decay in pineapple roots. It is in general saprophytic, but in certain conditions it becomes parasitic. A disease known as brown rot was traced to Fusarium. The fungus causing the very serious pineapple wilt is not yet isolated with certainty.

The fifth annual report of the work at Rosslynlee, by Messrs. Lauder and Fagan, on the variation in composition of cow's milk, shows what a small effect ventilation of the cowshed has on the yield of milk. The shed was divided by a wood and felt partition into two parts, one of which was freely ventilated, even in the coldest weather; the other was only partially ventilated, so that its average temperature was higher by about 9° F. In the cool, well-ventilated part the average yield per cow per day was 27·54 lb., and in the warm, badly ventilated part it was 27·14 lb., the percentages of fat being respectively 3·74 and 3·70.

Messrs. Schreiner and Skinner have published, in Bulletin No. 75 of the United States Bureau of Soils, an account of the soils most suitable for lawns in the United States, and of the detailed cultivation and manuring necessary to obtain a good growth of grass. Some of their recommendations, however, seem quite inconsistent with the official views of the Soil Bureau; thus their advice to use phosphatic manures seems intelligible only on the old view that phosphates are needed to feed the young plant. It is significant that gardening has become of sufficient importance in American life for a great State department to undertake such an investigation as the present one.

An article by Dr. H. v. Ficker on the interesting subject of the advance of cold waves in Asia and Europe appears in the Proceedings of the Vienna Academy of Sciences for December last. The data upon which it depends are drawn chiefly from the Russian Meteorological Annals for 1898–1902. About fifty cold waves were investigated, and nearly 200 charts drawn, in this laborious work; a few typical cases only, with charts, are included in the article, with a short discussion of the majority of the other periods. The greater frequency of cold waves in winter would lead one to suppose that they proceeded from the cold centre in north-east Siberia, but this view has not been confirmed. In the majority of cases they were found to come from the Arctic coast, between long. 30° and 90° E. Distinction is drawn between those proceeding from the west of Novaia Zemlia, accompanied with north-west winds, and those proceeding from the east of that island, accompanied by north-east winds. The spread of the cold air is found to take place earlier towards Europe than towards Siberia. The maximum velocity of the waves is about twenty-five miles an hour, and thus corresponds fairly well to the rate of propagation of thunderstorms. Their irruption causes a sharp rise of the barometer; they are preceded by low pressure, and generally with a rise of temperature.

The classification of the visible forms of the various sextic plane curves forms the subject of a paper by M. W. Sierpinski in the *Bulletin international* of the Cracow Academy, No. 10 A (1910).

THE Proceedings of the Royal Society of Edinburgh, xxxi., 3, contains three papers by Dr. T. Muir, F.R.S., dealing with the historical development of certain determinants up to 1860. The papers refer respectively to "Wronskians," "Recurrent Determinants," and "The less common special Forms."

IN two notes contributed to the *Atti dei Lincei*, xx., 5, 7, Dr. U. Cisotti works out *in extenso* the solution of the problem of discontinuous stream-line motion of a jet which is divided in two by impact on a fixed plane, the jet being of finite breadth and bounded by free stream lines.

IT is announced that after the close of the present volume the *Annals of Mathematics*, hitherto published in October, January, April, and July, under the auspices of Harvard University, will be transferred to Princeton University, New Jersey, to which address editorial and other communications are in future to be sent.

IN the Bulletin of the American Mathematical Society for May Prof. Florian Cajori publishes a paper in which it is claimed that the now familiar "Horner's method" of solving an algebraic equation had been previously given by Paolo Ruffini in an Italian paper. The methods adopted by Ruffini and Homer seem to have been identical to a very great extent; the main differences which Cajori mentions are that Horner explained a special procedure for separating a pair of nearly equal roots, and, further, that he contemplated the application of his method to transcendental equations. It need hardly be pointed out that the solutions of such equations as $\tan x = x$, which can be expanded by Taylor's theorem, constitute some of the most useful and well-known applications of Horner's method.

WE have received a copy of Mr. W. J. Lyons's paper read before the Royal Dublin Society recently on a method of exact determination of the continuous change in absolute density of a substance in passing through its fusion stage. The apparatus consists of a dilatometer bulb, from the lower end of which a capillary issues, and is bent first upwards and then horizontally. This tube and the lower part of the bulb are filled with mercury. The upper part of the bulb contains the substance the expansion of which is to be determined, and the magnitude of the expansion is calculated from the motion of the mercury meniscus in the capillary tube. Experiments on wax show that the fusion lasts over a considerable range of temperature, and that in the neighbourhood the volume on cooling is, at the same temperature, greater than on heating. As the apparatus only differs from Pettersson's of 1881 in the absence of taps for the admission of the substance, it is to be regretted that Pettersson's name is not mentioned in the paper.

THE address given by Prof. Planck to the Société française de Physique on April 21, and reproduced in the May number of the *Journal de Physique*, constitutes one of the clearest expositions we have seen for some time of the present difficulties of the attempt to express the relation between energy and temperature. The doctrine of the equipartition of energy amongst the various degrees of freedom of a molecule, deduced by Boltzmann and Gibbs, has led to serious difficulties owing to the smallness of observed specific heats as compared with the calculated values. Planck's own theory, that energy exists in multiples of a certain atomic quantity, leads to difficulties with regard to absorption of energy, and, as we pointed out in these columns on March 16 (p. 90), he has now modified it so that only emission takes place by the step by step process, absorption being continuous and energy content of a body no longer an integral multiple of the atomic energy. Whether this change gives us a satisfactory theory only time can show.

The Builder for June 9 contains an illustrated article, by Mr. Percy J. Waldram, on the need for horizontal tie-rods in arched timber roofs. Generally, the introduction of such rods is owing to the designer assuming that the joints are flexible, and constructing a force-diagram based on this assumption. Actually, the stiffness of the joints as constructed in practice renders the fitting of tie-rods quite unnecessary in a properly designed arched roof. The author cites the case of the fine arched hammer-beam roof of Eltham Parish Hall, which has no tie-bars, and gives account of an interesting experiment carried out on one truss, which was mounted on pipe rollers on the ground and loaded with bricks laid on a platform slung from the truss. With a span of 42 feet and a load of 7 tons the calculated outward spread was 0·63 inch. Upon the first application of the load, the spread was found to be slightly more than 1 inch, owing partly to the tightening up of the joints. On removing the load, the truss came back 0·75 inch, and in each of the two reimpositions of the load, at intervals of two days, the spread was found to be 0·75 inch. The object of the test was attained, inasmuch as the district surveyor withdrew his requisition for tie-rods.

THE report of the Indian Association for the Cultivation of Science for the year 1909 has now been received. The association's chief work seems to be the arrangement of lectures on scientific subjects. During the year about 280 lectures on various branches of physics and chemistry were delivered, and in addition upwards of a hundred practical demonstrations were arranged. The chemical laboratory conducted by the association has been remodelled, and it is hoped soon to inaugurate a research department. The report also contains a set of meteorological observations taken at Calcutta during 1909.

IN a review of Prof. Leduc's book on biological aspects of osmotic phenomena in NATURE of May 25 (p. 410) the writer gave examples of the need of proof-reading, and stated that there were errors in the title of a book by Rhumbler. He inferred, unfortunately without verification, that the strange words "organismischer" and "anorganismischer" were typographical errors, but Prof. Leduc writes to point out that they are the words Rhumbler used in his title. The reviewer regrets that he was guilty of the kind of carelessness for which he reproached Prof. Leduc, but he is afraid that his remark as to misprints remains true.

OUR ASTRONOMICAL COLUMN.

A REMARKABLE METEORIC PHENOMENON.—In No. 4503 of the *Astronomische Nachrichten* Dr. Max Wolf describes a curious phenomenon observed on May 22, at about 11h. 49m. (Königstuhl M.T.), at Heidelberg. A faint meteor, pursuing a 4° path obliquely from east to west, passed over the star γ Aquilæ with great velocity; its breadth was about 15′, and it left a faint trail, which disappeared immediately. But although this trail was only momentarily visible, the star remained invisible for at least 3·5 seconds, its light apparently cut off by the material left behind by the evanescent meteor.

THE DIFFERENT QUALITY OF THE LIGHT REFLECTED FROM DIFFERENT PARTS OF THE MOON'S SURFACE.—The results obtained by Herren A. Miethe and B. Seegert in photographing the moon's surface through colour-selective screens are further described in No. 4502 of the *Astronomische Nachrichten*, and illustrated by a two-colour

reproduction of a composite drawing made from their photographs. On this drawing those parts which reflect a greater amount of light from the red end of the spectrum are shown in red, and those which reflect chiefly light of shorter wave-length are represented in green. The complex mixture of colour cannot be described in detail here, but we note that the walls and several streaks about Tycho are red, as are also the greater parts of the Mare Serenitatis and the Mare Humorum. On the other hand, Tranquilitatis, Fecunditatis, and Crisium are almost wholly green, while the Mare Imbrium is quite an intricate mixture.

THE SILVER DISC PYRHELIOMETER.—In 1909 Mr. Abbot, director of the astrophysical observatory of the Smithsonian Institution, designed a pyrheliometer which, although not readily providing results reducible to calories per sq. cm., furnishes readings proportional to the intensity of the solar radiation, and can be made of a standard form, so that a number of widely distributed observers may work in consonance. This instrument, as described in No. 19, vol. lvi., of the Smithsonian Miscellaneous Collections, consists of a silver disc in which a radial hole has been bored. Into this hole a thermometer bulb is inserted and packed, a mercury filling ensuring good conduction. The whole is carried in a tube provided with suitable diaphragms, exposing shutters, and packing, on an equatorial stand, and the observations simply consist of reading, very carefully, the thermometer at definite intervals. In order to secure cooperation, the Smithsonian Institution has furnished several other institutions with copies of the standard instrument, and is willing to furnish others. Standardised and packed ready for shipment, such an instrument costs the institution about 100 dollars.

THE PHOTOGRAPHIC DETERMINATION OF STELLAR MAGNITUDES.—Two sections of the Harvard College Observatory Annals recently received deal with the difficult but important question of the determination of stellar magnitudes by photography.

In No. 1, vol. lxxi., Prof. E. C. Pickering discusses the numerous difficulties attending the determination of standard magnitudes, and briefly reviews the various methods that have been tried. He then shows by tables and curves that the method adopted at Harvard, in which the photographic magnitude can be derived from the photometric by adding a constant depending upon the class of spectrum of the star, gives results in which the deviations, at least for the brighter stars, are probably too small for determination at present. A comparison of the results obtained by thus treating the magnitudes given in the Uranometria Oxoniensis and the Potsdam Catalogue shows the smallness of the residuals. The photographic magnitudes of all stars of mag. 4·25 and brighter from these two catalogues and the Harvard Revised Catalogue are given in Table V., and should prove a useful reference for standard photographic magnitudes; other tables give the magnitudes of double stars and of stars having a photographic magnitude of 3·0 and brighter. The paper concludes with an interesting note on the apparent changes well-known groups of stars would undergo if we saw their photographic, instead of their photometric, brightness; Betelgeuse would become from 0·5 to 1·0 mag. fainter than the belt stars; Antares would appear a little less bright than σ and τ Scorpionis, and the Southern Cross would be greatly altered by γ Crucis becoming much fainter than δ.

In No. 6, vol. lix., Mr. E. S. King gives the photographic magnitudes of 153 stars determined by the method of measuring images taken at different foci; these magnitudes are absolute, and the scale is independent of any other system. The determination of these absolute magnitudes provides a surer basis for the derivation of the constant corrections to be applied to existing photometric magnitudes according to the class of spectrum, and these corrections are tabulated. Mr. King also discusses his material to educe evidence of the absorption of light in space, and finds, from the increased redness of the more distant stars, that there probably is some such absorption.

JUPITER'S EIGHTH SATELLITE.—The eighth satellite of Jupiter was observed at Heidelberg on May 22, and at 10h. 26·2m. (Königstuhl M.T.) its position (1855·0) was 14h. 19m. 37·4s., −13° 56·8′. Its magnitude was between 16 and 17, and Dr. Wolf remarks that its position is so low as to place its observation with the reflector on the limit of possibility, mechanically (*Astronomische Nachrichten*, No. 4503).

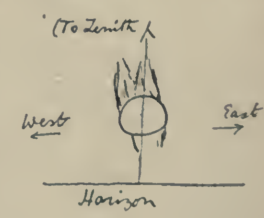
THE BRITISH SOLAR ECLIPSE EXPEDITION.[1]

H.M.S. "Encounter."
April 29,
Eclipse Day, 11.30 p.m.

THE eclipse is over, and we have only seen quite a little of it. For a long time we have been making our preparations, and for more than a week we have been drilling nearly daily. The weather has not been very kind, and either heavy showers or light rain have fallen during the day or night. However, it seemed that we might be lucky and secure a cloudless moment, or we might repeat the Palma eclipse of 1905 and be partially clouded out. Well, it has been very much worse than Palma.

The early morning of the eventful day was far more cloudy than usual, in fact, there was a great amount of cirrus cloud and numerous cumuli. As eclipse time came along, evidently the reduction of the temperature in this very humid climate (nearly always 75 per cent. or more of saturation) caused the aqueous vapour to condense into cloud, and the cloud increased and increased in amount as the time for second contact approached. So cloudy was it, and so disturbed was the air, that the observer who was watching the cusps could not be certain of giving the correct observed time of totality by them.

By chronometer time the eclipse clock was started, and the whole party went through their programme as if it were a rehearsal. The greater part of totality was hardly observed at all, and the whole of it was seen through fairly thick cirrus cloud. After the eclipse was over the clouds gradually dispersed, and long before fourth contact was reached a nearly cloudless sky was *en évidence*. The whole affair has been a great disappointment, both to the astronomers and the ship's company.



The corona was distinctly of a minimum type, the fish-tail portion of it being pointed towards the zenith (see sketch). One large prominence in the north-west quadrant was conspicuous towards the end of totality, and gave a ruddy hue to the corona in that quarter. Owing to the great amount of cloud, long extensions could not be observed, but the fish-tail portion extended, to my eye, one diameter away. Clouds prevented me from seeing any conspicuous feature on either the east or west limbs, but on the lower limb there seemed to be the indication of the stump of a large streamer.

At the time of writing, the following results have been secured, but only a few plates of some of the instruments have been developed. Steward equatorial, three plates developed, two of which may be useful. These show the lower corona only, including the stumps of some streamers. Two plates only of the De la Rue coronograph have been developed, and they are not dense, owing to the cloudy nature of the sky. One plate from the 4-inch 16-foot coronograph has been developed, and this seems very much underexposed. No plates of the large grating spectrograph have as yet been developed, but one (the only plate developed), taken with the 6-inch prismatic camera near the end of totality, shows a considerable number of lines in addition to some continuous spectrum. In fact, the photographic results so far obtained seem to be better than what was anticipated from the cloudy conditions.

One may really sum up the whole results of the expedition as a failure, considering what we might have obtained had the weather been more propitious.

Nearly all, if not all, the eclipse parties have obtained almost similar results; but it is early yet to say for certain until the plates have been developed.

W. J. S. LOCKYER.

[1] Continued from p. 499.

SCIENCE AT THE WHITE CITY.

At the Coronation Exhibition, which was recently opened at Shepherd's Bush by Prince Arthur of Connaught, a section devoted to pure science has again been included. This is the third of these science exhibitions, the first having been in the Franco-British Exhibition some three years ago. The formation of such a section at that time was suggested by the British Science Guild, and it was managed by a committee nominated by the Guild. The second science section was in connection with the Japan-British Exhibition last year, and it was larger and more comprehensive than the previous one, and was managed by a separate committee of the exhibition; and the third, which is now to be seen at the White City, is again on a still larger scale, and occupies no fewer than three large courts in what are called the "overhead buildings" leading from Shepherd's Bush Station to Wood Lane. That sections devoted to pure science are now being included as a matter of course in most of the important exhibitions is shown by the fact that the International Exhibition now open at Turin has a rather large science collection, including two laboratories actually at work.

The object of such sections is to bring together the methods and results of recent scientific research and invention in a form which will attract the notice of the general public, and will have an educative effect on all who may examine the exhibits. The results of the two previous science sections in the White City have been very satisfactory, and many men of science have been much surprised at the intelligent interest taken in the collections by the ordinary visitors to the exhibition, who must be entirely unacquainted, as a rule, with pure science and with the nature of scientific investigations.

The section in the present exhibition is divided into fourteen parts, representing the different sciences. The whole work has been under the control of a strong representative committee, and each division has been under the care and control of an expert in the particular science dealt with. All this work has been honorary, and grateful thanks are due to those gentlemen who have devoted much time and labour to the work of collecting and arranging the exhibits, while equally grateful thanks are due to the many investigators of science who have so kindly lent their apparatus and the products of their researches for exhibition. It must, however, be clearly understood that the domain of science is so wide and large that the collections merely illustrate portions of the fields of various sciences, and only such portions, indeed, that lend themselves easily to demonstration in an exhibition.

In the present exhibition an attempt is made to give parts of the collection a more living interest than had hitherto been possible by showing certain apparatus actually at work. To take, for instance, the section devoted to physical science; in this, by the courtesy of the Marconi Company, an apparatus is being installed for sending and receiving Marconi telegrams. The apparatus is that which is actually employed in sending messages to shore from a Cunard steamer, and it will be possible to send wireless messages from the end of one of the long science courts to the end of a second, and visitors to the exhibition will be able to send off and receive such wireless messages without charge.

A good many of the pieces of apparatus too in the physical science section will be actually at work, being driven by a separate electrical installation, which has been erected at considerable cost.

It is almost impossible to review all the fourteen divisions of the science section, but a few of the exhibits perhaps may be mentioned.

A large and important collection is shown under astronomy, including some excellent photographs and transparencies of star clusters and nebulæ, while M. Deslandres sends some illustrating clouds of calcium and hydrogen in the upper atmosphere of the sun. There is also a collection of sundials and astrolabes, including one belonging to Mr. Knobel, and dated so far back as A.D. 1224.

In meteorology, the Meteorological Office is well represented. In anthropology, a very complete collection of skulls (or casts of them) is shown which have been found in different parts of Europe, and which throw light upon the ancient history and evolution of mankind. Anthropometric measurements will also be made in this division. Very interesting, but rather technical, collections are shown in geology and palæontology, while in the mineralogy and crystallography section the emerald exhibited by the Duke of Devonshire is said to be the largest in the world. A very fine collection is shown under the head of chemistry, one case, dealing with the rusting of iron and the corrosion of propeller blades, being specially noticeable, while vanadium steel and ferro-silicon are also shown. The last-named compound, it may be remembered, has sometimes caused loss of life when carried on ships, and the conditions of such accidents are explained.

The London School of Tropical Medicine has also a most important and interesting exhibit dealing with such diseases as sleeping sickness, plague, &c. Under agriculture, the remarkable experiments of Prof. Percival, of Reading, on the growing of wheat are illustrated, while other exhibits deal with stone-ground flour. Models are also shown of the methods of growing crops by the help of high-tension electricity, such as would be used in a field or in a greenhouse. Under seismology, the delicate instruments used for recording earthquakes, and also Prof. Milne's tide recorder, are shown, while one seismograph has had to be erected in the Machinery Hall, as it has to rest on the ground itself, while the science attractions are housed in raised buildings. This seismograph will be at work throughout the exhibition, and will record any earth tremors or earthquakes which may happen during this time. Interesting collections are also shown under the head of geography and oceanography.

ANTHROPOLOGICAL EXPEDITION TO NEW GUINEA.

An interesting anthropological expedition to New Guinea is about to take place under the auspices of the University of Oxford as represented by the Committee for Anthropology. The sum of money required for the purpose has been made up out of considerable grants of equal amount furnished by the Common University Fund (with the condition that whatever specimens of native handiwork are procured, duplicates excepted, shall be offered as presents to the Pitt-Rivers Museum) and Balliol, Magdalen, and Brasenose Colleges, whilst smaller but still considerable contributions of varying amount have been made by University, Exeter, Lincoln, Corpus Christi Colleges, Christ Church, and Jesus College, Sir William Anson and Dr. Arthur Evans having likewise in a private capacity afforded welcome help to the expedition fund. The Committee for Anthropology has selected Mr. D. Jenness, of Balliol College, to undertake the work of exploration. Mr. Jenness holds the Oxford diploma in anthropology, and went on to Balliol as the holder of several scholarships from New Zealand, where he not only graduated with first-class honours in classics at the University, but likewise had occasion to acquire practical experience of the conditions of camp-life in the bush.

So far as can be foreseen at present, Mr. Jenness will reach Papua in November, and will take as his base of operations Bwaidoga, on Goodenough Island, one of the almost unknown D'Entrecasteaux Group, off the south-east coast of New Guinea. When Sir W. Macgregor arranged for the partition of British New Guinea amongst the various missionary societies, the islands of south-east New Guinea fell to the Methodists, and the station of Bwaidoga is one of the latest fruits of their enterprise. The Rev. A. Ballantyne, who is in charge of the D'Entrecasteaux Group, will render Mr. Jenness all the assistance in his power, and the help of all the Methodist missionaries in that region is similarly assured. Further, the Lieutenant-Governor of Papua, the Hon. J. H. P. Murray, has given his full approval to the expedition as thus arranged, and has promised it his official support.

Mr. Jenness will probably begin with a general survey of the D'Entrecasteaux Group, but as soon as he has got thoroughly into touch with the natives, hopes to be able to settle down to a detailed study of Goodenough Island

in particular. The examination of its trade relations, however, may entail a visit to the neighbouring Trobriands. If it prove possible, he will also proceed so far afield as Rossell Island, where certain ethnological problems of peculiar interest await solution.

SOME AMERICAN ORE DEPOSITS.[1]

NEW MEXICO has one of the longest mining histories of the western United States, for its semi-civilised aborigines, the Pueblo Indians, mined gold and turquoise before the arrival of the first white explorer in 1534. The Jesuit missions converted the Indians to Christianity, and then sweated them as miners until they were goaded into revolt, and the Spaniards were only readmitted on condition that their industrial operations were confined to agriculture. Mining was only resumed with the discovery of the copper-bearing sandstones at the close of the eighteenth century. Placer mining was started in 1828; the modern era of active mining was begun about 1866 upon the silver-lead ores, followed during the present century by the opening of mines of copper, lead, and zinc. The State contains large deposits of bituminous coal of Cretaceous age.

The geology of the country has a long and scattered literature. A general survey of its metalliferous mining fields was made in 1905 by Dr. W. Lindgren, Louis C. Graton, and C. H. Gordon, and a preliminary account of their results was issued as a Bulletin (No. 285) by the United States Geological Survey in 1906. The volume containing the detailed account of their researches consists of a general summary of the economic geology, followed by descriptions of the separate fields and mines. The work will no doubt remain for years the standard authority on the mines of New Mexico, and will repay study by all students of ore deposits. It contains, moreover, instructive evidence on some problems of general geology. The volume is illustrated by instructive topographic maps, mine plans, and plates; a geological map of the State, however incomplete, would have been very useful.

New Mexico has a base of Archæan crystalline rocks covered unconformably by Cambrian quartzites. The northern part of the State shows the stratigraphical gap so characteristic of the Rocky Mountain sequence, for the Cambrians are followed by the Carboniferous; but the intermediate Palæozoic systems are represented in the Southern districts. The Mesozoic series, usually complete in the Rocky Mountains, is imperfect, as the Jurassic is sparsely represented. The Carboniferous beds include marine limestones, followed by "Red Beds," some of which belong to the Trias. The Cretaceous system includes 6000 feet of marine beds; their deposition was followed by active earth movements, and the intrusion of sheets and laccolites of granodiorites which lifted the overlying Cretaceous rocks into domes. Igneous activity was renewed in the middle Cainozoic, when wide lava flows were erupted from numerous volcanic vents; at the close of the Cainozoic came a third period of igneous activity, and the outpouring of vast sheets of basalt. The last eruptions were of very recent date.

The "metal deposits," as the Monograph calls them, for the term metallisation is replacing mineralisation, though both assume similar limitations—are divided by the authors into six groups. The oldest series, the ores in the pre-Cambrian rocks, contain gold and copper, and were developed as fahlbands in shear-zones.

The second group of ores are contact-formations around the laccolites. The evidence offered by the mines as to the range of the contact metamorphism is of much interest. The shales are altered for a very narrow width, but the limestones may be completely changed for half a mile. The authors are emphatic that the metasomatic are more important than the paramorphic changes, and that the addition of silica, iron, and sulphides from without is "positively proved." The fresh materials are attributed to emanations from the intrusive magmas. The limitation of contact metamorphism "simply to a rearrangement of molecules in a single bed is absolutely contrary to the facts." That these ores were not introduced in solution after the intrusive rock had cooled is shown by the unaltered condition of its border.

The igneous rocks belong to that granodiorite- and quartz-monzonite series which is so often associated with ore deposits. The rocks are granular, although they solidified at the comparatively shallow depth of sometimes only 2000 feet. The toughness of their cover appears to have prevented their reaching the surface.

The third series of ores are veins connected with the granodiorite intrusions. They are usually pyritic gold-quartz fissure-veins. The veinstones include albite, tourmaline, and fluorite, and the ores often include much blende. They are usually normal fissure veins, one of which is illustrated by a fine coloured plate of part of the vein. Such figures are very useful. The regular trend of the veins is doubtless due to compression during the intrusion of the igneous rocks.

Ore bodies and veins due to the replacement of limestone form a fourth group. They are associated with the igneous rocks, but occur some distance from the contact. The chief ores are of silver, lead, and zinc; the two chief minerals are galena and calcite. The most famous of these deposits is the ore-body known as the Bridal-Chamber, a mass of almost pure kerargyrite found in limestone beneath a cap of andesite. The authors regard the ore as older than the andesite, and as formed above a hidden intrusion of porphyry.

The fifth group of ores are veins connected with the Cainozoic volcanic rocks. They occur in shoots where the lavas have been propylitised, and have no doubt been formed by the action of hot mineral waters at a slight depth below the surface.

In connection with these veins the authors describe an interesting fluorite vein formed in gneiss by the hot springs at Ojo Caliente. The vein contains barite, limonite, oxide of manganese, silver, and gold. The richest examples assayed contained $75 of silver and $30 of gold to the ton. The mineral waters, owing to their predominant sodium carbonate and chloride, are described as of well-defined volcanic affinities (p. 71), and they supply an interesting addition to the known mineral veins formed by existing hot springs.

The last group of minerals are copper ores, usually chalcocite, in the Red Sandstones. The ores are epigenetic, but their distribution shows no relation to that of any igneous rocks; they contain no gold and very little silver. A coloured plate of these ores includes one in which the chalcocite has replaced coal. In the San Miguel Mine tree trunks 60 feet by 2½ feet in diameter have been almost completely replaced by glance. The widespread occurrence of copper in Red Sandstones of late Palæozoic and Triassic age has given rise to considerable discussion, and is a very suggestive fact. Dr. Lindgren discusses the origin of these ores, and rejects the theories of their precipitation from solution or formation by adsorption; and he concludes that they are due to minute traces of copper, some of which may have been sedimentary, by meteoric waters containing chlorides and sulphate. Mr. Graton offers a somewhat different explanation owing to the lack of evidence of descending acid solutions. He regards the chalcocite as introduced by ascending alkaline carbonates containing metallic sulphides in solution. As in the historic case of Mansfeld, the ores in the Sandstones appears to be most abundant above the richest copper-bearing veins in the underlying rocks, a fact which is in favour of Mr. Graton's view.

Mr. E. C. Harden's bulletin on the manganese deposits gives a summary of the known manganese deposits in the United States, and brings up to date Penrose's well-known monograph. The author's personal observations were made during a tour from January to April, 1908. The information then collected is supplemented from the literature and by chapters on the manganese deposits of other countries and on the chemistry and uses of the metal. The manganese ores of the United States belong to four main series. The first includes residual peroxides left by the

[1] "The Ore Deposits of New Mexico." By W. Lindgen, C. C. Craton, and C. H. Gordon. Pp. 361.
"Manganese Ore Deposits of the United States," with sections on Foreign Deposits, Chemistry, and Uses. By E. C. Harden. Pp. 298.
"Some Ore Deposits in Maie and Milan Mine, New Hampshire." By W. H. Emmons. Pp. 62. (Washington: Government Printing Office, 1910) (U. S. Geological Survey-Bulletins 432, 427, and Professional Papers 68).

decomposition of manganiferous silicates in crystalline rocks. The second type includes bedded ores; their manganese was derived from the silicates of crystalline rocks, and was deposited in the sedimentary rocks and then concentrated; this group includes the Appalachian ores, the most important in the United States. The two last groups comprise the manganese minerals associated with the silver ores of Leadville and other western mining fields, and the deposits with the Jurassic radiolarian jasperoids of California, which, according to Prof. Lawson, were deposited by suboceanic springs.

The chapter on the protean chemistry and uses of manganese describes the introduction of manganese steel in consequence of Hadfield's discovery that though the addition of 5 per cent. of manganese renders steel brittle and useless, the presence of about 12 per cent. produces a metal so hard, tough, and nonmagnetic that it has very important industrial applications.

Maine and New Hampshire are States in which mining is of secondary importance, but Mr. W. H. Emmons' short and interesting bulletin shows that ore deposits occur which have some features in common with those in the adjacent provinces of Canada. The geology is well known from Hitchcock's memoir and the later researches of Dr. G. O. Smith. The valuable minerals include gem-bearing pegmatites, which are not described in this bulletin, and some pyritic veins and ores of lead, zinc, silver, copper, and molybdenum. The basement of the area consists of metamorphic rocks, which are regarded as probably Archean; they are succeeded by sediments and volcanic rocks attributed to the Cambrian; the volcanic rocks were followed or accompanied by some igneous intrusions, beside which ores were formed as contact deposits. These rocks were then crushed to schists, at a date which is pre-Silurian, "but how much older is not known." Granitic intrusions followed in the Devonian.

The most interesting ores are the pyritic bodies, which here, as in other cases, give clear evidence of the depth at which the rocks were foliated, for the change took place where the ores were in the zone of fracture and the slates were in the zone of flow.

The bulletin contains some excellent illustrations of the microstructure of the ores. One of the most novel is of molybdenite ore from the Catherine Hill Mine. It is given to illustrate the author's view that the molybdenite was a primary constituent of the granite, and that the felspars floated in the liquid molybdenite; whereas the photograph, showing that the sulphide is permeating the large crystal of orthoclase and that a thin felspathic tongue with a disconnected end projects into the solid ore, rather indicates the secondary nature of the molybdenite.

J. W. G.

RECENT CONTRIBUTIONS TO THE STUDY OF HEREDITY.[1]

(1) PROTOZOA have as yet played but little part in the literature of heredity, and there are even some writers who belittle and disparage the evidence afforded by this group of animals on the ground that there is in them no separation of germ-plasm from somato-plasm. On the other hand, Jennings and Bateson have pointed out the importance of following the behaviour of conjugating and dividing Protozoa, since at such phases of life the phenomena of heredity are seen in a simple form. It is now known that this simplicity is deceptive. The protozoon does not simply cleave into two daughter cells, but first of all absorbs certain organs of its body, and after dividing its substance between the two or more descendants, leaves to them the further task of reforming these lost organs and other parts afresh. Moreover, in such a way is the cleavage carried out that the regenerating parts required by each daughter cell are not optically symmetrical. One may form a "head," the other a "tail," from what was the middle of the parental body. In other words, a dividing protozoon exhibits heredity under the form of alternate symmetry.

In the first paper on our list, this form of heredity is dealt with as fission. The particular animal studied is a species of Euplotes, a genus of ciliate infusoria commonly found on Hydra. Before division takes place, a new mouth is formed, independently of the existing one, by a depression of the ectoplasm, and a modification of its substance develops into a definite peristome. Meanwhile, the meganucleus elongates and becomes segmented into definite regions. The old cirri are gradually absorbed, and are replaced in the daughter cells by new structures. The author describes these changes in great detail, and promises another contribution upon the changes in Euplotes during conjugation.

(2) The pomace-fly, Drosophila, has been the subject of much recent investigation in America owing to its short life-history and the ease with which it breeds in captivity. The present paper, by Mr. F. E. Lutz, deals with the inheritance of abnormal venation in the wings of this fly. The facts, put very briefly, are that in wild specimens a few additional veins are occasionally, but rarely, met with, and the experimental evidence shows that in a large number of matings the percentages of such abnormally veined specimens are:—normal × normal, 9·6 per cent.; abnormal ♂ × normal ♀, 35·8 per cent.; normal ♂ × abnormal ♀, 54·7 per cent.; abnormal ♂ × abnormal ♀, 85·9 per cent. Discussing these remarkable increases in the ratio of abnormal to normal offspring, the author suggests that in *all* Drosophila gametes there is a factor tending to produce additional veins, but that its effects are often obscured, and only become visible in what may be called the upper part of its range. Especially interesting is the rise in the intensity of this factor when an abnormal strain is selected for breeding, and its rise and subsequent fall in a normal strain. Another point of importance is the observation that normally veined flies select normal mates when given a choice of both kinds. Mr. Lutz also gives a most interesting appendix on the question of disuse and degeneration of wings in this fly. Drosophila is a good flier, but when bred for forty generations under conditions that preclude the use of the wings, no degeneration or diminution in these organs can be detected. Altogether this is a very laborious and careful piece of research with bearings on many problems.

(3) The next two papers deal chiefly with the ovarian tissues of mammals. Much importance has been attributed to Guthrie's experiments on the transplantation of hen's eggs to foster-mothers of a different colour from that which produced the egg. According to this writer, the offspring of such foster-birds developed from the transplanted egg and were influenced by the foster herself. Davenport has recently denied both of these results, and now we have a contribution by Prof. Castle and Mr. Phillips upon similar experiments in guinea-pigs and rabbits. The results arrived at are not a little confusing. In the clearest case the procedure was as follows. The two ovaries of an albino were removed at intervals of a week, their places being taken by an ovary from each of two black sows of differing ancestry. After recovery, the albino foster-mother was put to an albino guinea-pig. Two hundred days later two ♀♀ were born, both of which were black with red hairs, and two months later one ♂ of the same colouring. Some three months afterwards the albino died of pneumonia, and was found pregnant with three full-grown ♂♂, again black and with red hairs interspersed. One of her daughters mated with the same albino ♂ threw two albinos and one black. A control mating between a pure black ♀ and the same albino ♂ gave five young, all of which were black with red hairs.

These results are held to show that the engrafted ovarian tissue was the source of the black young produced by this cross albino × albino, and that no foster-mother influence could be detected. But, on the other hand, all the remaining cases go to show that, as in Davenport's fowls, extirpation of the ovary is not complete, and is followed by regeneration, the regenerated ovary being the source from which the young produced

during the experiment are derived. A review of recent work on this difficult subject is appended to this paper.

(4) The last paper on our list deals with the egg of the mouse. By most observers the egg of this animal has been regarded as an exception to the rule that two polar bodies are formed during maturation. In order to clear up this point and to settle many other doubtful features of this egg, Prof. Mark and Mr. Long have undertaken an elaborate research involving the examination of 1000 eggs from 147 mice. The methods employed are given in welcome detail, and a special feature of the apparatus was a balance and recording drum so arranged as to indicate automatically the time of parturition. The histological results show that all mouse-eggs form two spindles and a first polar cell, and that all eggs on coming into contact with spermatozoa form a second polar cell. With regard to details, the authors conclude that the number of chromosomes is twenty. The chromosomes of the first spindle are "tetrads," and show indications of both transverse and of longitudinal fission, whilst those of the second spindle are "dyads," and divide longitudinally. The work is most carefully executed, and is fully illustrated, but the cytoplasmic structures are scarcely visible in the plates. The paper is one of great value to embryologists.

THE AMERICAN PHILOSOPHICAL SOCIETY.

THE annual general meeting of the American Philosophical Society was held at Philadelphia on April 20–22, and more than sixty papers on scientific and literary topics were presented.

It has been the custom for several years to devote one half-day session to a symposium on some special subject in science. This year the afternoon of April 22 was devoted to this feature, the topic being modern views of matter and electricity; and the following papers were offered:—The fundamental principles, by Prof. D. F. Comstock, of Boston; radio-activity, by Prof. B. B. Boltwood, of New Haven; thermionics, by Prof. O. W. Richardson, of Princeton; the constitution of the atom, by Prof. H. A. Wilson, of Montreal. The general conclusion seems to be that the atom of matter, groups of which compose the molecules of different substances, is built up of much smaller parts, called electrons, identical with the smallest unit of negative electricity. It was also explained how it is possible to estimate the actual number of electrons in any particular atom. As the inertia of an electron emitted from an atom of a radio-active substance, such as radium, has been experimentally proved to be a function of its speed, the evidence is strong that all inertia or mass may be electrodynamic in its nature.

Physiology.

The secretion of the adrenal glands during emotional excitement, by Prof. W. B. Cannon, Harvard University. The adrenal glands and the sympathetic nervous system are intimately related. The sympathetic system innervates the glands, and the glands in turn secrete a substance that affects bodily structures precisely as the sympathetic system affects them. The sympathetic system is aroused to activity in states of emotional excitement. Examination of the blood of excited animals reveals the presence of adrenal secretion, which was not found in the blood before the excitement. Possibly the adrenal secretion continues the excited state. Possibly also the adrenal secretion caused by emotional disturbances has some of the effects produced by injection of the substance, such as glycosuria and atheroma of arteries. Indeed, two of the author's students, Shohl and Wright, have recently shown that glycosuria can be produced in the cat by fright. The suggestion, however, must be put to further experimental test.

Coagulation of the blood, by Prof. W. H. Howell, Johns Hopkins University. The theory of the coagulation of blood most commonly accepted at the present time holds that three of the four necessary factors in the process are present in the circulating blood, but that the fourth, which initiates the process in shed blood, is furnished by the tissues outside the blood or by the disintegration of corpuscular elements in the blood itself. This fourth factor is an organic substance of the nature of a kinase, which, in conjunction with the calcium salts of the blood, serves to activate the prothrombin, also present in the blood, to thrombin. The thrombin then acts upon the fibrinogen and converts it to fibrin, which constitutes the essential phenomenon of clotting. In opposition to this theory, the author gave experimental evidence to show that in normal blood the fluidity is due to the constant presence of an antithrombin, and that in shed blood the tissue elements furnish a substance, thromboplastin, which neutralises the antithrombin, and thus allows clotting to take place. In the vertebrates below the mammals, the thromboplastin is furnished by the cells of the outside tissues, and without their cooperation clotting would not occur. In the mammals, thromboplastin is furnished by elements in the blood itself, the platetets, so that the blood may clot promptly without cooperation on the part of the outside tissues. In human beings, the condition known as hemophilia, in which there is delayed clotting and danger of fatal hæmorrhage, the defect is due, not to a lack of kinase in the tissues as a whole, the view usually taught at present, but to an excess of the antithrombin normally present in the blood.

The cyclic changes in the mammalian ovary, by Leo Loeb, director of the Pathological Department, St. Louis Skin and Cancer Hospital. In the mammalian ovary cyclic changes of a very far-reaching character take place. They concern the follicles, corpora lutea, and ova. There exists in the ovary a mechanism (in the corpus lutem) regulating those changes; the corpus lutem prolongs the sexual cycle, not by retarding the maturation of the follicles, but by preventing the rupture of the mature follicles. The author's recent observations make it very probable that a partial parthenogenetic development of some ova accompany those cyclic changes in the follicles in a certain percentage of animals.

Electrical Engineering.

The high voltage corona in air, by Prof. J. B. Whitehead, Johns Hopkins University. The author described the limitation to the long-distance electrical transmission of power imposed by the insulating properties of the air, and a new method for determining accurately a voltage at which the air in the neighbourhood of electric wires and cables will break down, and also gave the results of a series of experiments on the influence of the size of the wire, the stranding of the wire into a cable, the frequency, the pressure, the temperature, and the moisture content of the air. He also reviewed the bearing of present physical knowledge on the nature of the phenomena which are involved.

Geology.

Supposed recent subsidence of the Atlantic coast, by Prof. D. W. Johnson, Harvard University. The author briefly reviewed the evidence in support of the generally accepted theory that the Atlantic coast is subsiding at the rate of from 1 to 2 feet per century, and showed that the phenomena supposed to indicate subsidence might be produced by fluctuations in the height of ordinary high tides resulting from changes in the form of the shore-line. A study of the Atlantic shore-line indicates that conditions are there favourable to marked local changes in the height of the tides, independently of any general movement of the land. On the other hand, the structure of certain beaches along the coast afford very strong proof that there can have been no long-continued progressive subsidence of the coast within the last few thousand years. The theory of fluctuating tidal heights, and the theory of stability of the land mass, were illustrated by selected examples of shore-line phenomena.

Alimentation of existing continental glaciers, by Prof. W. H. Hobbs, University of Michigan, Ann Arbor. It was in the Alps of Switzerland that the early studies, and by far the larger number of subsequent investigations, of glaciers have been made. The Swiss type of glacier is one of the most diminutive, but as the theory of former continental glaciation was derived from these studies of puny glaciers, it is not surprising that their attributes were carried over unchanged to the reconstructed extinct types thousands, and even tens of thousands, of times larger,

and this before any continental glaciers had actually been studied. The recent explorations of Norwegian, German, Swedish, and Danish explorers, but more than all of Peary in Greenland, and of Scott, Nordenskiöld, von Drygalski and others, but especially of Shackleton in Antarctica, have at last afforded us observations upon the existing continental glaciers. When these reports are carefully studied and compared, it is found that, as regards their form, their erosional processes, and especially their nourishment and waste, continental glaciers are as different as possible from those of the Alpine type. Instead of being nourished by snow precipitated from *surface* air currents, which are forced to *rise*, their snow supply is derived from the fine ice grains contained in *high-level* cirrus clouds which have been *drawn down* to the glacier surface, been melted, and there reprecipitated. This action is the work of a refrigerating air engine, which is developed directly by the snow-ice mass itself.

Front range of the Rocky Mountains in Colorado, by Prof. W. M. Davis, Harvard University. The front range of the Rocky Mountains in Colorado, now easily accessible by various railroad lines which enter and cross it from Denver and Colorado Springs, is an unusually fine example of a mountain highland, which in a former cycle of erosion was reduced to moderate relief, and since elevation to its present altitude has been submaturely dissected by its streams. The highland is surmounted by numerous hills and mountains of from 500 to 2500 feet relief, which represent the unconsumed residuals of the former cycle of erosion, and therefore presumably consist of the most resistant rocks of the region. The uplift of the mountain belt to its present altitude was not perfectly uniform, but arched gently from the plains westward; thus the crest of the range seems to correspond to the crest of the arched uplift. A notable feaure of the higher valley heads, among the surmounting mountains near the range crest, is the occurrence of numerous amphitheatres or cirques, and over-deepened valley troughs, the work of glaciers which for a moderate time, as geological time is reckoned, replaced the water streams in the highest districts. The contrast between forms due to ordinary or normal erosional processes and to glacial erosion is thus displayed with unusual clearness.

Astronomy.

An important astrophysical paper was presented on the solar constants of radiation, by Mr. C. G. Abbot, director of the Astrophysical Observatory, Smithsonian Institution, Washington. If we had no eyes we should still know of the sun by the feeling of warmth. The most exact measurements of the intensity of the rays of the sun, whether they be visible to the eye or affect the photographic plate or not, are made by an electrical thermometer called the bolometer. This instrument is so sensitive that a millionth part of a degree change of temperature is recorded by it. For seven years the bolometer has been used by the staff of the Astrophysical Observatory of the Smithsonian Institution to measure the solar constant of radiation. This constant represents the number of degrees (centigrade) which 1 gram of water would rise in temperature if all the solar radiation which could pass through an opening 1 centimetre square outside the earth's atmosphere, but at the earth's mean distance from the sun, could be used for one minute to heat the water. As all life, and almost all forces on the earth, depend on the supply of solar rays, the solar constant of radiation is at least equal in importance to the knowledge of the sun's distance.

The value of the solar constant was unknown within wide limits only five years ago. It is now believed to be within 1 per cent. of 1·93 calories per square centimetre per minute. Measurements made at Washington (sea-level), Mount Wilson (1 mile elevation), and Mount Whitney (nearly 3 miles elevation) agree in fixing this conclusion.

Nearly 500 determinations have been made. They indicate that the value is not really a "constant," but fluctuates about the mean just given within a range of 8 per cent. This conclusion means that the sun is a variable star. It is hoped soon to verify it completely, and it may prove for meteorology hardly less important than the determination of the mean value of the solar constant itself.

On the evening of April 21 Prof. Arrhenius, of Stockholm, gave an illustrated lecture on the physical conditions of the planet Mars. He directed attention to the many similarities between Mars and the earth which have caused some to think that Mars is inhabited, but gave it as his opinion that later investigations are not favourable to this view.

At the executive session on Saturday, April 22, the following new members were elected:—*Residents of the United States:* Dr. G. A. Barton, Bryn Mawr, Pa.; Dr. B. B. Boltwood, New Haven, Conn.; Dr. Lewis Boss, Albany, N.Y.; Dr. J. M. Clarke, Albany, N.Y.; Dr. W. M. Late Coplin, Philadelphia; Dr. J. Dewey, New York City; Dr. L. O. Howard, Washington, D.C.; Dr. J. P. Iddings, Chicago; Mr. Alba B. Johnson, Rosemont, Pa.; Dr. A. A. Noyes, Boston; Dr. G. H. Parker, Cambridge, Mass.; Mr. A. Lawrence Rotch, Boston; Dr. L. S. Rowe, Philadelphia; Dr. William T. Sedgwick, Brookline, Mass.; and Dr. A. Trowbridge, Princeton, N.J. *Foreign residents:* Prof. Svante Auguste Arrhenius, Stockholm; Prof. J. B. E. Bornet, Paris; and Sir John Murray, K.C.B., F.R.S., Edinburgh.

As has been customary, the meetings ended with a banquet at the Bellevue, Stratford, on Saturday evening, at which the following toasts were responded to:—"The Memory of Franklin," by President Schurman, of Cornell; "Our Universities," by Count von Bernstorff and President Hadley, of Yale; "Our Sister Societies," by Sir John Murray and Prof. W. M. Davis, of Harvard; and "The American Philosophical Society," by Prof. E. C. Pickering, of Harvard. Thus ended one of the most successful meetings in the history of the society.

ARTHUR W. GOODSPEED.

PHOTOGRAPHY AN AID TO ASTRONOMY.[1]

IN my address last year I endeavoured to put before you some of the problems which confronted the astronomer, and to illustrate the reasons why the most refined methods of physical measurement available were necessary in order to secure data for the solution of such problems. To-day I propose to deal rather with the methods in use, and the progress which has been, and is being, made in securing the necessary data for discussion, and in particular to sketch to you the advances which have been rendered possible through the introduction of photography as an aid. In these days, when portable hand cameras are accessible to everyone, when photographs can be taken by the mere expedient of pressing a button, leaving the manufacturers who supply the material to "do all the rest" at a trifling cost, or when even the processes of development can be performed by an inexperienced operator without the aid of any more elaborate equipment than a supply of fresh water, one is apt to forget how recent is the development of photography, not merely as a science or art in itself, but still more as a useful adjunct to almost every other branch of scientific investigation.

To appreciate the use of photography, try to imagine, if you can, a state of existence deprived of the sense of sight, not only in the individual, but throughout the human race. The phenomenon of light could doubtless still exist, and even be capable of exerting certain physiological action, but this phenomenon is one with which we are primarily cognisant through the direct physiological action on the optical nerves, and without which the intercourse of the individual with the external world is, perhaps, limited by the further senses of "sound," "touch," "smell," and "taste." All these senses, even including the first, are brought into operation only by closely adjacent surroundings, whereas the additional sense of sight, apart from its use as a means of communication between individuals, is the sole remaining sense by which we can obtain information regarding unexplored and otherwise inaccessible regions. I venture to doubt whether, under such conditions, the human intellect would have

[1] Presidential address delivered before the Royal Society of South Africa on April 19, by Mr. S. S. Hough, F.R.S.

risen to such primary conceptions as that of a "point" and a "line," let alone a "straight line," and whether even the most primitive of the sciences—that of geometry—could have originated, though, perhaps, a sense of geometrical form might have been developed through the touch. Be that as it may, however, it is perhaps not too much to say that our knowledge of the extra-terrestrial universe has at least until recently been derived solely through the medium of those æthereal vibrations which we call light, to which our eyes respond, thus communicating with the brain, and though this physical phenomenon might conceivably have existed apart from the existence of human or other eyes, its existence could scarcely have been recognised, and the science of astronomy, which deals primarily with extra-terrestrial phenomena, could hardly have been. Thus it is that the development of this science has been largely concurrent with the development of those instruments by which the optical efficiency of the eye has been increased. The earliest observations were made with the unaided eye, the results of which have come down to us, being duly recorded either in the form of descriptions or drawings, or even, in some cases, by more or less exact measurements. The introduction of the telescope not only immediately opened up fields of vision previously inaccessible, but facilitated in a very marked degree the precision with which measurements could be made, and for about three centuries the telescope has been used as a direct aid to the visual organ. It is improbable that this method of observation will ever be superseded, but there is to-day a growing tendency to replace the human eye at the end of the telescope by the photographic camera.

The advantages of the method are two-fold:—(1) objects which are too faint to be seen with the eye may yet be photographed by a sufficient extension of the time of exposure, and our powers of penetrating the confines of space is thereby increased; (2) the photographs themselves form a permanent record of what is seen more trustworthy than can be obtained from any drawing or description executed at the hands of man. The early application of the art of photography to astronomy related to the subject from its descriptive aspect rather than to those branches of the science which depend on exact measurement. With the aid of reflecting telescopes of large aperture, it was found possible to delineate with certainty the forms of vast nebulæ, so as to establish with great nicety the extension of their convolutions into regions where to the eye alone their traces were quite invisible, even with the aid of powerful telescopes. But, fascinating as these photographs are in aspect, valuable as they are as early records, and suggestive as they are with regard to the cosmical significance of the objects photographed, it can scarcely be maintained that they have so far been prolific in scientific results. Such phenomena as the wonderful spiral forms assumed by many of the nebulæ, though proved to be far more common than was previously realised, remain as obscure as ever in their origin. In making this statement, I do not wish to underrate the work of the earlier pioneers in astronomical photography. They have developed methods which we continue to use, and have but little to improve on, and they are not to be blamed if the full value of their work has not been attained in their own generation. Visual work had already been carried so far that the extended vision afforded by photography could hardly have been expected to lead instantaneously to any new and startling phenomenon which should revolutionise existing ideas of the extra-terrestrial universe. It is only as time lapses, and we are able to study the changes which are taking place since these photographs were secured—changes which, as a rule, take place so exceedingly slowly as not yet to be fully established—that the full advantage of the new method over the old will be realised.

The earliest attempts at the photography of celestial objects seems to date back so far as the year 1840, when photographs of the moon were obtained by daguerreotype processes, but beyond its use for pictorial representation—to which, perhaps, I might add the daily photographic record of the sun's surface, instituted at Greenwich in 1873, the unsuccessful attempts by Pritchard at the instigation of Warren de la Rue to utilise it for the determination of the constant of nutation—for a long time it seems to have been regarded with suspicion for purposes requiring the use of exact measurements. While photography might supplant the astronomical draughtsman, its limitations were in other respects similar to those affecting the draughtsman's art and skill. The latter aspects of its uses are those which I propose chiefly to deal with tonight, not that I wish to underrate the importance of other applications, but that I prefer rather to confine myself to those branches with which I have myself been more directly concerned. The year 1882 saw the first introduction of astronomical photography into the Cape Observatory. No special appliances for the purposes were at the time included in its equipment, but the unexpected appearance of the great comet of that year demanded that an effort should be made to secure a representation of this comet by photographic methods, which had been vigorously developed elsewhere for such purposes. Accordingly, the services of a local photographer were secured, and in order to obtain a sufficiently long exposure to bring out the faint detail of the comet's tail, his camera was attached to one of the equatorial telescopes of the observatory, so that it might partake of the motion imparted to the telescope, and thus be kept pointed on the comet for a prolonged interval. Valuable photographs showing much detail of the structure of the comet were obtained, but the feature to which particular attention was directed was the large number of stars, some of them extremely faint, which, besides the comet, were all duly recorded on the plate. Moreover, the sharpness of the photographic images suggested that they would permit of very accurate measurement, and that, if only similar definition could be obtained in photographs on a more open scale, it might be possible to replace many of the laborious methods of measurement hitherto conducted by direct visual observations on the sky itself by somewhat similar methods applied to the photographs.

There existed at the time no comprehensive survey of the southern skies. A complete catalogue of the stars in the northern heavens, known as the Bonn "Durchmusterung," giving the positions and magnitude of all stars down to the ninth visual magnitude, with a precision at least accurate enough to ensure their identification in the sky, had been formed by Argelander, and extended to a portion of the southern hemisphere by his successor, Schönfeld, but the remainder of the heavens from 23° S. declination to the South Pole was still comparatively unknown. The photographs I have above referred to suggested a means by which this lacuna might be filled, and no sooner was this idea conceived by Sir David Gill than steps were taken to put it into active execution. Partly at his own personal expense, and partly by means of assistance from the Government Grant Fund, administered by the Royal Society of London, the necessary equipment and the services of a photographer were secured, and between the years 1885–9 a complete series of photographs of the region extending from 18° S. declination to the South Pole was obtained. In order, however, that these photographs might be of value to science, it was necessary that the facts duly recorded on them should be minutely examined and rendered accessible to astronomers generally, in the form of a catalogue. As more than 400,000 stars were involved, this in itself was no light task, and might well give rise to the question as to whether the necessary measurements could not be more advantageously made on the sky rather than on the photographic plates by which it was represented. The method which was subsequently adopted for the formation of this catalogue forms sufficient answer to this question. The resources of the observatory were unequal to so large an undertaking, at least without the cessation of a large proportion of its normal work, and it appeared probable that the photographs would have to remain in the record room of the observatory, valuable for consultation regarding specific points which might arise, but that their complete discussion would have to be relegated to a perhaps remote future. The difficulty was at this juncture met by a generous offer received from Prof. Kapteyn, of Gröningen. Prof. Kapteyn was himself an enthusiastic astronomer, eagerly desirous of devoting himself to work of this character, with full appreciation of its value, but unfortunately unprovided with an observatory equipment. He foresaw that, with the aid of a comparatively small laboratory equipment,

much of the work of a character which had hitherto been performed by reference to the sky could be effectively and rapidly carried out through the medium of photographic representations thereof. The series of photographs secured at the Cape formed a promising field for research, and he voluntarily undertook the laborious task of the measurement of these plates and the preparation of a catalogue, which has since been issued among the publications of the Cape Observatory, and to-day is in constant use by astronomers concerned with the southern hemisphere. Besides many incidental results of high interest, the catalogue forms the basis for statistical investigations of stellar distribution, &c.

The success of the project, even in the early stages of its execution, pointed to the possibilities of a still more extended use of the photographic methods, and gave a direct stimulus to the study of the details by which its efficiency could be increased. The surveys of Argelander and Schönfeld, completed by the "Cape Photographic Durchmusterung" (as the above catalogue is entitled), and independently by a visual "Durchmusterung" emanating from the observatory at Cordoba, under the direction of Dr. Thome, could but be regarded as preliminary pioneer surveys; but, stupendous as the task seemed, the possibility was recognised by Sir David Gill of utilising the photographic method for the production of a complete map of the heavens, which should be on a sufficiently large scale and sufficiently precise in its detail to meet all the requirements of modern astronomy of precision. He succeeded in securing the interest of astronomers generally, and in particular of Admiral Mouchez, the then director of the Paris Observatory, at whose instance, with the support of the Paris Academy of Sciences, an international conference of astronomers was invited to meet in Paris in 1887 to discuss the possibility and desirability of carrying out this extended project. While the plan in outline met with universal acceptance, much useful discussion took place at this and at subsequent conferences as to the details of its execution, such as the type of instrument to be employed, the scale of the photographs, the duration of exposure which would serve to bring out what should be considered essential detail, &c. The outcome was that an agreement was arrived at by which the execution of the work was partitioned among eighteen cooperating observatories, who between them undertook to secure photographs of the whole sky with instruments of similar dimensions and design, and, so far as possible, similar conditions of exposure. Two series of photographs were to be taken, one of long exposure, designed for direct photographic reproduction to form an atlas which should show all stars down to the fourteenth visual magnitude, and a second series, of shorter length of exposure, designed for exact measurement, which would form the basis of a catalogue of precision of all stars to the eleventh magnitude. Minor details were largely left to the discretion of the directors of the cooperating observatories.

It would take too long to describe in detail the progress of this work from its initiation, and I propose, therefore, to confine my attention to the share in it which has been taken by the observatory over which I have the honour to preside, a share which, partly from the origin of the project and partly from the scarcity of suitably situated observatories of a sufficiently permanent character in the southern hemisphere able to offer cooperation, has exceeded that assigned to any other single establishment. The type of instrument agreed upon was the photographic refractor, similar in dimensions to that which has been used by the Brothers Henry in Paris, giving pictures on such a scale that 1 millimetre on the plate corresponds with a minute of arc on the sky. The plates were to be 160 mm. square, so as, apart from the marginal edges, to yield an effective field of views of two degrees square. The area covered by each plate will perhaps be better presented to you by the statement that the length of the edge of the plate corresponds, roughly, with four times the apparent diameter of the sun or moon, *i.e.* four suns and four moons photographed side by side on the same plate would just reach from one edge of the plate to the other. On this scale it would require rather more than 10,000 plates to cover the whole sky. The programme, however, provided not merely for the photographing of each region once, and once only, but that the various regions covered by the separate photographs should overlap in such a way that every star would be contained in two of the regions at least. Thus any doubtful features shown in one plate could be verified by reference to the second plate, which includes the same area. This requirement raised the total number of separate regions to be photographed to 22,054, of which 1512 were assigned to the Cape Observatory. The construction of the telescope and the provision of suitable housing accommodation was sanctioned in 1888, and the telescope arrived at the Cape in 1890. About two years were spent in its erection, adjustment, and testing, the delay being largely due to the necessity for returning the object-glass for necessary alterations and the remodelling of the breech-piece, which could not be effected locally. From July, 1902, onward, the work of taking the photographs was steadily proceeded with until its completion in 1910. At the present time we have stored at the Cape three almost complete series of photographs of the 1512 regions, besides many duplicates and triplicates, which, though not attaining the desired standard of perfection, are still available for reference with regard to many issues that arise. Of these plates, one series of long exposure is destined for direct photographic reproduction; the other two series of shorter duration of exposure for measurement for the purposes of the catalogue. On account of the comparatively insignificant amount of work involved in taking these catalogue plates as compared with the more laborious work of measurement, after its original completion in 1896 it was decided to repeat the whole series of catalogue plates, so as to bring the dates of the photographs nearer to the epoch 1900, and thereby more fully attain the ideal before the International Conference of leaving for a future generation as exact a record as possible of the appearance of the heavens at the beginning of the twentieth century.

After some early experiments with the view of ascertaining the most economical means by which these plates might be measured with the desired accuracy, the definitive programme of measurement was commenced in 1897, and completed last year. The number of stars measured on a plate varies between 45 and 3431, the total number of star images which have been measured exceeding a million. To illustrate the precision attained, the discordances in the position of a star, relatively to the stars immediately surrounding it, as derived independently from the measures made on two overlapping plates, but rarely amount to so much as a second of arc, *i.e.* apparent angular distance between the two edges of a halfpenny at a distance of about three miles from the observer. Now, however exactly the measurable features of each plate may be determined, it will be clear that the information thus derived can be of little value without some external data to enable the identification of the region on the photograph with the corresponding region of the sky from which it is derived. A plan of this room might have been useful to enable you to find your seats to-night in positions corresponding to the numbers on your tickets, but I venture to think a stranger visiting Cape Town for the first time would prefer to have been provided with a map of the town, which would indicate the position of this hall, rather than to have to search the town for a room arranged according to such a plan. So with our photographs, the detailed study of each photograph can be of minor value without some indications enabling us to identify the field shown on the photograph, not only in relation to the surrounding fields, but in relation to the sky as a whole. It is certainly a desideratum that these indications should be not less precise than those involved in the measures themselves. Of course, if each photograph contained some familiar group of stars, such, for instance, as the constellation Orion, the identity of the region could not be easily mistaken; but the scale of which the plates are taken is such that two such familiar stars are rarely to be found within the limits of a single plate, while many plates are devoid of stars to which accurate positions could have been previously assigned.

The necessity has thus arisen of determining with high accuracy the absolute positions as opposed to the relative positions indicated by the plate itself, or at least two stars contained on each plate. The distance between the

images of these stars as compared with the corresponding apparent distance on the sky serves to furnish a determination of the scale of the plate, while the direction of the line joining them serves to fix the orientation of the plate, *i.e.* enables us to turn the plate round in its own plane, so that the true N. and S. line may be placed exactly in a truly horizontal, truly vertical, or, in fact, any other desired direction. With these quantities correctly assigned, either star will be sufficient to correlate the plate exactly with the sky. In practice it is customary to refer to a larger number of stars than two on each plate. Not only are the determination of these necessary "plate constants" strengthened thereby, but in the consistency with which the photographic pictures reproduce the actual distribution of the stars, we have a valuable check on our methods and a test of the faithfulness with which also other features on the sky are represented on the photographs. For the Cape plates, the determination of the "plate constants," *i.e.* of those elements which serve, as it were, for the coordination of the isolated maps contained on each plate with a general map of the whole, has been made to depend on a number of stars on each plate varying, as a rule, between 8 and 12. In all, 8560 stars, so far as possible evenly distributed over the whole of the zone, were selected as comparison stars. These stars constitute a framework to which the detailed results derived from the photographs may be attached, but the structure of which requires to be independently built up. For such a purpose, photographic methods have not as yet proved available, and recourse was necessary to the older method of visual observing with the meridian circle. From observations made in the years 1897–1900 with the transit circle an accurate catalogue of these 8560 stars has now been formed, and has been utilised for the purpose of standardising each of our plates. The heavy arithmetical work involved in applying to each of our original measures more than two millions in number, the derived correction to refer the whole to a common standard is now rapidly proceeding, and at the present time is about half completed.

I have above referred to the catalogue of 8560 comparison stars as framework for the support of the more extensive photographic catalogue. Such a framework, at least on the basis on which the one was constructed, is not entirely self-supporting, and it thus behoves us to carefully consider its foundations and to ensure that they possess the necessary solidarity. Not the least of the important questions brought up for discussion at the last meeting of the International Committee charged with the conduct of the photographic work was that of the steps to be taken for this purpose. It was recognised on all sides that even the best existing meridian catalogues were inadequate, and that they would have to be supplemented by extensive additional observations. The main object of the discussion was to secure the most extensive cooperation from observatories provided with suitable meridian equipment, and to classify the work in various grades of accuracy, so that each establishment might devote itself primarily to that branch for which its equipment was best adapted, at the same time keeping in view the coordination of its work with the larger scheme. The resolutions adopted have since been favourably received by meridian observers, and we may look in the future to a systematic organisation of meridian astronomy throughout the world, the results of which, apart from the mere economic aspect, cannot fail to be of the highest importance to science. It may well be asked, What is the use of such a chart as you have been describing? or, Will it repay the enormous cost involved in compiling it? As regards its use, I endeavoured to indicate in my address last year some of the problems which awaited solution, and which serve to inspire the astronomer in conduct of the lengthy routine operations involved. These motives are, perhaps, for the most part scientific and intellectual rather than utilitarian, and it is possible, even probable, that to many of the questions arising answers which will afford complete satisfaction will not be forthcoming at least for a generation or two to come. I think I am sufficiently voicing the view of those who took part in the original discussions at Paris when I state that they, as a body, attached greater importance to the complete and thorough systematic record of the phenomena prevailing during their own generation than to the immediate interpretation of these phenomena. It was felt to be a scientific duty, incumbent on them to provide, so far as lay within their means and capacity, data which should be beyond reproach. By this means they were preparing the ground and planting the seed, which they hoped would yield a rich crop of scientific results, even though it should remain for their children's children to reap the harvest.

Much has already been attained. The ghosts which beset the use of photography in relation to the science of exact measurement have in a large measure been laid, and photographic methods have now been successfully used for some of the most delicate measurements ever attempted even by direct visual operation. I have in mind such questions as the determination of the distance of annual parallaxes of the fixed stars, and of the parallax of the sun, in connection with which, under the auspices of the Paris conference, an extensive photographic campaign, combined with visual methods, was undertaken on the occasion of the near approach of the planet Eros in the years 1900–1. The discovery of the latter planet was itself a product of photography, while by similar means the number of known minor planets has within the last few years increased by leaps and bounds, until at the present day they are nearly seven hundred in number. Photography has also been prolific in the discovery of variable stars and new stars, and the tracing of their light changes. All these purposes will be greatly facilitated by the existence of a trustworthy chart or catalogue containing more especially the fainter stars about which our exact knowledge hitherto has been almost non-existent. Time must elapse before we may expect to be able to evaluate with any certainty the slow changes of position due to the proper motion, at least, in relation to the previously uncatalogued faint stars; but this is to-day one of the greatest desiderata for the advancement of our knowledge of the universe, and is one of the purposes for which the photographic catalogue was primarily intended. By photographic methods and by cooperative effort throughout the world alone has it been possible to collect evidence on a sufficiently wholesale scale, so that already we are beginning to feel the solution of some of the most profound problems relating to the universe almost within our grasp.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Public Orator, Dr. Sandys, spoke as follows in presenting for the degree of Doctor in Science, *honoris causa*, (1) Dr. G. E. Hale, director of the Solar Observatory on Mount Wilson, California, and (2) Prof. T. W. Richards, professor of chemistry in Harvard University:—

(1) Adest vir in republica maxima transmarina caeli in orbibus observandis iam per annos plurimos maximo cum fructu exercitatus, qui Californiae sub caelo sereno, montis Wilsonii in vertice excelso, instrumentis novis adhibitis, solis ipsius materiem exquisivit et stellarum remotissimarum mutationes investigavit. Rerum caelestium auguri tam perspicaci stellarum ipsas origines nebularum (ut aiunt) formae obscurae illustrant; stellae autem colore primum candido, deinde flavo, denique rubro coruscantes, orbium illorum vitam per seriem exorientem, maturescentem, deficientem indicant; orbis denique terrarum noster quasi imago stellae est ex qua lumen calorque iam dudum evanuerunt. Newtoni nostri in Opticis dicitur in montibus summis, supra nubes densiores, in aëre maxime sereno et tranquillo, stellas melius posse observari:[1] gratulamur auguri nostro caelesti quod Californiae in monte altissimo arcem nactus est, caelo observando tam opportunam, unde orbis terrarum incolis vallium et camporum in obscuritate degentibus rerum naturae lucem ipsam possit desuper transmittere. Viro tot titulis aliunde cumulato, etiam nostram coronam libenter donamus.

Duco ad vos astronomum insignem, Georgium Ellery Hale.

(2) Filiam suam, aequore Atlantico a se divisam, studiorum communium amore coniunctam, mater alma

[1] Newton's "Optics," Book I., part i., *ad finem*.

Cantabrigiensis non sine superbia quadam contemplatur. Ergo matris almae nomine scientiae chemicae professorem Harvardianum non sine gaudio salutamus, virum et inter suos et inter Germanos doctrinae in sedibus sex praeclaris educatum. Quod si Latino potissimum in sermone de meritis eius vultis admoneri, videor mihi "propter egestatem linguae et rerum novitatem"[1] rem admodum difficilem ingredi. Peritis tamen comprobavit, sese, in rerum elementis fere quindecim, atomorum pondera ipsum comperisse, atque discipulis suis primordiorum tam minutorum subtilissime examinandorum exemplum praetulisse viamque ostendisse. Idem primus indicavit, elementi cuiusque in atomo quo minor vis insit, eo artius elementum illud comprimi posse. Idem etiam metallorum in provincia, computationibus usus accuratissimis, Faradii legem quandam praeclare confirmavit. Academiae nostrae, scientiarum accuratarum cultrici tam assiduae, pro certo novimus rerum exploratorem tam accuratum perquam esse cordi.

Duco ad vos scientiae chemicae professorem accuratissimum, Theodorum Willelmum Richards.

The general board of studies has reappointed the following university lecturers from October 1, 1911, until September 30, 1916, and the appointments have been confirmed by the special boards with which they are connected:—Botany, A. G. Tansley; mathematics, H. W. Richmond and R. A. Herman; pathology, Dr. Cobbett.

Dr. James, Provost of King's College, has been nominated to represent the University at Rennes on the occasion of the inauguration, in October, of new university buildings and of a monument commemorative of the union of Brittany with France.

The board of managers gives notice that an Arnold Gerstenberg studentship will be offered for competition in the Michaelmas term of 1912. The competition will be open to men and women who have obtained honours in part i. or part ii. of the natural sciences tripos, and whose first term of residence was not earlier than the Michaelmas term of 1906.

GLASGOW.—Captain Lyons, F.R.S., has announced his resignation of the University lectureship in geography, on his removal to London to take up his duties at the Royal Geographical Society. He has succeeded in establishing a flourishing department at the University, where geography is now recognised as a subject for the M.A. and for the B.Sc. degree. The University Court will proceed to make an appointment to the office during the summer.

Prof. R. A. Stewart Macalister, of Dublin, has been appointed Dalrymple lecturer in archæology for the ensuing academical year.

A scheme for the affiliation to the University of the Glasgow and West of Scotland Technical College has received the approval of the Scottish Universities Committee of the Privy Council. Ordinances for the purpose of carrying the scheme into effect and admitting the students of the college to university privileges and degrees will now be framed and laid before Parliament in due course.

The Royal Infirmary of Glasgow has received a new charter, which, *inter alia*, provides for the representation of the Court and Senate of the University on its board of management. From the University side an ordinance has been promoted, and now awaits the approval of his Majesty in Council, which establishes four new professorships at the Royal Infirmary, namely, in medicine, surgery, obstetrics, and pathology. The existing (regius) chairs in these subjects continue to be connected with the Western Infirmary. Both institutions, which between them contain about 1200 beds and well-equipped extern departments, will thus have equal rank as the clinical schools of the University. All the instruction provided at the Royal Infirmary will be open to women students of the University on the same terms as to men. A new clinical laboratory for study and research has been erected at the Western, to which a director will presently be appointed. A pathological institute on a large scale, including a clinical laboratory, is approaching completion at the Royal; and by the gift of an anonymous benefactor, a similar building is in progress at the Victoria Infirmary, which will also be available for university students. The medical school of Glasgow is becoming one of the best equipped in the country, especially as regards its provision for scientific teaching and investigation.

[1] Lucretius, i. 139.

OXFORD.—On Tuesday, June 13, another stage was reached in the discussion of the proposed statute exempting students of natural science and mathematics from compulsory Greek. An amendment prohibiting exempted candidates from offering themselves in any other final honour school except these two was carried by 93 to 36. A further amendment, moved by the Master of Balliol, which sought to limit the exemption to candidates who should obtain certain qualifications before entering the University, was rejected by 105 to 39. The statute as amended will now be submitted to Congregation, and if it passes will come before Convocation for final decision.

Prof. John Milne, F.R.S., has been appointed Halley lecturer for 1912.

WE learn from *Science* that Mr. T. C. Du Pont has given 100,000*l.* to the Massachusetts Institute of Technology toward its proposed new site. Announcement is also made of two bequests of about this amount. A trust fund of between 100,000*l.* and 120,000*l.*, created by Mr. Francis B. Greene some five years ago, will be received by the institute for the assistance of students, and it will receive nearly 100,000*l.* from the bequest of Mrs. Emma Rogers, widow of the first president of the institute. These large gifts, in addition to the 20,000*l.* for ten years voted by the State, will make it possible for the institute to purchase a new site and erect the necessary buildings. From the same source we learn that, by the will of Mrs. Lydia A. Barnard, of Milton, Mass., Radcliffe College receives 23,000*l.* and Harvard University 12,000*l.*

THE fourteenth annual Conference of the National Head Teachers' Association was held in Manchester last week. The association adopted a resolution to the effect that no exemption should be allowed from school attendance until the age of fourteen has been reached; that there be compulsory attendance at continuation schools from the age of fourteen to seventeen; that a well-devised scheme of physical development of young people should form part of the curriculum of every continuation school; that it be the statutory duty of every local education authority to make suitable provision for the carrying on of such continuation schools in its area as may be necessary; that the Government provide suitable grants for this purpose; and that it should be the statutory duty of employers of young persons under seventeen to enable them to attend continuation classes at such hours as may be required by the Act.

THE Department of Agriculture and Technical Instruction for Ireland would appear to have adopted the view that geography is a science, and should be taught as such in schools. For the session 1911–12 a course of physical and commercial geography will form one of the subjects of experimental science which may be taken up in Irish intermediate schools. Anticipating the difficulty which principals of schools may experience in finding teachers competent to deal with geography in a scientific manner, the Department is arranging for a summer course of instruction in the subject, to be held, from July 4 to 28, at the Royal College of Science, Dublin, for teachers who have already qualified themselves in elementary experimental science. The Department has circulated an outline syllabus in physical and commercial geography suitable for pupils in their third and fourth years. The work for the former year includes a practical study of the geography of the home district; the figure, motions, and position of the earth; the atmosphere; the land; and the general geography of Ireland. The fourth year's work comprises the physical geography of the sea and a course of commercial geography of a general kind.

THE second volume of the report of the U.S. Commissioner of Education for the year which ended on June 30, 1910, is now available. The 746 pages are devoted almost exclusively to statistics, which supplement in an admirable manner the descriptive articles in the previous volume, already noticed in these columns.

During the year under review, the Bureau of Education at Washington received reports from 602 universities, colleges, and technological schools in the United States. Of these, 142 are for men only and 352 for both sexes. The entire teaching force of these 602 institutions of higher education numbered 27,279. The aggregate enrolment of students reached 301,818, including students in all departments—preparatory, collegiate, graduate, and professional. The aggregate of gifts and bequests reported by the 602 institutions for the year 1909–10 was 3,747,430*l*. Of this amount, 1,228,700*l*. was given for buildings and improvements, 1,954,200*l*. for endowment, and the remainder for current expenses. The largest amounts were received by the following institutions:—Columbia University New York, 409,000*l*.; Yale University, Connecticut, 403,000*l*.; Princeton University, New Jersey, 342,000*l*.; University of California, 248,000*l*.; University of Chicago, Illinois, 239,000*l*.; and Bryn Mawr College, Pennsylvania, 142,000*l*. Twenty-seven institutions altogether each received 20,000*l*. or more during the year.

THE report for the year 1910 of the council to the members of the City and Guilds of London Institute is now available. During the year a petition was made to the King for a supplemental charter to enable the institute to cooperate more effectively with other bodies in the coordination of technological work, more especially in the metropolis, and on December 16, 1910, the supplemental charter was granted, and its provisions are printed in the report. The Imperial College of Science and Technology has obtained from the Commissioners of the Exhibition of 1851 a grant of a large piece of land at South Kensington, on part of which a building is being erected which will eventually be added to the Central Technical College, and will with that college form the engineering section of the Imperial College. The enlarged college, towards the cost of which the Goldsmiths' Company has made a grant of 50,000*l*., will be known as "The City and Guilds College" (Engineering), thus perpetuating the connection of the institute with the engineering work in London. Among other matters, it may be noted that the course in railway engineering for post-graduate and other duly qualified students, organised by the college in 1908–9 in connection with the Imperial College of Science and Technology, has been continued and considerably enlarged. Reports are included also of the year's work at the City and Guilds Technical College, Finsbury, the South London School of Technical Art, and the Department of Technology.

IN a suggestive article on "Scientific *versus* Personal Distribution of College Credits" (*Popular Science Monthly* for April), President William T. Foster, of Reed College, Portland, Oregon, directs attention to the want of a uniform standard in the classification of students in different subjects in American universities and colleges, but his criticisms are equally applicable to similar institutions on this side of the Atlantic. Adopting the system of grading students in five classes, of which four represent a pass and the fifth represents failure, the author tabulates for several colleges the percentages of students receiving the several grades in different departments, and the numbers show very large discrepancies. Thus in Harvard College in one year the percentage of students in the highest grade varied from 1 per cent. in English to 35 in Greek; in the second grade from 11 per cent. in English to 33 per cent. in fine arts, and so forth. The result of these discrepancies is that the poorer students seek the courses which give the larger proportions of high grades. The author points out that to all students who are prompted by unworthy motives his charts indicate the easiest way to a degree; moreover, it is useless to suppress such information, as students in all colleges are guided by such charts more or less accurately plotted. In the University of Missouri, on the other hand, a system has been introduced of equalising for different departments the percentages of students placed in the several classes, with the result that "we come nearer to knowing what a grade stands for at the University of Missouri than at any other institution in the country." For this purpose a normal distribution is adopted in which 25 per cent. of the students are in the first two classes, 50 per cent. in the middle class, and 25 per cent. in the fourth and fifth. The author suggests that instructors should be required to tabulate the actual distribution of grades in their departments each year, and that all marked divergences from the normal distribution should be made the subject of a special report.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society June 1.—Sir Archibald Geikie, K.C.B., president, in the chair.—Dr. R. **Kennedy**: Experiments on the restoration of paralysed muscles by means of nerve anastomosis. This communication is the first of three series of experiments on restoration of paralysed muscles by means of nerve anastomosis. The present series consists of ten experiments on monkeys and dogs, in which, after division of the facial nerve, the peripheral segment of the latter was attached to a neighbouring nerve. Sometimes the hypoglossal and sometimes the spinal accessory was the substitute. The experiments also varied in mode of uniting the nerves, and in interval of time elapsing between section of the facial and union with the substitute. Among the conclusions are the following:—Where spinal accessory or hypoglossal is substituted for facial nerve, restoration of voluntary co-ordinated movements of facial muscles is possible. Restoration commences sooner when the hypoglossal is used, although the ultimate results, so far as recovery of facial movements is concerned, do not appear to show much difference. On the other hand, the new paralysis produced temporarily or permanently in the distribution of the substitute nerve is more serious when the hypoglossal is employed. Where association movements are present in consequence of the anastomosis, these are more objectionable when the hypoglossal is used. As regards interval of time between section of the facial and performance of anastomosis, there is no decided difference in date of commencing recovery between immediate anastomosis and a secondary anastomosis after the lapse of one month. An addendum gives a report, twelve years after operation, of a case of spino-facial anastomosis published in Phil. Trans., 1901; also of a case of facial paralysis of three years' standing in which spino-facial anastomosis was done, and in which recovery commenced three years subsequently.—Sir David **Bruce**: The morphology of *Trypanosoma evansi* (Steel). In previous papers published in the Proceedings the morphology of various trypanosomes, such as *Trypanosoma pecorum*, *vivax*, *uniforme*, *nanum*, and *brucei*, has been described somewhat more fully than is usually done. It is proposed to do the same for *T. evansi* in this paper. This trypanosome causes the disease in elephants, camels, horses, cattle, and dogs known in India as surra. It was discovered in 1880 by Evans in the Punjab. It is curious that in India this is the only pathogenic trypanosome of the domestic animals which has up to the present been described. In Africa many species are known—in fact, here may be said to be the home of the trypanosome diseases. In Africa these diseases are associated with tsetse-flies. In India there are no tsetse-flies. The carrier of surra has not yet been identified. It is generally thought that surra has been introduced into Africa by means of the camel, but this is by no means established. Up to the present it has been usual to look upon the trypanosomes of surra and nagana as indistinguishable morphologically. In this paper 820 individuals of *T. evansi* have been carefully measured, and a curve representing the distribution in respect to length made. This curve is very different from that of *T. brucei*. It is therefore evident there should be no difficulty in future in separating these two species by this means. Again, on comparing the curve of the Indian camel disease with that of the African, the similarity is very striking, and affords some proof that the two diseases are caused by the same species of trypanosome.—H. S. **Stannus** and Dr. W. **Yorke**: The pathogenic agent in a case of human trypanosomiasis in Nyasaland. During the past three years a considerable number of cases of human trypanosomiasis have occurred in Nyasaland, notwith-

standing the fact that *Glossina palpalis* has not, as yet, been discovered in the Protectorate. The authors have examined the trypanosome obtained from the blood of a European infected in the Dowa sub-district of Nyasaland. The parasite was also examined in the blood of a monkey, rabbit, and goat infected from the patient. Morphologically the trypanosome was found to present the same peculiarity as was observed in the case of a trypanosome from a patient infected in the Luangwa Valley of north-east Rhodesia. This peculiarity consisted in the fact that amongst the short forms some have the nucleus at the posterior (non-flagellar) extremity. In a condition of heavy infection these posterior nuclear trypanosomes form from 2 to 5 per cent. of the total parasites present. A second interesting point in the morphology of this parasite is that the cytoplasma was frequently found to be vacuolated in a remarkable manner. Whether or not this is a constant feature we are unable to state from the small amount of material at our disposal. A monkey, rabbit, or goat inoculated with the parasite became infected, and in all the disease ran an acute course. As a result of their observations, the authors are of opinion that the trypanosome in question is not *T. gambiense*. On the other hand, it very closely resembles *T. rhodesiense*, and is probably identical with it. The disease was contracted in a district (Dowa sub-district of Angoniland) where *G. palpalis* has never been found, but where *G. morsitans* is known to exist in large numbers. It appears probable, therefore, that this trypanosome (*T. rhodesiense*) is a distinct species, capable of transmission by some other agent than *G. palpalis*, probably *G. morsitans*.—Captain R. **McCarrison**: The experimental transmission of goitre from man to animals.—Dr. Helen **Chambers** and Dr. S. **Russ**: The action of radium radiations upon some of the main constituents of normal blood. Experiments have been performed *in vitro* with the following results:—When blood is mixed with radium emanation hæmolysis occurs with gradual conversion of oxyhæmoglobin into met-hæmoglobin. The hæmolysis is a gradual process, and has been found to occur as a direct result of α radiation. Leucocytes show marked degenerative changes when exposed to α rays. During the process of clothing leucocytes appear to move away from a region radiated by α rays. This motion is not due to a direct action of the rays on the leucocytes, but has been attributed to changes found to occur in the surface tension of blood serum when radiated. The specific properties of opsonin and hæmolytic complement are lost when serum is exposed to α rays. The progressive changes caused by these rays indicate the separate identity of opsonin and complement. The β and γ rays have yielded negative results in analogous experiments.—F. L. **Usher** and J. H. **Priestley**: The mechanism of carbon assimilation.—Part iii. Details are given of further experiments supporting conclusions arrived at in parts i. and ii. of this series, as to the primary products of photolytic reduction of aqueous solution of carbon dioxide. By the use of other sources of energy, viz. (1) α and β rays from radium emanation and its products, and (2) the radiation from a quartz mercury vapour lamp, solutions of carbon dioxide have been decomposed with formation of small quantities of formaldehyde and hydrogen peroxide. The hydrogen peroxide formed was identified by the titanium sulphate reaction; the formaldehyde by Schryver's reaction. Further experiments with chlorophyll films are described, leading to the conclusion that bleaching of chlorophyll in sunlight, whether carbon dioxide is present or not, is due to formation of hydrogen peroxide; but the production of formaldehyde in such condition and quantities as to be recognisable by the use of Schiff's reagent seemed only to occur when carbon dioxide was present. Evolution of oxygen from green tissues in which the catalase has not been killed, and from gelatin films containing catalase over which a film of chlorophyll has been spread and exposed to light in an atmosphere containing carbon dioxide, has been established by further experiments. Qualitative tests for emission of oxygen have been made by methods involving the utilisation of Beijerinck's photo-bacteria; quantitative tests by the use of apparatus enabling very small quantities of oxygen to be measured. Further evidence that some of the energy supplied to a film of chlorophyll by sunlight is used in the photolytic reduction of carbon dioxide has been obtained by an experimental proof that such film in sunlight, in presence of carbon dioxide, is at a lower temperature than a similar film also in sunlight, but in air free from carbon dioxide. The paper concludes with brief replies to some criticisms upon the experimental evidence and conclusions recorded in parts i. and ii. of this series of papers.—T. **Goodey**: A contribution to our knowledge of the protozoa of the soil. The paper is an account of work carried out on the soil protozoa which are considered to be chiefly instrumental in limiting the activity of bacteria in the soil, and thus in helping to render the soil comparatively infertile. Methods of obtaining protozoa in cultures of soil are described, and a list of the different species found so far is given. An experimental method for quickly finding the earliest ciliated protozoa occurring in a soil culture is described, in which use is made of the galvanotactic response which many of the protozoa show when stimulated by means of a continuous electric current. By means of this method, active ciliated protozoa have been found in from 1½ hours to 4 hours. Experiments on the length of time required for a ciliated protozoon, *Colpoda cucullus*, to develop from its resting cysts have also been conducted in similar media and at the same temperature as used in the soil cultures. It has been found that the times required for development in both soil and cyst cultures are comparable, and that the first *C. cucullus* to occur in soil cultures are almost identical in appearance with those which emerge from resting cysts. The conclusion drawn from the experiments is that the ciliated protozoa are only present in the soil in the encysted condition, and do not, therefore, function as the factor limiting bacterial activity in the soil.—G. **Stead**: The anode and kathode spectra of various gases and vapours.

Geological Society, May 10.—Prof. W. W. Watts, F.R.S., president, in the chair.—Prof. E. J. **Garwood**: The Lower Carboniferous succession in the north-west of England. The area dealt with includes Westmorland north and west of the Dent Fault, North Lancashire to the north of the Lune Valley, and the northern corner of Yorkshire. The value of the zonal indices selected is discussed and their distribution described. Whereas the zonal indices chosen for the larger groups of beds are often sporadically distributed in the zone, the bands form remarkably trustworthy horizons, extending over large areas. In no one district is a complete development of all the zones observed, and only by taking a broad survey of the whole area can the detailed faunal sequence be established. In the Shap area the *Michelinia megastoma* zone is scarcely represented, while farther west the fauna of this horizon is one of the richest in the whole of the north-western province. The changes in the fauna of certain zones often depend more on the lithological characters of the rocks than on the introduction of new forms at definite horizons. The deposits are shown to be, for the most part, of shallow-water origin. The lowest deposits are characterised by highly magnesian limestones. The majority of the limestones throughout the series are rich in foraminifera, and the more shaly layers in ostracods and bryozoa. Both silicification and dolomitisation of the limestones were practically contemporaneous with the deposits in which they occur. The movements which have affected the rocks in the Arnside district have been the result of nearly horizontal thrusts, and it is shown by means of zoning that the beds have in places been inverted, and are dipping at more than 120°. The palæontological divisions are correlated with their probable equivalents in the Bristol area. Several new species of corals and one new genus are described, and the affinities of several corals and brachiopods are discussed.—Prof. S. H. **Reynolds** and Dr. A. **Vaughan**: The faunal and lithological sequence in the Carboniferous limestone (Avonian) of Burrington Combe, Somerset. Lithology.—The series is almost continuously calcareous from the base of Z to D_1, where the section ends; the K beds are, to a large extent, shales. Crinoids are the prevalent limestone-builders throughout K, Z, and C_1; in C_1 the rock is of the crinoidal type, known as *petit granit* by the Belgian geologists. A band of oolite occurs in the upper part of K_1. C_2 and

S_2 are very largely oolitic, conspicuous white oolite prevailing at the top of C_2. There is much oolite in the upper part of S_2. An important point is the prominent part played by foraminifera, which are the principal limestone-builders in C_2, S_1, and much of S_2. In the upper part of S_2, peculiar concretionary limestones, showing imperfect "Cotham-Marble" structure, occur. The Burrington section agrees with the other sections in showing dolomitisation in the upper C_1 beds.

Linnean Society, June 1.—Dr. D. H. Scott, F.R.S., president, in the chair.—Prof. W. A. **Herdman**: The recent occurrence (April) of the minute dinoflagellate *Amphidinium operculatum*, Clap. and Lachm., at Port Erin in the Isle of Man, in such profusion as to discolour the sand between tide-marks in patches extending on some days for many yards. *A. operculatum* has been recorded from several places on the coasts of Europe and America, but has apparently not been previously found in Britain.—Dr. A. Smith **Woodward**: The fauna of the Carboniferous period, so far as it has been discovered in the same deposits as the Carboniferous flora. The fauna agrees with the flora in consisting, for the most part, of highly specialised representatives of the lower groups, but is singularly modern in some respects. Some of the freshwater and land Mollusca are scarcely distinguishable from genera still existing. All the crustaceans are of primitive groups, and some of the most interesting are related to Anaspides, which still survives in Tasmania. The myriapods, scorpions, and spiders are similar to those of later date, but a few of the scorpions retain obvious remnants of the characters of their aquatic ancestors. Limuloids also occur. Insects are numerous, but all belong to the lower groups in which there is no complete metamorphosis, and there are many generalised types which can scarcely be referred to existing orders. Cockroaches are numerous, but have transparent fore-wings. Primitive dragon-flies occur, and some of these are the largest known insects, with a span of wings measuring 2 feet. Among fishes, the spiny acanthodian sharks, which are typically Lower Palæozoic, are still found in the Carboniferous fauna, and are known to have been preyed upon by the higher fishes. The pleuracanth sharks are characteristic of the period, and interesting as showing a more generalised vertebrate skeleton than any later fishes. The cochliodont sharks with grinding teeth appear to be closely related to the existing Cestracion, but have many of the teeth fused into extensive plates. Some of the sharp-toothed sharks also seem to have had their teeth fused into rigid masses. The highest fishes are the palæoniscids and platysomids, which exhibit all the fundamental characters of the present-day sturgeons, obscured beneath a normal covering of ganoid head-plates and scales. Large dipnoan fishes are numerous, and differ little from Ceratodus, except in showing traces of the separate points of which their dental plates are composed. Most important are the crossopterygian fishes, of which Rhizodus and Megalichthys are typical genera. These fishes make a closer approach to the earliest lung-breathers than any fishes which have existed before or since. Lung-breathers were certainly in existence just before the beginning of the Carboniferous period, and all seem to belong to a very primitive group of Amphibia, variously termed Stegocephalia or Labyrinthodontia in allusion to the complete roofing of their cheeks by bone and to the complicated structure of their teeth. In their possession of supra-temporal plates and often of post-temporal bones, as also in the marking of their superficial bones by the course of the slime-canals, these amphibians more closely resemble fishes than any later members of the order. Towards the end of the Carboniferous period some of the smaller Stegocephalia, the so-called Microsauria, seem to have passed into true reptiles very similar to the surviving Sphenodon or Hatteria.

Mathematical Society, June 8.—Dr. H. F. Baker, president, and temporarily Mr. J. E. Campbell, vice-president, in the chair.—Dr. H. F. **Baker**: The roots of multiple θ functions.—G. H. **Hardy**: The multiplication of Dirichlet's series.—G. H. **Hardy** and J. E. **Littlewood**: The range of Borel's method of summation of series.—Dr. W. H. **Young**: The convergence of Fourier series and of the allied series.—W. M. **Page**: Some two-dimensional problems in electrostatics and hydrodynamics.—Prof. W. **Burnside**: The determination of all groups of rational linear substitutions of finite order which contain the symmetric group in the variables.—Dr. W. H. **Young**: The nature of the successions formed by the coefficients of a Fourier series.—Lieut.-Colonel A. **Cunningham**: Note on Mersenne's numbers.—Prof. A. E. H. **Love** and Dr. T. J. I'A. **Bromwich**: The conditions that a homogeneous strain may be reducible to a plane strain and an extension at right angles to the plane.

CAMBRIDGE.

Philosophical Society, May 22.—Sir George Darwin, K.C.B., F.R.S., president, in the chair.—Prof. **Pope** and J. **Read**: Attempts to resolve asymmetric nitrogen compounds of low molecular weight.—Dr. **Fenton** and W. A. R. **Wilks**: "Aldehydo-glyceric" acid. All of the eleven possible direct oxidation products of glycerol are now known with the exception of tartronic dialdehyde, hydroxypyruvic aldehyde, and one other. The latter is either hydroxypyruvic acid or tartronic semi-aldehyde (aldehydo-glyceric acid). One of these is Wills's acid, which is obtained from nitro-cellulose by the action of alkalis, but, owing to the contradictory evidence of different observers, its constitution still remains uncertain. An acid having the same composition, but different properties, is formed by the oxidation of glyceric acid in presence of iron, and probably by the initial decomposition of dihydroxymaleic acid. The present authors have now succeeded in isolating this acid, and are making experiments with the view of establishing its constitution.—S. **Ruhemann**: Triketohydrindene hydrate.—J. E. **Purvis, McHattie,** and **Fisher**: The non-nitrification of sewage in sea water. Systematic chemical and bacterial investigations on the decomposition of sewage in sea water have been described in researches previously published. The results proved that sewage undergoes slow decomposition in sea water, and the primary cause appears to be the rapid destruction of the nitrifying organisms. To meet the criticism that the method of incubation partially eliminated the oxygen necessary for the growth of the nitrifying organisms, the authors have passed dry air, and containing no CO_2, through various mixtures of sewage and sea water for more than seven weeks. The mixtures were examined from time to time for the two ammonias and for nitrites and nitrates. Neither nitrites nor nitrates were found at any time, and the total ammonia was only slightly decreased. The results confirm the earlier researches, and that even when abundant oxygen is there no nitrification occurs in sewage when mixed with sea water.—H. O. **Jones** and C. S. **Robinson**: Complex thio-oxalates. Salts of nickel, cobalt, iron, and palladium form complexes with salts of dithio-oxalic acid, which show intense colours even in dilute solution. Several salts of nickelo-dithio-oxalic acid, $Ni(CSO)_4H_2$, with metals and organic bases, have been isolated, and also several salts of the corresponding palladio acid, $Pd(CSO)_4H_2$. The salts of the cobalt acid with metals and with organic bases correspond to the formula $Co(CSO)_6H_3$ for cobalti-dithio-oxalic acid.—J. A. **Crowther**: (1) Further experiments on scattered Röntgen radiation; (2) the energy of the scattered Röntgen radiation from different radiators. Experiments have been made to determine the relative amounts of Röntgen radiation scattered by equal masses of different substances. It has been found that the amount so scattered is not independent of the nature of the radiator, but increases with the atomic weight.—R. **Whiddington**: The production of characteristic Röntgen radiations.—A. Ll. **Hughes**: The velocities of the electrons produced by ultra-violet light.—F. **Horton**: (1) The origin of spectra; (2) the positive ionisation produced by phosphates when heated.

PARIS.

PROBLEMS OF POTABLE WATER.

Modern Methods of Water Purification. By J. Don and J. Chisholm. Pp. xvi+368. (London: Edward Arnold, 1911.) Price 15*s*. net.

WHEN Mr. Don read his paper on "The Filtration and Purification of Water for Public Supply" before the Institute of Mechanical Engineers in January, 1909, it was generally thought that a very useful addition had been made to the literature on this subject, and in following this up with the volume under review, which is in effect an amplification of the former publication, the authors have done a great service to those whose duty it is to provide a pure and efficient supply of water for domestic purposes.

Following a general introduction, the first chapter deals with the sources of supply. The possible pollutions that may be expected are fully discussed, and some most useful information is given of the best means of detecting, and, as far as may be, preventing them.

Obviously, all water destined for domestic purposes cannot be taken from sources unimpeachable, both as to purity and constancy of supply, and the next two chapters in the book deal with the first steps towards remedying these evils under the general heading of "Storage."

The main inference that is to be drawn from this section is that, in addition to ensuring constant and adequate supply from sources which depend largely on the rainfall over a limited catchment area, storage undoubtedly has a very marked effect in purifying and rendering harmless an otherwise polluted and dangerous water. The work of numerous investigators is quoted in support of this contention, particularly the valuable researches of Dr. Houston on the storage of water from the rivers Thames and Lea, published in his reports as Director of Water Examination to the Metropolitan Water Board.

The result of these researches are very lucidly summed up by the authors in the following sentences:—

"1. The microbes of disease, and those which are indicative of sewage (*B. coli*) perish rapidly in stored water. In about three weeks, generally speaking, the safety change is complete, and the dangers imminent from sewage pollution minimised.

"2. After being impounded for two or three weeks the water is in a better state from a chemical point of view, seeing that there is a well marked decrease of ordinary ammonia, oxygen consumed, oxidised nitrogen, lime salts, and occasionally of albuminoid nitrogen.

"3. Storage deprives the raw water of nearly all its sediment, and therefore serves to prolong the life of the filter beds."

There is one danger, however, occurring sometimes after prolonged storage, which should not be lost sight of; that is the abnormal development in the reservoir of algæ and other minute vegetable growths at certain seasons of the year. These growths not only cause great inconvenience by rapidly choking the filter beds, but certain species give rise to exceedingly unpleasant odours and tastes in the water, which cannot usually be got rid of by filtration. A remedy for these evils, however, is suggested in the book, namely, the addition of exceedingly small doses of copper sulphate, which, it is stated, not only will cause the death of myriads of these organisms, but if added in anticipation of a rapid development will prevent the growth taking place. The use of hypochlorites is also recommended.

Following on this exhaustive and extremely valuable discussion of *storage*, the authors devote a large section to the question of *filtration*. There are three chapters devoted to this subject, entitled respectively, "Sand Filtration," "The Management of Sand Filters," and "Mechanical Filters."

Under the first heading elaborate and exceedingly interesting and instructive explanations are given of the theory of sand filtration, which bring out very conclusively the precautions which are necessary to ensure efficient purification. The action of a sand filter appears to be threefold; first, the mechanical straining of the grosser suspended matter, this causes a film or skin composed of silt, algæ, and bacteria to form on the surface of the sand; secondly, the living algæ in this skin seem to have a power of consuming the bacteria which come within their orbit, thus retaining many of the minute organisms which would otherwise pass through the interstices between the sand grains. The third action is brought about by the slimy or gelatinous film which forms round the grains of sand in the lower layers of the bed; this has the power not only of retaining most of those microbes and minute particles of matter which escape the filmy skin, but also by a process of adsorption, of acting on the organic matter *dissolved* in the water, "mineralising" it, and converting it into innocuous nitrates, sulphates, and carbonic acid.

It is pointed out that to ensure all these actions taking place properly it is necessary that the rate of filtration should be slow (about 4 inches per hour) and uniform, as an irregular flow causes disturbance to the microbes adhering to the slimy coating of the sand grains.

All the operations in connection with the management of filters are dealt with under this heading, and details are given of their construction. Descriptions are given of many of the elaborate processes employed in different parts of the world, and the chapter concludes with a discussion on the use of coagulants for the rapid sedimentation of matter in suspension, and also for the formation of an artificial filtering skin. This leads up to an important chapter on mechanical filters, which are rapidly gaining favour in various parts of the world. Numerous appliances are described, differing chiefly in matters of detail. The general features are the use of a much greater head of water or of artificial pressure, and the use of an artificial skin produced by the addition of alum, and, if necessary, lime or some other alkali, if the water has not sufficient natural alkalinity to precipitate the alumina. The filtering medium employed

consists of sand or crushed quartz, and in some cases layers of some such oxidising material as polarite or oxidium are used, in addition to sand, as in the Candy filter.

The advantages of this method of filtration seem to be the much more rapid rate at which the water can be passed through the filters, and consequently the much smaller area which they occupy, and the ease and rapidity with which they can be cleaned by mechanical means. This effects a great saving of labour, and also does away with the workmen coming in contact with the filtering medium. As regards efficiency, it would appear that these filters are at least as efficient as ordinary sand filters.

After two very useful chapters on "The Purification of Water by Ozone" and "Water Softening and Household Appliances," two chapters follow on the testing of water. They consist of a discussion of the bacteriological, chemical, and microscopic examination of the raw and filtered waters and the inferences to be drawn from them.

The bacteriological tests suggested, and the methods of applying them are, however, somewhat open to criticism, and need revision in subsequent editions, and the suggestion that these tests should be undertaken by the water managers themselves (unless specially qualified) is also perhaps not of the happiest. To anyone acquainted with the bacteriological and chemical analysis of water, it will be apparent that unless these tests are carried out by skilled operators errors of execution and judgment are likely to crop up. The growing necessity of dealing with impure and polluted sources of supply renders frequent and careful analysis imperative, and the example of the Metropolitan Water Board and some of the Continental and American water undertakers in appointing a staff of qualified analysts might well be followed by other bodies.

As the authors point out, the interpretation of the results of analysis depend largely on local conditions, yet they give a table of the standards of purity required in Britain and America, which, by the way, are not applicable to a very large number of water supplies, and they do not state from what source these standards, in so far as they apply to British supplies, are obtained.

In the remaining chapters, the book deals with problems of distribution, and, in addition to engineering problems, several pages are devoted to the development of such growths as crenothrix in the mains and the action of peaty waters on lead. This latter subject was exhaustively investigated by Dr. Houston about fifteen years ago, on behalf of the Local Government Board, and the authors quote extensively from his work; the two kinds of action, plumbosolvency and erosion, although attributed to different causes, are frequently caused by the same water.

The authors have surely misunderstood Dr. Houston's work when they state (on p. 324) that erosion, which results in the formation of the hydroxide of lead, has probably no consequences obnoxious to the consumer, for they go on to say that the hydroxide scales away and mixes with the current. The section concludes with a general discussion on public health in relation to water supply, and an account is given of several outbreaks of cholera and typhoid fever, which have been attributed to that cause. It should have been pointed out, however, that in the case of the epidemics at Belfast, mentioned on p. 348, the water supply was completely exonerated by the Health Commission appointed to inquire into the matter.

The arrangement of the book is exceedingly good, the type clear, and the numerous diagrams and photographs make the descriptions of the various appliances very easy to understand. As appendices there are some useful tables of filtration constants and other engineering data, and a concise and well-arranged bibliography of works on water purification.

DENISON B. BYLES.

GERMAN AND FRENCH BOOKS ON CRYSTALLOGRAPHY.

(1) *Lehrbuch der Kristallphysik (mit Ausschluss der Kristalloptik).* By Prof. W. Voigt. Pp. xxiv+964. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 30 marks.

(2) *Leçons de Cristallographie.* By G. Friedel. Pp. v+310. (Paris: A. Hermann et Fils, 1911.) Price 10 francs.

(3) *Die Kristallgruppen nebst ihren Beziehungen zu den Raumgittern.* By Prof. E. Sommerfeldt. Pp. vii+79 (Dresden: T. Steinkopff, 1911.) Price 3 marks.

(1) THIS treatise is based upon the lectures delivered for some years past by Prof. Voigt at the University of Göttingen, and it concentrates also into a single volume of 964 pages the original work in physical crystallography other than optical contributed in numerous memoirs during the course of a long and active career. Prof. Voigt's name is, perhaps, most familiar from his work on the elasticity of crystals and their piezo- and pyro-electrical properties. These branches of physical crystallography are well represented in the book before us, and the only criticisms that suggest themselves are that Prof. Voigt has not given us more experimental details and illustrations of the interesting forms of apparatus employed in the researches, and that British work in this branch of science, especially the thermal expansion and elasticity of crystals, is not referred to. The result of these omissions is that in the first place the book presents a somewhat forbiddingly mathematical aspect, the theoretical and mathematical side vastly predominating and entirely overshadowing the practical experimental side of the subject, and that in the second place a certain narrowness of outlook is inevitable.

Having said so much, however, and remembering that Prof. Voigt's chair is that of theoretical physics, the thorough manner in which the subject is dealt with inside these somewhat narrow lines cannot fail to impress the reader. The most valuable consideration is, moreover, that we have here brought together for us the facts and theories for which hitherto investigators and students have had to search through the numerous original papers of Prof. Voigt. The

specialised portion of the book is preceded by an admirable review of the morphology of crystals and the structure theories of Bravais, Wiener, Sohncke, von Fedorow, and Schönflies (again we notice the omission of a British name, that of Barlow). Such a review is of special value, as it gives us the considered opinion of one who regards crystals essentially from the physical and mechanical point of view, and whose original investigations have brought him more than usually in touch with the phenomena dependent on the internal molecular and atomic arrangement of crystals. The influence of such an experience and of the character of this field of research is evident in a most interesting manner throughout. As Prof. Voigt so truly says:—

"Die besonderer Bedeutung welche die Krystallform für den Aufbau der Krystallphysik besitzt, liegt darin, dass dieselbe eine einfachste und anschaulichste physikalische Wirkung der Konstitution der Substanz darstellt."

The specialised portion of the book deals with pyro-electricity, pyro-magnetism, thermal dilatation, electrical and thermal conduction, thermo-electricity, dielectric influence, ferromagnetism, elasticity and internal friction, piezo-electricity and piezo-magnetism, and the effect upon them of change of temperature, all being considered specially with reference to crystals, as organised and perfect solids. The ground covered is thus very wide, and the practical investigator is most grateful to Prof. Voigt for placing within easy reach the theory and mathematics of all these branches of the subject. If only a few more practical hints as to the mode of carrying out the experiments, and more and better illustrations of the apparatus could have been given, the work would have been well-nigh perfect.

(2) This book does not profess to be a complete treatise on crystallography, but embodies the earlier lectures of the course in mineralogy given for some years by the author at the Ecole Nationale des Mines at Saint-Etienne, of which he is the director. Crystallography is considered first of all as the necessary introduction to the study of mineralogy by students training for mining engineers, and is therefore limited to those properties of crystals which are useful for the identification of mineral species. Hence, many of the less apparent physical properties of crystals are passed over, and those which are considered are dealt with from this limited point of view rather than for their own intrinsic interest. Indeed the author almost apologises for the necessity of treating even cursorily the fundamentally important optical properties of crystals.

The above will have sufficiently indicated the severe limitations of the book, and the narrow aspect from which it is presented. Crystallography has suffered, perhaps more than any other science, in the past from such limitations, imposed by being relegated to a corner in a course of mineralogy, which is itself frequently merely taken as a subsidiary part of a course in geology. There are strong indications that the time has now arrived, however, when these limitations should be swept away, and the fact boldly recognised that the child has outgrown the parent, and that crystallography has become a wide and important subject on its own account, embracing (1) crystal morphology; (2) the optics and other physical properties of organised solids; (3) mineralogy; and (4) the crystallography of metals. Recent progress in the subject has been so rapid, its importance has become so palpably enhanced, that partial presentments of the character of the book before us are entirely behind the times, and no longer called for, except for the convenience of a particular set of students who may desire to have their professor's lectures before them in print.

While from the latter point of view it is possible to say much that is good about the book, there are some defects that cannot be ignored. The illustrations of crystals, for instance, are obviously in many cases inaccurately drawn, that is, not in clinographic or any other projection correctly to their proper elements, but are merely approximations of the nature of ruled rough sketches; hence, lines which should be parallel are often conspicuously not so. Also while one is glad to see a greater tendency than in other French books on this subject to employ the simple and scientific symbols of Miller for the crystal faces and forms, the advantages of which are fully admitted by the author, the notation of Levy is still given as well in conformity with French usage, although the probable confusion to the mind of the student would appear to dictate its abandonment as an unnecessary complication, especially considering the limited time available for the crystallographic part of the curriculum of these students.

A further limitation is the marked tendency to base the whole crystal morphology exclusively on the laws of Haüy as expanded by Mallard, and on the space-lattices of Bravais. Now it will be clear from the following review of Prof. Sommerfeldt's book how great is the importance of the space-lattice; but this book goes to the other extreme in stopping short at this work of the French savants. The only work on homogeneous structures referred to beyond it is that of Schönflies, and this, moreover, is only dealt with briefly as an afterthought in an appendix, and apparently largely as a development of the mathematical work of Jordan. No mention could be found of the work of Sohncke, von Fedorow, or Barlow, in developing the 230 types of homogeneous structures possible to crystals.

Curiously enough, the part of the book most diffidently presented, the optical, is the most readable and interesting, and is marked with originality of distinct value. Indeed, this section leaves the reader with the wish that it had been extended, as the author appears to be on specially familiar and congenial ground.

(3) This is a suggestive little book, the main object of which appears to be to present a simplification of the mode of regarding the homogeneous structure of crystals as a complicated point-system of the character indicated by Sohncke. Its essence is that the space-lattice (Raumgitter) is considered as the basis of the structure. The method is to drop the idea of essen-

tial parallelism, same-ways orientation, of the structural units, and to develop systematically in stages, starting from parallelism in the holohedral class of a crystal system, the possibilities of alternation and other forms of partial parallelism. The idea is justified from two points of view, first, that of the simplification for the student, who can readily construct the fourteen models of the Bravais space-lattices, by means of knitting needles and spherical balls impaled on them, and indicate on them if he chooses the stages of parallelism, corresponding to the various classes, by means of little inclined rods or other devices for indicating differences in the nature of the nodes of the space-lattice; and secondly, from the point of view of the undoubted importance of the space-lattice as regards crystal structure, and the fact that the space-lattice represents the arrangement of the molecules, while the Sohnckian points clustered around its nodes represent the arrangement of the atoms, and that models of such Sohnckian systems of points are very difficult to construct.

An excellent series of stereoscopic photographs of the fourteen space-lattices are given, forming quite a feature of the book, the photographs not merely representing the spherical balls on the steel rods but the shape in stereographic projection of the solid formed by the elementary cell or unit "brick" of the crystal edifice. The photographs were taken from models in the laboratory of Prof. von Groth at Munich. It is interesting to note also that the system of closest packing, as used by Pope and Barlow, is adopted in the book.

After a few pages of instruction in the elementary facts and nomenclature of crystallography, the author passes on to compare holohedral and partial symmetry, and shows how by placing a short inclined stroke, rod, or bar at each point of intersection or node of a space-lattice, and doing so either parallelwise or in an alternately arranged manner, the idea of parallelism or otherwise, and even of a screw arrangement, may be indicated directly on the space-lattice itself, the disposition of the cluster of Sohnckian points about each node of the space-lattice being thus indicated by the mode of arranging the little stroke or rod. It is shown that such an arrangement fulfils Wiener's principle, that homogeneity consists in the continual repetition throughout space of the same relation between an elementary atom and the entire structure. The diagrams in the second part of the book indicate how this idea of constructing all the variations of class symmetry of a crystal-system on separate models of the same space-lattice can be carried out, and the book is well worth attention on account of the simplification which it thus presents of the admittedly most difficult part of crystallography. The difference between right- and left-handed mirror-image forms is also very clearly brought out.

While the particular mode of applying these ideas of Prof. Sommerfeldt is new, it can scarcely be said that the principle is. For Mr. Barlow long ago employed models of the human hand at the nodes of the space-lattice, or about them, to indicate orientational differences of the atomic cluster which each such node represents. But the present mode of differentiation employed by the professor of mineralogy of Tübingen has the especial merit of emphasising in an unmistakable manner the importance of the space-lattice as the fundamental basis of crystal structure.

A. E. H. T.

MODERN EXPLOSIVES.

Les Explosifs modernes. By Paul F. Chalon. Troisième édition. Pp. 787. (Paris: Librairie Ch. Béranger, 1911.) Price 25 francs.

THIS volume is really an encyclopædia on the subject of explosives, although many of the materials described, however interesting, are scarcely to be regarded as explosives, for it is only in very exceptional circumstances that they can behave as such or enter into the composition of explosive mixtures.

The book is divided into five parts, dealing respectively with (i.) explosive substances and the primary materials employed in the industry; (ii.) the manufacture of powders and explosives; (iii.) pyrotechny; (iv.) the methods of employing powders and explosives; (v.) employment of explosives for mining and various other applications; (vi.) legislation.

It would indeed be difficult to turn to the book for information on any substance which has either been employed or suggested for use as an explosive for any purpose, and the author has certainly carried out the descriptive part of the work in a thorough manner, the recent improvements in manufacture, for example, with guncotton and nitroglycerine at Waltham Abbey, being satisfactorily dealt with.

No doubt the author as a mining engineer feels the necessity of including much matter which is familiar to the chemist or manufacturer, such, for example, as the percentage composition of common salts, the different series of hydrocarbons, alcohols, &c., but it is to be regretted that chemical formulæ are so frequently incorrectly given that a lengthy errata, mainly to correct these chemical faults, is required, but even this fails to cover all the sins of commission.

Many interesting substances, unfamiliar even to those engaged in the industry, are briefly described, such as the remarkable crystalline explosive salts resulting from the electrolysis of solutions of antimony with an antimony anode, the sulphides and selenides of nitrogen, the sulphide of carbon C_8S_5, which compares with iodide of nitrogen in sensitiveness. In dealing with the explosive nature of compressed acetylene, the author states that its use has had to be abandoned in view of its explosive character, yet by the simple compression into steel cylinders containing porous blocks saturated with acetone, acetylene is now a valuable commercial product, and is largely employed in conjunction with oxygen for cutting steel plates, welding, and other purposes where a high temperature is demanded.

The author's connection with mining ensures that the application of various explosives for blasting purposes, submarine blasting for the removal of obstructions to navigation, including sunken vessels, is

fully treated, and many of the testing galleries employed for investigating the safety of explosives in coal mines are described. Many suggestions for the substitution of perfectly safe bodies in lieu of true explosives for this purpose are referred to. Among these may be noted the use of quicklime and its expansion on slaking; cartridges charged with liquid carbon dioxide or oxygen; but one of the most interesting methods was that introduced by M. Linde for the use of liquid air, in some cases a paper cartridge filled with kieselguhr and saturated with petroleum was then dipped in liquid air, the firing being carried out by a Bickford fuse or fulminate detonator. When the Simplon Tunnel was commenced in 1899 several attempts were made to utilise the explosive force of liquid air mixed with flour for blasting the rocks, but with unfavourable results. Liquid air alone, in metal cartridges, has also been tried for bringing down coal, but the author concludes that it does not seem an economic success.

Of more general interest is the important question of modern smokeless powders as propellants for military purposes. The Powers are fairly evenly divided in the choice between a gelatinised nitrocellulose powder or a nitrocellulose-nitroglycerine colloid. At one time the majority favoured the simple nitrocellulose powder, which is still retained by France and Russia, whilst Great Britain remains faithful to cordite, and Italy to ballistite. Germany may be said to be in a transition stage, for whilst employing a nitrocellulose for field guns, for the larger naval weapons a powder very similar to our modified cordite is employed.

All have had troubles to face with premature decomposition in magazines, and especially France. At Saigon in 1897 a quantity of poudre B ignited without setting fire to some black powder stored near by. 19,500 kilogrammes of this same powder had burnt with little damage in the previous year at the Saint-Médard factory, but the *Jena* disaster will ever be most prominently associated with this particular explosive, to which, in the author's opinion, it was wrongly attributed, whereas the special Commission appointed to inquire into the cause of this disaster believed it to be due to spontaneous decomposition of poudre B.

The instability of smokeless powders has led to the introduction of "stabilisers," the action of which is to absorb the oxides of nitrogen resulting from decomposition, which oxides, if present uncombined, greatly accelerate further decomposition. The author mentions a number of these, which include urea (American powder), diphenylamine (ballistite and the French powder BBo, first introduced after the *Jena* disaster), amyl alcohol (in the most recent French powders, AM_2 and AM_8), which appears to give excellent results. In cordite the vaseline acts as the stabiliser, although originally introduced for quite other purposes. It does not follow that for powders containing both nitroglycerine and nitrocellulose two stabilisers, one for each constituent, should be provided, as the author appears to think necessary.

Summarising the question of relative stability of the two classes of propellants the statement is made that gelatinised nitrated cottons possess more stability than the nitroglycerine-nitrocellulose powders, and although the velocity of the projectile is lower for the same charge they have marked advantages in lower temperatures on detonation, less erosive action on the rifling of the guns, and give less smoke. In view of the troubles experienced with simple nitrocellulose powders, the claim of their superior stability, *per se*, to cordite is open to question.

On the whole the volume will be found a useful work of reference on the composition, manufacture, and application of explosives for practically all purposes. It is more essentially a book suited to the requirements of the engineer or mining expert, and would not afford much information to the chemist or those engaged in the manufacture of explosives.

J. S. S. B.

A STATE MEDICAL SERVICE.

The Dawn of the Health Age. By Dr. B. Moore. Pp. ix+204. (London: J. and A. Churchill; Liverpool: The Liverpool Booksellers' Co., Ltd., 1911.) Price 3*s*. 6*d*. net.

THIS is a remarkable and noteworthy book, powerfully written, and very convincing on most of the points raised. Its aim is to demonstrate the necessity for entirely remodelling the present system of medical service, in the interests of the whole community. It goes far to show that hundreds of thousands of lives and millions of money could be saved annually if diseases were attacked on more scientific principles; and the main theme is that we allow diseases to invade and enfeeble us, and then make an attempt (often a poor one) at cure, instead of concentrating our efforts on prevention.

The first chapter is headed, "How we tinker with disease instead of stopping it." Therein it is pointed out that concerted, statesman-like action is demanded. The present undisciplined mob must be converted into a disciplined army; and there are signs foreshadowed by legislation dealing with some of the great problems of social reform, commencing with invalidity insurance and reform of the Poor Law, that we are turning in this direction. The organised army of doctors would cost the nation from eight to ten millions a year—an amount which is at present exceeded, but in a nationalised medical service the money would be paid through different channels. Under the new *régime*, medical treatment would be as free to everyone as is the education of to-day, and everyone would be bound to accept medical treatment in his own interests, just as to-day he accepts the education of his child. The author estimates that tuberculosis costs the country 16,000,000*l*. a year, and that it can be eradicated for an expenditure of less than 10,000,000*l*. a year for ten years, further expenditure almost stopping at the end of that period. He further maintains that tuberculosis and preventable infantile mortality together cost us more than double the price of an effectual national service for their prevention.

The main object of the national medical service would be twofold:—

(1) To give instruction in the laws of hygiene and healthy living, sowing this knowledge broadcast in both school and workshop.

(2) To take effective steps to stamp out infectious disease, assuming compulsory powers for this purpose.

We require a new system, including in organic coordination the private practitioners, the hospitals (voluntary and Poor Law), and their staffs, the infectious diseases and municipal hospitals and their staffs, the dispensaries, public and provident, the district medical officers and relieving officers, and the present so-called public health service.

"Let us wake up and be truly ashamed of ourselves," and having taught the school teachers the principles of hygiene, provide that this subject is taught in our schools as a compulsory and important one. Under our present medical service neither the medical practitioner nor the public health officer has any ambition to go forth and find the disease, not even if an epidemic is on; the disease must come to the doctor. The service is the more defective and incomplete in that many infectious diseases, and these often the most dangerous, are not even compulsorily notified.

It is maintained that a national medical service must arise in the end out of the general sickness and invalidity scheme now being contemplated by the Government. It is obvious that both the more economical and scientific way of dealing with disease is to catch it early and to stop it at its source.

"So much of medical practice is becoming inefficient under the action of some of the local cooperative systems, clubs, societies, and tontines, that it is making the name of medical science a disgrace. It is turning doctors' private practices into fraudulently conducted business concerns, in which the doctor loses all dignity and self-respect, and the patient is cheated of that advice and treatment which he imagines is being given to him, and upon which his very life depends."

The last thing in this world to have cheap is medical advice. State insurance with a nationalised medical service is the only way out from this chaos. The medical officers should be transferable from one local centre to another, and open to promotion from one place to another. It is a liberal estimate to take the average income of the profession at 250*l.* per annum. The average annual pay for the doctor, under the State national medical service, would be somewhat more than 300*l.* a year, and taking it that a junior commenced at about 150*l.* a year, this would mean a system rising on ordinary promotions and good service to a maximum of 1000*l.*, and a small number of administrative officers at higher salaries. Probably about one-third of the profession would elect to remain on in private practice. The whole scheme would not be nearly so costly as the provision required under the Old Age Pensions Act, and it would prove quite as popular and as beneficial. The gain in disease stopped at incipient stages, and in increased health and corresponding power of his workpeople, together with regularity of work, less interrupted by illness, would more than repay the employer for his part of the contribution.

"At least one adult in every seven of us is going to die of consumption, all because of this nefarious 'Wait till your ill system,' which no one has the courage to attack, and because we will not send doctors out on the highways and byways to find disease and haul it apart, so that they may stand between the healthy and infected, and the plague be stayed. As it is with consumption so it is with a hundred and one other disease conditions."

The author deals with our hospital system, its evils and abuses. It is argued that these provisions are only capable of doing about 15 per cent. of the work which they are intended to do; but they are a hopeless failure and a positive drawback, because they stand in the way of the introduction of a properly organised scientific effort. An organised system of State-controlled hospitals, in true coordination instead of chaos, would bring about a reduction of at least 50 per cent. of both disease and expense. The present hospitals are hopelessly out of touch with the present medical practitioners throughout the country, and this is highly detrimental to the public service, the hospitals themselves, and to the medical profession.

"Under a State medical service and State hospitals for all members of the wage-earning classes, hospital abuse is done away with, because it simply cannot exist. The out-patient departments of our hospitals, like the 6*d.* dispensary practice of our slums, are two disgraces on the fair name and reputation of medical science. In both cases the times given are wholly inadequate for observation, care, and attention to the cases."

The writer demonstrates that the race is not relieved from suffering and death by the existence of a cure for the individual.

"There is only one way given under heaven by which disease can be abolished and a finer and fitter race evolved, and that is by stopping the cause of disease, and throwing all our energies into the resistance of its spread."

Without a fairly complete separation of infective consumptives, no progress of any kind is possible. Therein lies the solution of that problem.

"If we could only see the patients hit by the infection of phthisis as we do in smallpox the present order of things would not long be tolerated. As we are free from hydrophobia, so can we be free from tuberculosis when we find a statesman of the courage and fortitude of Mr. Walter Long to lead us to victory."

It is pointed out that in the evolution of the national medical service the friendly societies will be absorbed, the service will be thrown open to the whole of the medical profession, retiring allowances will be provided, and a State medical examination would become the single portal of entry to the medical profession which is so desirable. The voluntary hospitals would soon step into line with the rest of the service, and accept State support and control. The district assigned to each doctor would contain some four or five hundred families or houses. He would have a surgery; he would have no rivals worrying him, no bills to bother about, no suspense lest his patient

thought he was after fees, and it would be to his interest to reduce work by keeping in touch at all times with the people for whose health he is responsible. He would at the same time act as an educating influence, and the absence of the dread of a fee to pay would further promote early treatment.

GEOLOGY FOR STUDENTS.

A Text-Book of Geology. By P. Lake and R. H. Rastall. Pp. xvi+494. (London: E. Arnold, 1910.) Price 16*s*. net.

THIS text-book will fill the gap between several excellent books of a more primary character and the great English work of reference which we owe to Sir Archibald Geikie. Mr. Rastall is responsible for the physical portion, and Mr. Lake for that dealing with stratigraphy.

Dr. J. E. Marr, as editor of "Arnold's Geological Series," to which the work belongs, states in his preface that

"the stratigraphical portion of the book is occupied almost entirely with the study of the stratigraphy of the British Isles, which is sufficient for the purposes of elementary teaching."

This, however, is just the point on which there may be most difference of opinion. It may seem to some of us that in elementary teaching a view of the earth's history should be imparted on the broadest scale. The gaps in our insular stratified series should be filled in unhesitatingly from other lands. The progress of living things from Palæozoic to Quaternary types can be followed with interest even by a beginner in geology; but few people can take delight in British genera and species unless they can picture them in a setting of the successive faunas of the globe. The early editions of Lyell's "Principles of Geology" are appealed to by Dr. Marr as an example, yet nothing is more prominent in Lyell's work than his desire to establish a stratified sequence by observations made in many lands. Consider his table of "Recent and Tertiary Formations," on p. 61 of his third volume, published in 1833, and compare it with Mr. Lake's treatment of the same formations on pp. 439 and 453 of this modern text-book. Lyell, with a fascinating sweep, reminds us in his table of the delta of the Ganges, of Uddevalla, of Asti, and Perpignan, of the Superga, and of the volcanoes of the Velay. On p. 46 he regrets his ignorance of "many deposits known to exist in Spain and Portugal."

Many of us still share Lyell's regret, not because we want to carry in our heads the list of fossil species found on particular horizons, but because we want to fit the beds into the general scheme of stratified deposits. Lyell took his marine fossils as "medals which nature has chiefly selected to record the history of the former changes of the globe." Our universities, since his time, have established the cult of zones and horizons within the British Isles. The British Isles, moreover, have been accepted as consisting of England and Wales, and attention has become more and more concentrated on a limited area of the European outpost. Mr. Lake has worked well under these conditions, and no one will accuse him of ignorance of the wider aspects of the earth. We expect, however, a "text-book of geology" to convey to us some picture of the progress of life upon the globe. Of this we find only scanty traces in the 200 pages devoted to stratigraphical geology. The word "stratigraphical" has been allowed to dominate this section rigidly. In this respect numerous smaller text-books come nearer to the Lyellian conception of geology.

Mr. Lake's treatise, however, is indispensable for those who wish to bring their knowledge of British strata up to date. He has included, for instance, Mr. J. F. N. Green's revision of the St. David's area (p. 298); the probability of an unconformity in the Bala series, emphasising its division into Caradocian and Ashgillian (pp. 318 and 320); and Mr. Clement Reid's assignment of an Upper Oligocene age to the plant-beds of Bovey Tracey (p. 452).

A Scottish geologist may be provoked to find that the rocks which form the main mass of his highlands are described in six lines (p. 297). An Irish geologist will regret that the Dingle problem is dismissed in twenty-six words (p. 352), while the Lower London Tertiaries occupy two noble pages. But this lack of proportion is written large in the programmes of our public examinations.

Mr. Rastall's chapters on physical geology naturally make a wider appeal. Even the Dwyka conglomerate of South Africa is shown in one of the photographic plates, though no explanation appears to be given of its remarkably interesting characters. Spitsbergen and Alaska are well referred to, and the Tonga Islands, the great cone of Misti, and the wind-scored Sphinx, are used as illustrations of features that have a broad significance. The plates are chosen with much care, and the diagrams are as lucid as the accompanying text. Good examples of the author's treatment are to be found in the passages on desert-erosion (p. 69), and on river-capture (p. 45). Where so many physical matters have to be dealt with, few authors will agree as to the degree of prominence to be given to each. We should have liked to hear more of the many varieties of gneisses, and we note that the author regards thermal metamorphism as "usually of comparatively limited extent," a statement that is true enough of the rocks exposed in England. In the Transvaal, Rhodesia, Fennoscandia, and Canada, examples of a very different order may be found. Rock-cleavage is clearly described, and is illustrated by plates iv. and v., which might well be transferred, with their text, to the chapter on metamorphism two hundred and forty pages further on.

Mr. Rastall shows as much caution (pp. 100, 101, &c.) in dealing with the work of ice as his colleague does (p. 464) in dealing with the glacial epoch; but the main results of observation are very fairly stated, and the lessons of Arctic lands are applied to the British Isles. Is Spitsbergen, however, to be described (p. 99) as "a region of heavy precipitation"? Where the actual amount of melting is slight, glaciers, fed by broad snow expanses, can be maintained in an almost arid climate.

In this excellently produced book we have come across no misprints. "Porphyry," in the table on

p. 238 seems a slip for the "syenite-porphyry" of p. 243. On p. 147, for "Skeat" read "Skeats." One or two prominent terms, like *roches moutonnées* and strain-slip cleavage, remain unnoticed in the truly admirable index. GRENVILLE A. J. COLE.

BIOLOGICAL CHEMISTRY.

An Introduction to Bacteriological and Enzyme Chemistry. By Dr. G. J. Fowler. Pp. viii+328. (London: Edward Arnold, n.d.) Price 7s. 6d. net.

IN this work we welcome a valuable contribution to the scanty English literature of a subject of vast and constantly growing importance. A great increase of interest in biological chemistry and a consequent rapid development of the subject along almost innumerable lines have been among the most noticeable features in the history of chemistry during the last ten or fifteen years. Stimulated by the brilliant successes of Fischer and the important researches of Buchner, many workers have devoted themselves to the study of biochemical problems, and especially to the investigation of enzyme action. Accompanying this scientific movement, and no doubt in part responsible for it, there has been a widespread introduction of biological methods into the routine experience alike of the industrial and analytical chemist. The subjects of agricultural and dairy chemistry, water analysis and sewage disposal, to say nothing of the advance in the old-established fermentation industries, at once suggest themselves as instances of this tendency, and an audience has thus been created anxious for authoritative information on the principles underlying the application of biology to all these questions.

It is to this audience that Dr. Fowler has addressed the main portion of his book. Anxious to meet the needs not only of the chemist, but of the engineer and medical officer of health, and even of the general reader, he has, however, included a chapter on general organic chemistry which it is to be feared will be found superfluous by the chemist, and will be "caviare to the general." Apart from this the plan of the book is excellent. The chief types of enzyme action and of the chemical action of bacteria are first discussed, along with the chemistry of the sugars and proteins, substances which play so important a part in all biochemical changes, and the book culminates in three chapters describing the relation of all these matters to agriculture, sewage disposal, and various industries. The treatment throughout is clear and practical, the excellent method being adopted of quoting as far as possible actual experimental results and methods from the original sources, and thus enabling the reader to appreciate the lines on which successful investigation of such problems must be shaped.

As might be expected in a book ranging somewhat lightly over a large field of detailed information, occasional inaccuracies are to be found. Thus the lactic and acetic fermentations (p. 13) have both been obtained by Buchner with cells killed by acetone; the discussion of the mutarotation of glucose might easily be understood to mean that the change is due to equilibrium occurring between the aldehyde and one of the oxide forms of glucose (p. 98). More serious fault is to be found with the description of the well-known guaiacum test for peroxidases, along with the typical albumin reactions, as characteristic properties of enzymes in general (p. 104). Peroxidases are now recognised as a distinct and individual class of enzymes and it is at least highly probable that many enzymes are not proteins, and among them diastase itself, in connection with which these tests are quoted. Something, moreover, has gone seriously wrong both with the formulæ and argument on p. 173.

Some of the subjects touched upon are of fascinating interest, a notable example being found in the chapter on the "Cycle of Nitrogen." This is, of course, a matter of the most fundamental economic importance, and one with which the author is specially qualified to deal.

For all who feel any curiosity about biological chemistry this book should serve as an excellent introduction, and it should be difficult for anyone to read it without realising some of that glamour which has attracted so many workers to the investigation of the chemistry of living beings. A. HARDEN.

WEST GREENLAND ESKIMO.

Bei den Eskimos in Westgrönland. Ergebnisse einer Sommerreise im Jahre, 1906. By Dr. R. Trebitsch. Nebst einem ethnologischen Anhang, von Dr. M. Haberlandt. Pp. xxiii+162+map. (Berlin: Dietrich Reimer (Ernst Vohsen), 1910.) Price 8 marks.

DR. TREBITSCH gives a very readable and capitally illustrated account of his twelve weeks' journey in western Greenland. Considering how large was the distance covered in this short time, it is creditable to him how much information was collected. West Greenland, between 73° N. lat., and Cape Farewell, is in the possession of Denmark. The entire trade is in the hands of the Kgl. grönländischen Handel, a Government concern, somewhat similar to our old East India Company, and there are stringent regulations to prevent intrusion by other Powers. Travellers must have a valid pretext for going, must undergo medical inspection, and are not allowed to take intoxicants into the country.

It was only as a collector of phonographic records for the K. Akademie d. Wissenschaften of Vienna that Dr. Trebitsch could get leave at Copenhagen to visit West Greenland. The country is divided into districts, the chief town of each is a "colony," where lives a Government official, who is at the same time the sole trader; other officials, mainly natives, are scattered about at trading centres. The Danish *régime* is apparently beneficial; for the West Greenlanders have increased from 6,286 in 1820 to 11,790 in 1904, a striking contrast to the state of affairs among the Eskimo of Alaska. The writings of Dr. Boas and others have taught us to expect some degree of uniformity of culture among the Eskimo, despite their vast extension over some 5000 miles of coast line, but the similarity between the seal-hunting appliances of the Alaskan Eskimo and West Greenlanders is none the less striking; the same talent for drawing and the custom of vying with each other in composing songs are met with among both groups.

The author collected masks, though Andree and others have denied this occurrence in Greenland, which are probably used for magico-religious purposes, as in Alaska. He unduly emphasises the similarity of type occasionally found between Eskimo and American Indians, which he attributes to kinship of race. The low stature of the Eskimo he regards as an adaptation to the climate of the far north, as the strong storms do not permit tall plants to grow, and suggests that the lack of hair on the face of the pure Eskimo is consequent on the inconvenience caused by the formation of icicles! West Greenlanders are for the most part of mixed Eskimo and Danish origin; in fact, the largest "colony" boasts of only one pure-bred Eskimo.

The seal plays a very large part in the life of the Eskimo, and Dr. Trebitsch gives some interesting details of the methods employed in capturing it. The kayak is provided with a square white sail, almost concealing the hunter, which the seal is supposed to mistake for an iceberg. The seal is first shot with a rifle, and then harpooned, so that the harpoon float may prevent it from sinking. In winter two men use a harpoon with a composite shaft some 6 metres long. A very large and a small hole are bored in the ice; one hunter lies down peering into the former, and when he catches sight of a seal he moves the harpoon point to and fro in the small hole, which attracts the seal. At the right moment both men thrust the harpoon with all their might. This mode of hunting is called "he looks through a hole." In East Greenland bait is employed. The mainland Eskimo, however, always wait for a seal to come up to a breathing hole.

Native social customs are considerably in abeyance among the Christianised Eskimo, but the author was sometimes able to secure traces of the past; for instance, one missionary allowed the performance of one of the old native dances. The songs and stories, of which a large collection of phonographic records was taken, are in many cases modern, but some are manifestly old, and refer to cannibalism, exchange of wives, and the mating of girls with animals. Many of the songs have a homely vein. In some cases the distribution of the folk-tales is discussed. There is an ethnological appendix by Dr. M. Haberlandt, who describes the objects collected by Dr. Trebitsch for the Vienna Museum. A. C. HADDON.

A VETERAN ANTHROPOLOGIST.

Memories of Eighty Years. By Dr. John Beddoe, F.R.S. Pp. xi+322. (Bristol: J. W. Arrowsmith; London: Simpkin, Marshall and Co., Ltd., 1910.) Price 7s. 6d. net.

DR. BEDDOE has followed the example of another distinguished anthropologist, the late Sir Francis Galton, in writing the memories of his life. This practice is to be commended, as it furnishes not only pleasant reading with a great deal of human interest, but also valuable material for the future historian of anthropology.

Dr. Beddoe, who may well be regarded as the founder of field anthropology, since he began making observations on hair and eye colours seventy years ago, records in this book the leading events of a long and active career. Born in 1826, on the English side of the Welsh border, he started life as a student of law, but soon abandoned that for the more congenial study of medicine. He acquired his medical knowledge at University College, London, and the University of Edinburgh.

In 1854 he went out to the Crimea as a member of a civil medical staff, where, though he had very little medical service to perform, he had the opportunity of making observations on many Oriental races. After his return from the Crimea, he decided to complete his medical studies at Vienna, and he gives an interesting account of his journey through Holland, Germany, and Bohemia, with many valuable and original observations on the ethnological features of the races he encountered on the way. He met van der Hoeven in Holland, and Virchow at Berlin. In Vienna he found the upper classes were of the Germanic type, and the lower orders very mixed, with a large Slavic element.

On leaving Vienna he returned to England through Italy and France, adding much to his knowledge of the races of those countries, which at that date were unexplored fields for the anthropologist. He finally settled down as a medical practitioner in Bristol.

The long list of anthropological papers published by Dr. Beddoe shows how persistently the rest of his life has been devoted to his favourite science.

In 1867 he was awarded a prize of 100 guineas by the Welsh National Eisteddfod for the best essay on the origin of the English nation, which was afterwards embodied in his classical book on the "Races of Britain."

He was the proposer of the first anthropometric committee of the British Association, and also the initiator of a separate section for anthropology at the B.A. In 1889 he was president of the Anthropological Institute, and he gives many interesting details about the amalgamation of the two older anthropological societies to form the institution which at present represents anthropology in this country.

Even now, in his eighty-fifth year, Dr. Beddoe's mental keenness and activity would put to shame that of most younger men.

PHYSICAL CHEMISTRY.

Introduction to Physical Chemistry. By Prof. J. Walker, F.R.S. Sixth edition. Pp. xii+417. (London: Macmillan and Co., Ltd., 1910.) Price 10s. net.

AFTER a useful life of eleven years, this well-known text-book appears in a thoroughly revised edition, in which, no doubt, it will continue to be a standard work. At first sight it appears as if the size of the work had remained sensibly constant—to use a favourite term of physical chemistry—actually there has been an increase of 27 per cent., and the additional chapters on alloys, hydrates, colloidal solutions, dimensions of atoms and molecules, neutrality and salt hydrolysis, electromotive force, polarisation and electrolysis, and radio-active transformations have

added much to its value. Of these the chapter on alloys may be mentioned as a particularly successful piece of exposition.

The book reflects as much as ever the spirit of a very true believer in the ionic dissociation hypothesis, and little emphasis is given to the difficulties and objections or to the criticism by which it has been assailed. Although in an elementary work an author can scarcely be expected to go into great detail, it must be remembered that the English student still finds himself in an atmosphere where there is a good deal of objurgation about the ionic theory, and if Prof. Walker had dealt with the difficulties collectively it would probably have been a convenience to students.

The following points have been noted for remark in the course of reading. On p. 83 the wording may readily give the impression that the vapour rising from a boiling salt solution has a temperature of 100° C., a matter on which there is a widely prevalent misconception among students. On p. 227 it would have been well to explain why the Brownian movement is compatible with the conventional assumption that a body suspended in a liquid is subject to equal pressure in every direction. The explanation of "salting out," on p. 347, as a process depending *solely* on ionic concentration is scarcely justifiable. Lastly, Prof. Walker has used throughout the book his system of chloridion, sulphation sodion, &c., nomenclature. The present writer took exception privately to this nomenclature when it was first proposed, but was assured that with experience he would learn its value to students. This prediction has not been fulfilled, and whatever philosophical defence may be made of the system, he remains of the opinion that it is not helpful. A. S.

BRITAIN'S BIRDS.

Britain's Birds and their Nests. Described by A. Landsborough Thomson, with introduction by Prof. J. A. Thomson. 132 drawings in colour by G. Rankin. Pp. xxviii+340. (London: W. and R. Chambers, Ltd., 1910.)

ANOTHER gorgeous volume on Britain's birds and their nests! Truly of the making of books on this subject there seems no end. Happy the publishers, and authors we presume, supported by a public with so insatiable an appetite for British ornithology. We could exhaust the space at our disposal with a mere list of the books and serials on this subject which are issuing or have issued from the press within the past two years and have come under notice in these pages. The name on the title-page of a gifted professor in a great northern university, as introducer of his son as author has given special zest to the perusal of this particular volume.

Prof. Arthur Thomson writes an introduction to "Mr. Rankin's beautiful pictures and my son's text." We must, much to our regret, however, confess to considerable disappointment in the volume before us. The text is excellent. Indeed, the various biographies are pleasantly written, and very accurate as a whole, but little really appears to have been left for Mr. Landsborough Thomson to say that has not already been often told.

But it is with the plates that fault is chiefly to be found. They are all "very pretty," but we have more of art than of nature in them. We suspect that they are mostly studio pictures rather than out-of-door studies. Without exception the species Mr. Rankin has depicted are the most "proper" series of British birds we have ever made the acquaintance of. They never foul the ground, when 'tis their nature to; they never disturb a blade of grass or a single petal of the beautiful flowers that emborder their nests in nearly every case. They are indeed the most æsthetic company we have yet met with, in the choice of nesting sites.

We miss, too, in many of the plates, the characteristic attitude of the bird represented. There is something lacking in the pose of the herring gull to those familiar with it "in the open." In the thick-knee the beak is too thin and its eye too small; in the corncrake the true ralline attitude has not been caught. We failed to recognise the nidifugous nestling figured on plate 88, Fig. 3, as a young partridge until we had consulted the reference.

As to the eggs figured, it would be quite impossible for even one well acquainted with them in many cases to determine their parentage from the plates. Their size—no dimensions being given in the text—is also quite undeterminable, and their colour often far from true to nature. There is no doubt that as regards tint the three-colour process is very often to blame; but where it fails some indication should be given in the text.

The author, yet a very young man, shows by this ambitious venture into the world of books that he is possessed of "the passion of the ornithologist," and by it gives promise that we may expect from him an ornithological work "going far beyond the recording of occurrences," to quote his father's words, "and the observations of movements important and indispensable as these and similar inquiries are."

OUR BOOK SHELF.

An Introduction to Experimental Psychology. By Dr. C. S. Myers. (The Cambridge Manuals of Science and Literature.) Pp. vii+156. (Cambridge: University Press, 1911.) Price 1s. net.

IN this little book Dr. Myers gives a very interesting account of modern views in certain parts of the science of experimental psychology. The topics selected for discussion, and forming the headlines of successive chapters, are:—"Touch, Temperature, and Pain," "Colour Vision," "The Müller-Lyer Illusion," "Experimental Æsthetics," "Memory," and "Mental Tests and their Uses" (two chapters). On each of these subjects much important work has been done within quite recent years, and the exceptionally clear way in which the author sums up the latest results and brings out their theoretical importance will make the book of great value to physicians, educationists, and others who are finding a knowledge of the general methods and results of the science an indispensable supplement to their ordinarily-recognised intellectual equipment.

The first chapter contains a full account of the recent researches of Drs. Rivers and Head on human nerve division, which have modified so extensively our views on tactile sensibility. The chapter on the Müller-

Lyer illusion describes an extremely interesting example of the success with which careful psychological experimentation, supplemented by exact measurement, can analyse out the various hidden factors involved in the production of an optical illusion. Colour vision and experimental æsthetics are treated in a way which cannot fail to interest the ordinary educated reader. But the parts of the book which deserve to be singled out as of particular interest for applied science, educational or medical, and as a really masterly description, in a small compass, of work perhaps most characteristic of modern psychological advance, are the chapters on memory and on mental tests and their uses. Readers of the author's larger text-book of "Experimental Psychology," will recognise in the former a condensation of the excellent account of the subject in that book. The discussion of mental tests includes clear instructions as to the method to be employed in applying certain of the more important of them, and gives a summary of many of the results, which will be found exceedingly useful to readers who have not the time or the facilities for referring to the original publications. Such questions as the effect of alcohol and other drugs upon muscular work and fatigue, the standardisation of intelligence, and the correlation of mental abilities one with another, will all be found adequately treated.

The book contains a bibliography and index, and is artistically bound and very clearly printed.

W. B.

Grundzüge der Mathematisch-Physikalischen Akustik. by Prof. A. Kalähne. Teil i., pp. vii+130. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 3.20 marks.

This little work forms an excellent introduction to the mathematical basis of acoustics. Though using the calculus freely wherever needed, including differential equations, the treatment is simple and full, the analysis being illustrated by numerical examples and corresponding diagrams drawn to scale. The present part (being the first of two) is divided into seven chapters. Of these the first is devoted to vibrations and waves in general, the second to Fouriér's series and harmonic analysis, while the third deals with the musical intervals of the scale, and kindred topics. Then, the subject being introduced, its formal development follows. The fourth and fifth chapters treat the vibrations of a particle, undamped and damped respectively. The sixth chapter deals with resonance and forced vibrations, the concluding chapter extending the treatment to systems of more degrees of freedom and their coupled vibrations. Perhaps to the English reader the most valuable features of the work are the tables and the curves giving concrete expression to the numerical illustrations. The growth of forced vibrations and the sharpness of resonance are very well shown, and may serve as a reminder of the electrical work of V. Bjerknes, Zenneck, and others in Hertzian waves and wireless telegraphy.

E. H. B.

Physical Measurements. By Prof. A. W. Duff and Prof. A. W. Ewell. Second edition, revised and enlarged. Pp. x+258. (London: J. and A. Churchill, 1911.) Price 7s. 6d. net.

This book is intended by the authors for students who have already completed an elementary course of practical physics. It is not, however, a treatise on methods of physical measurement, but the authors have described upwards of seventy typical experiments of an advanced and modern character. While the descriptions of these experiments are usually applicable to apparatus in general, they are in many cases somewhat sparse in detail. Thus, for example, in Expt. lxiii., "Strength of a Magnetic Field by Bismuth Spiral," no remarks are made on the necessity of maintaining the temperature of the spiral constant, which is of primary importance if trustworthy results are to be obtained by this method. These defects are, however, partially remedied by the references given by the authors at the commencement of each experiment to more advanced treatises and sources where the subject under investigation is dealt with more exhaustively. Such well-known text-books as Kohlrausch, Watson, and Stewart and Gee figure conspicuously in this respect. The authors consider that the books and papers referred to in this way should be consulted by the student before commencing the experiment. A few questions are usually appended to each experiment bearing upon its subject-matter, At the end of the book are tables of logarithms and physical constants.

In the diagram on p. 70 (hypsometer) surely it is better to connect the pressure gauge directly with the inner cylinder of the hypsometer. The following experiment, No. xiv., p. 71, would have been better described as "Linear Coefficient of Expansion" and not "Temperature Coefficient of Expansion."

If the book is used in conjunction with the references it will prove of value to the student of physics.

Unsterblichkeit: Eine Kritik der Beziehungen zwischen Naturgeschenen und menschlicher Vorstellungswelt. By Hermann Graf Keyserling. Zweite Auflage. Pp. iv+285. (Munich: J. F. Lehmann, 1911.) Price 5 marks.

In the review of the first edition of this work (Nature, vol. lxxxii., p. 5, November 4, 1909) it was pointed out that the fundamental idea was that of faith as a permanent and essential constituent of human movement along the lines both of thought and of action. In the present edition, this is the single point of view, and the concluding chapters of the original work, amounting to about sixty pages, are now included in the author's "Prolegomena zur Naturphilosophie." The work is rich in thought and represents a noteworthy contribution of a naturalist to the human concept of immortality.

Elementary Regional Geography. Europe and the Mediterranean Region. By J. B. Reynolds. Pp. viii+184. (London: A. and C. Black, 1911.) Price 1s. 4d.

Cambridge County Geographies. Berkshire. By H. W. Monckton. (Cambridge: University Press, 1911.) Price 1s. 6d.

Maps and other illustrations take the most prominent place in Miss Reynolds's little book on Europe. The volume should form a useful introduction to the subject for young people, but it would have been more suitable for this purpose if the children had been provided with more work to do for themselves.

Mr. Monckton's book on "Berkshire" is a worthy addition to an interesting series; it has all the good qualities noticed in connection with its companion volumes.

Space and Spirit. A Commentary upon the Work of Sir Oliver Lodge, entitled "Life and Matter." By R. A. Kennedy. Second edition. Pp. 64. (London: Charles Knight and Co., Ltd., 1911.) Price 1s. 6d. net.

The first edition of this booklet was reviewed at some length in our issue of February 24, 1910 (vol. lxxxii., p. 486). The new edition contains some further contributions by way of appendix, and a new list of definitions.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Solar Eclipse of April 28.

THE failure of the observers at Vavau to obtain a satisfactory view of the eclipse is very unfortunate, and the whole astronomical world will share their disappointment. It is welcome news to hear that perfect conditions prevailed at islands situated some distance from Vavau, and equally well placed as regards the line of totality.

I have received a letter from Mr. C. L. Wragge, who observed the eclipse under ideal conditions from the island of Moungaone in the Tongan group. He writes to me from Lifuka as follows:—

"It was entirely successful, with a clear sky, and magnificent beyond words. A lovely sketch to scale was also secured by another member of my special party at Lifuka—duration of totality, about two minutes. Four great streamers were seen.

"The shadow-bands rippling over the cocoanuts, and the dark purplish-black of the ocean, obliterating the lovely tinges of blue and green water around the coral reefs, were superb.

"The natives rushed into their houses, and came out and cheered when, with a blaze of glory, the sun reappeared."

The photographs secured have been taken back to New Zealand for development, but a sketch enclosed with the letter shows the corona with four magnificent streamers of the type characteristic of the solar sunspot minimum, and also a very large prominence. The streamers and inner corona are described as "silver-white," and the following *approximate* measurements are given:—

Highest streamer of corona, about 649,000 miles.

Large red flame, about 217,000 miles.

The streamers were in pairs, two extending north-east and two south-west, while silver-white ridges of the inner corona extended round the north-west quadrant.

2 Park Hill Road, East Croydon, Surrey, June 18.

Dinoflagellates and Diatoms on the Beach.

IN walking across the beach between tide-marks at Port Erin on April 7, I noticed a greenish-brown discoloration of the sand in places—especially along the edges of the ripple-marks and other depressions—which I supposed to be caused by a deposit of diatoms. The examination of a sample in the laboratory soon showed, however, that although a few diatoms (*Navicula amphisbaena*, or some closely allied form) are present, by far the greater part of the deposit is formed of the active little peridinian or dinoflagellate *Amphidinium operculatum*, Clap. and Lachm., which has not, so far as I can ascertain, been previously recorded on the British coast.

The innumerable specimens of Amphidinium were all alive, reproducing by longitudinal fission, and very active in their movements. They would leave the sand-grains to which they were adhering, swim round rapidly in the water, and then settle down again upon a sand-grain. These dinoflagellates remained abundant on the beach at Port Erin until the end of April, when the observers had to return to Liverpool. During these weeks the patches of discoloured sand changed a little with each tide, increasing, diminishing, shifting, or even disappearing for a day, and then reappearing. Samples placed in dishes of sand and sea-water in the Biological Station flourished, and the organisms increased so as to form a dark-coloured layer over the sand, eventually rendering the water impure and causing the death of the dinoflagellates.

At the meeting of the Linnean Society on June 1 I directed attention to this unusual occurrence of this small Amphidinium in vast quantities, and exhibited specimens. Two days later I was again on the beach at Port Erin, and found what were apparently the same patches of discoloured sand, but on examining scrapings with the microscope saw that the deposit was now wholly composed of a golden-yellow diatom, one of the "*amphisbaena* group" of Navicula. I searched the beach carefully between tide-marks, and examined samples from every suspected patch of sand, but could find no trace of the Amphidinium so abundant a few weeks before. The Navicula, which was present in April in very small quantities, seems completely to have replaced the dinoflagellate. We have probably much to learn in regard to the comings and goings of such microscopic forms and their physiological inter-relations in connection with what may be called "the metabolism of the beach."

W. A. HERDMAN.

Liverpool, June 12.

A New Method of Chemical Analysis.

WILL you permit me to step outside usual practice in this instance and to direct wider attention to the exceptionally brilliant and momentous work described to the Royal Institution on Friday evening, April 7, by its present professor of natural philosophy, as reported in NATURE of June 1, p. 466? OLIVER LODGE.

THE author of the present note is probably one of the few chemists living who was originally brought up in the Berzelian electrochemical theory (for which idea Berzelius was indebted to Davy), and, as shown in an article published in 1877 (see also Arrhenius-Jubelband), he made a sharp distinction between elements playing the "electro-positive" and "electronegative" *rôle*. So, *e.g.*, the connection between the position of elements in Mendeléeff's periodic system and their valency was expressed thus: The *positive* valency of the elements (towards the negative oxygen) may change between 1 and 8; the *negative* valency (towards the positive hydrogen) may change between 1 and 4 only.

But such ideas, for which I was formerly reproached of being "unmodern," are very modern indeed to-day.

This is seen from the highly interesting lecture, published in NATURE of June 1, by Sir J. J. Thomson, "A New Method of Chemical Analysis" (p. 466 *et seq.*).

Without referring to the results communicated in this lecture with anything but high admiration, I beg to point out that Sir J. J. Thomson finds that, when the elements hydrogen and carbon had passed—originally positively charged—through the kathodes of his tubes, they appear also *negatively* charged. This he calls "remarkable, for *hydrogen* is generally considered to be a strongly *electro-positive* element," and "the atom of *carbon*, also regarded as an *electro-positive* element, is also conspicuous on the *negative* side."

I desire to remark that there is an analogy, but also a certain difference, between the notion "positive" and "negative" as used by the chemist or by the physicist. Physically, and also chemically, a positive atom carries positive charges, and the negative atom *vice versa*. This holds good of Sir J. J. Thomson's atoms (see the article) and of the atoms in solutions which we chemists call "ions." The difference lies in the point that, as regards the atoms constituting the chemical *compounds*, the terms "*positive*" and "*negative*" have only a *relative* value, as pointed out in the introductory lines. Hydrogen is *positive* towards chlorine in hydrogen chloride, H_+Cl_-, and many other compounds, whereas it forms the *negative* constituent of potassium hydride, K_+H_-, and other similar compounds (CaH_2, LaH_3, CeH_4, &c.).

The physical analogy of this relativity is the zero position of hydrogen in the electrical tension series. It is *positive* compared with the "noble" metals and the metalloids; it is *negative* compared with the "ignoble" metals like those of the alkalies, alkaline earths, and the earths.

As regards carbon, it is *positive* in C_+O_{2-}, but it is *negative* in $H_{4+}C_-$ and in the more popular calcium carbide, Ca_+C_{2-}.

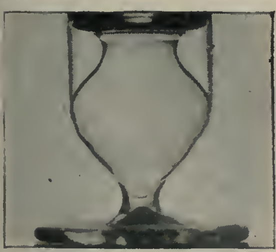
In the compounds KH, CaC_2, and also in $Na_{3+}N_-$ we had already suspected latent negative chemical ions. Chemists will be indebted to Sir J. J. Thomson that he has shown their existence physically. It is interesting, but not surprising, that the said elements take up negative charges under the conditions of his experiments.

BOHUSLAV BRAUNER.

Bohemian University, Prague, June 6.

The Formation of Stable Columns of Liquids.

When a liquid of slightly greater density than water is poured into a shallow layer of the latter, it is often possible to produce the formation shown in the accompanying photograph, in which the heavier liquid appears as a column of curved outline, stretched by its own weight, and hanging from the surface of the water. By performing the experiment in the following manner, the production of the column is rendered easy and certain. A test-tube of the dimensions shown in the photograph, preferably furnished with a foot, is filled to about one half the height of the hemispherical end with water, and 5 to 10 c.c. of aceto-acetic ether are then added. Usually, the formation of the column is automatic; if it should fail to form the contents should be shaken up, and the test-tube allowed to stand for a short time, when the liquids will settle as shown. Water globules entangled in the aceto-acetic ether may be removed by drawing to the side with a wire.



If the original layer of water be too deep, the column will break at its narrowest part, and the same occurs if water be poured gradually into the tube after the column has formed. By varying the width of the vessel, a great variety of shapes may be obtained, all of which are perfectly stable. The water is in all cases displaced from the lower part of the vessel, and bounds the sides of the column of heavier liquid. Similar results may be obtained with aniline, orthotoluidine, butyl benzoate, and some other liquids; but in these instances the manipulation is rather more difficult, owing to the tendency to break up into separate globules. By placing the test-tube in a flat-sided vessel and surrounding with water, the column may be projected on a screen, thus furnishing an interesting lecture experiment on the subject of surface tension.

Chas. R. Darling.

THE CORONATION.

From the point of view of social psychology to-day's great ceremony may be said to bind together in a circle of symbolism the past history of the English people and the present interests of the British Empire. From the point of view of individual psychology it may be regarded as a symbolic elevation of human personality to its highest power.

It is an interesting problem for the sociologist how far a given social ceremony succeeds in realising a modern content in an ancient form. The relation of form and content in social ceremonies and institutions alike is analogous to that of structure and function in organisms. But the inertia of social forms is far greater than that of organic structures, for in the case of the latter there is neither sentiment nor tradition to assist survival.

The development of the ceremony of crowning from Greek and Roman times is clear, but the origins of the crown-symbol itself are still obscure. Outside the sphere of classical antiquity its use is rare. But within it, as in mediæval and modern Europe, the crown is, next to the King, the central feature of coronation. Not only in popular language, but in legal phraseology, it is a synonym for the kingly office itself. It has, in fact, long ago superseded unction as the central element of royal investiture, making the recipient a king rather than a priest.

The crown of the kings of Egypt was, like regalia generally, considered divine. Kings of the Yorubas sacrifice sheep to their own crowns. In South Celebes it is the regalia that reign; the king is but their representative. If we attempt to penetrate to the strata of early custom which preceded the Greek and Roman kingly crown, the Athenian crowns which were given, just as ribbons of the Legion of Honour are given, the Roman crowns corresponding to the Victoria Cross and similar honours, the Greek wreaths of sacred leaves won in the games, and even the oak chaplet of the early Roman kings identifying them with the oak-god, we may follow some such line as the following. Like unction, crowning had its origin in personal decoration or accoutrement. Savage chiefs are sometimes invested with a girdle. Just as ankle and wrist straps and the like are frequently worn by rude peoples for the practical purpose of protecting the joints and ligaments, and afterwards attract superstitious ideas, such as the idea that they prevent the soul from escaping, so it may have been with the head-band or head-dress, originally used for protection or for confining the hair. The brain being the crown of the human organism, the head has always received honour. From this point of view the crown is the one royal symbol likely to be retained by enlightened peoples, who for various reasons retain kingship.

Coronations in other latitudes are instructive. Investiture with a special or sacred dress is frequently the main feature. The king-elect of the Aztecs went in procession to the temple. Here, after paying homage to the god, he was anointed over the whole of the body by the high priest, and sprinkled with holy water. The unguent was a black oil of rubber. He was then clothed in ceremonial robes, and about his neck was hung a gourd containing remedies against sorcery, disease, and treason. Hindu coronations took the form of a baptism or an unction. Eighteen ingredients were required for the holy water, one being the water of the sacred river Sarasvati. After a preliminary sprinkling, the king received a bow and arrows, with which he symbolically conquered the four quarters of heaven and earth. Then, seated on a tiger-skin, facing the east, he received the holy water in a shower from a rose-head of gold. Four officiators poured it. Many prayers were recited meanwhile, some "to enable him to discharge his duties," others to the "divine quickeners"; others stated that he was being consecrated by the gods, and being filled with divine force. Vigour and vitality, royal and priestly dignity, were contained in the ingredients of the holy water. His head was then adorned with stalks of holy grass and ears of corn. At the end he quaffed a draught of the sacred soma. His hair was not to be cut for a year after the ceremony. In modern times a Rajput raja is anointed with sandal-paste and rose-water, and the priest marks his forehead with the sacred Tika symbol. When the raja of the Bhuiyas is consecrated, a chief winds a flexible creeper round his head-dress to signify that he is "Lord of the forest."

Ellis describes the installation of Tahitian kings. The king bathed, and was then ceremonially struck by the priest with a sacred branch. He was then girded with a sacred girdle of red feathers, which rendered him divine. In old Siam the king was placed under the seven-tiered umbrella, the great symbol of royalty. A crown and a collar of diamonds were placed upon him, and he received a golden tube containing his name. In old China the king (like Plato's philosopher-kings) deprecated his elevation, declaring himself to be unworthy. No crown was used; the king was seated upon the throne of the Nine Heavens. In Abyssinia, that most curious pioneer of Christian kingdoms, there

was a pretty piece of symbolism. The king rode on horseback, to find his way barred by a company of girls holding a barrier consisting of a cord of crimson silk. They plied him with the question: Who are you? Then, after an exhibition of horsemanship, the king severed the barrier with his sword. The priests then intervened, anointed, crowned, and incensed him. It was, no doubt, at the same period that Ptolemy Philadelphus of Egypt reduced crowning to an absurdity. At his coronation, Athenæus tells us, three thousand two hundred crowns of gold were carried in procession, and one of these was a hundred and twenty feet in circumference.

Our own ceremony is a wonderful mosaic of survivals. Its main features are the recognition of the king by the people; the oath of good government; the anointing; the delivery of the regalia; the imposition of the crown; the delivery of "the most valuable thing that this world affords," the Bible; the enthroning; the reception of homage. Among the regalia the antiquary may miss "the hand of justice" of the emperors of the Holy Roman Empire. The most ancient feature, the unction, of course, derives from Hebrew ritual, as the crowning from Roman. The combination of the two marks the combination of spiritual and temporal power, and is a curious echo of "primitive" kingship, when the monarch possessed both material authority and supernatural *mana,* and was both president and priest. Unction in its evolution always shows a connection with spiritual ideas; the vehicle is itself a source of life, and, when consecrated, inspires the recipient. But its ultimate origin is the use of oil as part of the festal garb. At one end of the scale we have the Australian medicine-man "singing" a charm of power into a magic ointment; at the other Plato conceives the fancy that the Soul of the Universe was impressed upon material nature by the Creator as an unction in the form of a cross.

To the student of man it is interesting to observe that all these elements of the ceremony except the "recognition," have only lost their original magical import, and become symbolic, within the last eight or nine hundred years. He may ask himself whether the imagination of the people really accepts unction as expressive of modern thought and modern life; whether there is not too much "survival" in the whole ceremony to enable it to retain any living meaning. Dead forms, he may note, are always dangerous. If we still possessed the art and craft of ceremony, new forms might be evolved. It is remarkable that the whole essence of the ancient ritual not only does not contain any recognition of the one great motive force of modern civilisation, science, on which all progress, all wealth, and even all existence increasingly depend, but is actually a negation of it.

A really living symbolism is to be found in the "recognition" of the King by the people. This might form the nucleus of a representative ceremonial adequate to our times. Those present to "recognise" would be representative of every factor that helps to make the Empire, and in proportional numbers and prominence. Other countries have realised this opportunity. At every great State function in Germany a prominent place is assigned to the representatives of pure and applied science; the German mind realises that the wealth and well-being of the empire ultimately depend on science, and science alone. It is a pity that those responsible for the organisation of our ceremony sympathise so strongly with its archaic elements that they have not secured an adequate representation of the depositaries of modern knowledge, the true palladium of people and of empire.

A. E. CRAWLEY.

AËRIAL NAVIGATION AND MECHANICS.[1]

THE exigencies of modern aëronautics combined with the uncertainties attaching to aëroplane flight are slowly but gradually directing attention to the necessity of researches and original papers of a highly specialised character, dealing with air pressures and the motions of bodies acted on by them. The question thus becomes imminent: Where should such investigations be published?

Until now no attempt has been made to make use of journals and transactions of societies publishing physical papers, and articles full of formulæ, diagrams, and tables have generally found their way into periodicals of a semi-popular or practical character, devoted to general aëronautical or engineering questions. The result has not always been satisfactory, and it has often been a question as to whether the printing of the formulæ or the reproduction of the diagrams has suffered the most. The insufficiency of the existing media for the publication of theoretical articles on aëronautics is, however, more clearly shown by asking the question: What is to be done with a manuscript of 100 foolscap pages filled from beginning to end with long formulæ or diagrams? Further, whatever may be the drawbacks of the system of refereeing papers no doubt can exist as to the advantages of a collection of memoirs, all of which have been subjected to the judgment and criticism of external examiners.

The Government Blue-books contain exactly the kind of investigations to which these remarks apply, and the hope may therefore be expressed that these will in the future become a recognised medium for the publication of lengthy investigations which have been approved by the Government Committee.

The "Report" for 1909–10 consists of (1) records of experiments performed at the National Physical Laboratory; (2) original papers by members of the committee and others; (3) abstracts of papers of a scientific character dealing with aëronautical problems.

Probably the features which possess the greatest interest for the large majority of readers are the abstracts and reports on the state of science with regard to specified subjects. The thirty-five pages of general abstracts do for aëronautical science what is done for physics and electrical engineering by "Science Abstracts." In order to make the collection more complete the compilers have included papers published some time ago; for example, abstract No. 8, deals with Turnbull's experiments, which were published in *The Physical Review* for 1907.

Mr. F. J. Selby's special reports on the present state of knowledge regarding electrification of balloons and on papers by Ferber, Crocco, and Soreau, dealing with equations of motion and stability considerations, form a valuable contribution of a similar character. It is interesting to notice that several stability conditions in the papers referred to are defective, owing to the

Interim Report on the work for the Year 1910–11. Pp. 30. Cd. 5453. (London: H.M. Stationery Office; Wyman and Sons, Ltd.; Edinburgh: Oliver Boyd; Dublin: E. Ponsonby, Ltd.) Price 1*s.* 2*d.*

Report on the Theory of a Stream Line past a Plane Barrier, and of the Discontinuity arising at the Edge, with the application of the theory to an Aëroplane. By Sir George Greenhill, F.R.S. Pp. 96+106 figs. (Advisory Committee for Aëronautics Reports and Memoranda, No. 19.) (London: H.M. Stationery Office; Wyman and Sons, Ltd.; Edinburgh: Oliver Boyd; Dublin: E. Ponsonby, Ltd., 1910.) Price 5*s.*

"The Aëroplane, an elementary text-book on the principles of dynamic flight." By T. O'B. Hubbard, J. H. Ledeboer, and C. C. Turner. Pp. xi+128. (London: Longmans, Green, and Co., 1911.) Price 2*s.* 6*d.* net.

"The Mechanics of the Earth's Atmosphere, a collection of Translations." By Cleveland Abbe. Third Collection. Pp. iv+617. (Washington, D.C.: Smithsonian Institution, 1910.) (Smithsonian Miscellaneous Collections, Vol. li., No. 4 Hodgkins Fund.)

failure of the writers to take account of sufficient data, and in particular to appreciate the interdependence of the equations of motion, and this is the less easy to understand as this interdependence in the case of lateral stability is clearly pointed out in Lanchester's "Aërodonetics."

The report on electrification of balloons is followed by brief accounts of experiments by Messrs. G. W. Walker and W. Makower. The subject is an important one, the neglect of which may be responsible for at least one serious dirigible fatality in Germany. Rear-Admiral Bacon gives a translation and abstract of the programmes of the German Society for the Study of Airships.

Passing, however, to the articles dealing with "researches," we find voluminous descriptions of apparatus and diagrams of experimental details, none too easy to follow, which may well suggest to the uninitiated reader to ask, "What has all this to do with aëronautics?" A doubt may readily arise as to whether the structural details of a wind tower, experiments on a fish-shaped body moving in water, or a diagram showing the weather conditions prevailing on a certain day at Portsmouth or Berwick will in any way reduce the record of a score of people killed, besides those wounded by accidents during the first four months of the present year. The inclusion of unnecessary *minutiae* will only tend to strengthen the violent attacks which were made recently on the work of the committee by a well-known motorist writing in a popular magazine. The writer in question took up the well-known "practical" attitude, and suggested that if the Government wanted to do any good they should buy a commercial aëroplane; they should keep their committee muzzled (so to speak), and should only consult them when the machine got out of order, in which case they should be expected to rectify the mischief, presumably, at a few hours' notice. This, according to the writer, was the condition under which experts in English commercial firms labour, and he was shocked at the idea of a Government committee having any free will as to what they were to do.

It is hardly necessary to point out in NATURE that no body of scientific men would consent to serve on a committee under conditions so detrimental to efficiency, or to direct attention to the waste of money which occurs when experts are called on to patch up defects which, under more favourable conditions, they could have anticipated previously. But it does appear that the bearing of many of these researches on aërial navigation has been considerably obscured by the inclusion of unnecessary matter which would have been better filed for future reference instead of being published.

At the present time, apart from stability and the construction of light motors, the most important problem of aërial navigation is the behaviour of aëroplanes and dirigibles in gusty winds, the determination of the maximum fluctuations, of the stresses these set up in the various surfaces and frameworks, and of the changes of motion they produce, and whether these involve loss of control. Now Dr. W. N. Shaw, F.R.S., of the Meteorological Office, has drawn up a report of about sixteen pages on "Details of Wind Structure," in which he states at the beginning, "In drawing up this statement, endeavour has been made to summarise briefly. Additional details can be supplied in further illustration if required." After the concise and lucid exposition which the author gives, it is rather a striking contrast to find more than forty sheets of diagrammatic details of records taken at particular places. These greatly increase the bulk of the volume, and in view of the previous work by Langley on "The Internal Work of the Wind," the provisions stated on p. 10 for enabling the records to be consulted might well have been utilised to save the cost of printing all these diagrams. Moreover, the scale of time is too small to show the intervals between the gusts, a detail of some importance.

The sections dealing with the measurement of pressures also contain a profusion of diagrams and mechanical details of a purely subsidiary character, and the general conclusions are not well stated. A good deal of space is taken up with the details of experiments in water, which would find a more natural place in the transactions of the Institution of Naval Architects than in a report on aëronautics.

The splendid equipment of the National Physical Laboratory at Teddington is described in six pages of letterpress by Dr. T. E. Stanton, but here again the diagrams are unnecessarily large and bulky, and a more useful purpose would have been served if these had been reduced, and the space used for a fuller exposition of the bearing of the experiments on aërial locomotion.

We notice that for experiments on the pressure on planes the use of a whirling table is not considered satisfactory, and that a wind tunnel has been preferred for the purpose. The main objection to this plan is that no attempts have been made so far to investigate the pressure distribution on a plate which has a movement of rotation as well as of translation. The results therefore can only apply to an aëroplane driven steadily through calm air, since when either free or forced oscillations take place rotation plays an important part in them. The experimental determination of these rotational effects will necessarily be difficult, and a whirling table suggests a possible method; at the same time results possessing even a very rough degree of accuracy are better than no results at all, and their absence limits the systematic investigation of aëroplane motions to machines the supporting surfaces of which are narrow. No reference to rotating planes is made in the programme of the committee.

If the committee instead of confining its attention to ideal surfaces, had discussed the application of its conclusions to the successful types of aëroplane and dirigible of the present day, the report would have better corresponded with its title.

The interim report on the Motor Prize Competition offered by Mr. P. Y. Alexander in 1909, which took place last July, exhibits the same features as the other reports. It contains details and diagrams of the friction dynamometers used for testing the motors, particulars as to the mode of estimating the weight of the latter, the quality and price of the petrol, the insurance of the maker's servants for employer's liability, the number of representatives allowed to be present at the tests, the temperature of the room, the times of day at which two pints of water were added to the radiators, and other details carried to the same degree of elaborateness; in short, everything except a statement of the general conclusions of a scientific character to be derived from the tests, as apart from mere statistics.

Sir George Greenhill's report is essentially a mathematical treatise on discontinuous motion, covering all the problems which have up to the present been solved. An important improvement has been made on the treatment given in the earlier text-books, by the introduction of constants. Old students of hydrodynamics will remember a difficulty that suggested itself arising from the fact that a solution might apply to a stream flowing past a lamina of breadth π with velocity 1, but it was not obvious what could be done if the breadth of the lamina were a and the velocity v. This treatise will be of great use to workers in our universities who are seeking to extend the applications of pure mathematics to physical

problems, and thus to furnish fresh starting points for experimental research.

The utility of measurements of the tensile strength of fabrics, of diffusion of hydrogen through membranes, and of a search for light alloys, are too obvious to need further comment, and the fourteen pages of the first report dealing with these questions are concise and to the point.

If there is one conclusion to be derived from a study of these reports it is that a serious mistake was made years ago when in America the grant for the late Dr. S. P. Langley's experiments was withdrawn. If the work now being done does not altogether make up the deficiencies caused by neglect in the past, it is gratifying to learn that experiments are progressing in this direction.

In a recent review of a translation by the editors of *The Aëronautical Journal,* the suggestion was made that they might well bring out further books on aviation. "The Aëroplane" provides in a small compass a summary of the general principles involved in aviation, and the hope expressed by the authors "that the book will find a sphere of usefulness as a comprehensive introduction to the latest and the most fascinating of sciences" is well supported by an examination of the contents. The first chapter deals with properties of the air, including meteorological considerations and relations between pressure temperature and density. The next two chapters are devoted to the flow of air round variously shaped bodies, its pressure on plane and curved surfaces, formulæ for the centre of pressure, and lift and drift. Then comes a study of gliders, in which the reader is asked to make a few experiments with a sheet of paper; stability and steering next follow. In the chapter on propulsion the main notions regarding "pitch" and "slip" are clearly defined. If the authors prepare a revised second edition they might, however, point out a little more clearly that a limit to the efficiency of screws is afforded by the fact that to obtain the maximum thrust there must be no forward motion, while if there is no slip there is no thrust. The next chapter deals with the leading present-day monoplanes and biplanes, giving their dimensions and advantages. Under "Navigation" great emphasis is laid on the importance of the parallelogram of velocities, though not called by that name, and stress is laid on the impossibility of finding the way when the earth is invisible, owing to winds. The last chapter, on "Motors," extends from the simple elastic to the gnome, and the bibliography, glossary, and tables will be found useful. But is there any glossary that contains all that is needed? "Angle of attack," "bent-up wings," and "single- and double-lifting aëroplanes" should certainly be recognised, or better terms substituted by the Aëronautical Society's committee. And are Mr. Hubbard and his colleagues correct in defining "angle of incidence" as the angle at which a plane is inclined to the horizontal? Moreover, the entry occurs, "*Pressure.*—See Resistance"; but resistance is not to be found.

In the third collection of papers and translations issued under the title of "The Mechanics of the Earth's Atmosphere," Dr. Cleveland Abbe has continued the task he has for some time been undertaking of introducing English-speaking students to the rapidly increasing literature that has arisen out of the efforts to break down the line of demarcation between meteorology and physics. The earliest application of the notions of mechanics to the earth's atmosphere in the present collection is Hadley's paper of 1735, on the cause of the trade winds. The study of rotational effects is next taken up in the papers of Poisson (1837), Tracy (1843), Braschmann and Erman (1859–62), Sprung (1881), Gorodensky (1904). Kerber's paper (1881) on the limits of the atmosphere is now reprinted in view of the interest attaching to the subject arising out of explorations with sounding balloons. The translation of Guldberg and Mohn's studies (1876–83) is due to Prof. Frank Waldo. We next have a series of papers by Von Bezold, dealing with the thermodynamics of the atmosphere and other considerations, and dating from 1892 to 1906, and, finally, the two memoirs of Margules (1901 and 1904), which, as the editor points out, introduce us to the great problems of the future—that is, the thermal transformations of energy persistently going on in the atmosphere. The collection might with advantage form the subject of courses of lectures in our universities, and the openings which the subject presents for original work are as numerous as they are intricate and complex. The student will be glad to have such a collection of literature rendered so easy of access.

THE SEA DYAKS OF BORNEO.[1]

IT is obvious that this pleasantly written book is not intended for the anthropologist, but is rather meant for that large class of readers who take a general interest in remote countries and strange peoples. Nor is Mr. Gomes in any special sense himself an anthropologist, a matter it is well to mention, since in some reviews considerable stress has been laid on the fact that no mention is made of the so-called *nyarong,* the "spirit helper" of the Dyaks. But even if the *nyarong*, or, as it should be spelt *ngarong*, is not mentioned by name, its existence is not ignored; an undoubted example will be found on p. 188, and it may be assumed that the reference to a Dyak of whom it is recorded on p. 143 that "he treated a snake with the greatest kindness, because it had been revealed to him in a dream that the spirit of his grandfather dwelt in that snake," is another example of the same belief.

With the possible exception of the Kenyahs, the Sea Dyaks are the most companionable and pleasant race in Sarawak, and it is clear that the author has enjoyed so considerable a measure of their friendship and confidence that, had he but possessed the necessary knowledge, he would have been able to write a book of great ethnological value. The work is thus one of the strongest arguments in favour of the preliminary training of missionaries that has fallen into our hands, for it is clear that its weaknesses are due to nothing but the author's lack of knowledge of where and how to look for information, since every page indicates his interest in his people and the trouble he has taken to know them.

The honesty and truthfulness of the Dyaks are described and illustrated by the *tugong bula,* the "liar's mound," which, once started, seems to persist long after the liar it commemorates is himself dead. A pile of branches is heaped up in memory of the man who has uttered a great lie, so that future generations may take warning. The persons deceived start the *tugong bula* by piling up the branches in some conspicuous spot by the side of the path from one village to another. Every passer-by contributes to it, and at the same time curses the man in memory of whom it is raised. "Once started, there seems to be no means of destroying a *tugong bula.* There used to be one by the side of the path between Seratok and Sebetan. As the branches and twigs that composed

[1] "Seventeen Years among the Sea Dyaks of Borneo." By E. H. Gomes, and an introduction by the Rev. J. Perham. Pp. 343. (London: Seeley and Co., Ltd., 1911.) Price 16s. net.

it often came over the path, on a hot day in dry weather I have more than once applied a match to it and burnt it down. In a very short time a new heap of branches and twigs was piled on the ashes of the old *tugong bula*." The author points out that a man prefers almost any other punishment than that of having a *tugong bula* erected to his memory, for other punishments are soon forgotten, while this remains as mute evidence against him for succeeding generations, and is a disgrace even to his children's children.

Mr. Gomes gives a good account of the Dyak burial rites, though it may be doubted whether the cemetery shown in the plate facing p. 136 is not in fact of Kenyah origin, and some of the accoutrements of the warriors shown in the other plates are not strictly Sea Dyak. The illustrations are perhaps the weak part of the book, for although they are all of excellent quality, there is not that variety in the subjects selected for reproduction which might legitimately be expected from one who has lived so long among the Dyaks. It would, however, be unfair to blame the author's judgment for this, as he was dependent on borrowed photographs, but he may be strongly recommended to learn to use a camera before returning to Sarawak.

C. G. S.

Dyak Houses. From "Seventeen Years among the Sea Dyaks of Borneo."

THE BIOLOGICAL STATIONS OF EUROPE.[1]

PROF. KOFOID'S report referred to below admirably fulfils the purposes for which he prepared it, namely, to put in convenient form for reference an account of the history, organisation, equipment, and work of the various biological stations of Europe, and to indicate their relations to research and to education of advanced or popular character. In the introduction he lays down some general guiding principles regarding the situation and functions of stations of different types—for research, teaching, and economic work—and gives some useful hints on fittings. Then follow descriptions of the stations, that of the Naples Station coming first. The inception, organisation, staff, financial arrangements, plans of the building (including floor plans and sections), details regarding aquarium fittings, pumps, pipes, valves, storage and circulation of water, apparatus, boats, and many other matters connected with this famous station are considered in a clear and concise manner, and the account, which extends over twenty-four pages, cannot fail to be of interest and of great use to those who have the management of, or are planning, marine stations.

The descriptions of other stations are not so detailed, but the chief features of each are mentioned, and opportunity is taken to give the details, often with a photograph or a drawing to scale, of any specially ingenious device or effective piece of apparatus, which the author observed during his tour of inspection. Plans are given of all the more important buildings, showing the arrangement of the laboratories, aquaria, workrooms, &c. Prof. Kofoid has earned the thanks of biologists by providing this excellent account of equipments and working arrangements.

The opening paragraph in the introduction to the stations of Great Britain is quoted here, as it so accurately states the conditions and limitations under which they carry on their work. Prof. Kofoid writes:—"The direct support of biological stations by educational funds of local or State origin, often in connection with universities, so generally prevalent in other European countries, is almost wholly lacking

[1] "The Biological Stations of Europe." By Prof. C. A. Kofoid. U.S. Bureau of Education, Bull. 1910, No. 4. Pp. 13, 360. 55 Pls., 48 text figs.

in Great Britain. With the single exception of the Gatty Laboratory at St. Andrews, which is supported by the university, the biological stations of England derive only meagre rentals of a few tables directly from university or educational funds. The stations have been forced, therefore, to turn to memberships of supporting societies composed to a considerable extent of scientific men themselves, to private benefactors, and to the commercial interests of the fisheries for aid. The result has been a relatively meagre and fluctuating financial support, a large, but, fortunately, rarely predominating amateur, as over against strictly scientific control, and a relatively very large absorption of the funds and activities of the British stations in scientific fisheries work. The scientific fisheries work done by the British stations is unsurpassed in its excellence and effectiveness, and the popular features, such as public aquaria, elementary and technical instruction, are generally well developed, but the strictly scientific phases of the station's activities too often suffer for lack of adequate financial support and from consequent loss of scientific interest."

The report describes the marine stations at Plymouth, Lowestoft, Cullercoats, Port Erin, Piel, Millport, and St. Andrews, and the Sutton Broads freshwater laboratory (which owes its origin and support entirely to private benefaction), and points out their special features and the facilities they offer. Appreciative reference is made to the teaching work carried on among the fishermen at Piel, as being mutually beneficial and leading to a better understanding, on the part of the investigators, of fisheries problems, and on the part of fishermen to a more just appreciation of the efforts of those who seek most wisely to preserve the resources of British waters.

The author urges that a well-equipped and scientifically maintained aquarium should form part of every marine station easily accessible to the public, for in no other way can attention be secured and instruction so forcefully conveyed as by the never-failing interest presented by living creatures well displayed.

The bulletin before us affords striking proof of the vitality of the principle carried into practice by the late Prof. Dohrn, for it shows that there are nearly one hundred institutions in Europe which may be classed as biological stations. These and the laboratories of a similar type in other lands, which owe their foundation to the stimulus and example given by Prof. Dohrn, have exerted an inestimable influence on biological science by placing the investigator in positions of greatest advantage with respect to living creatures, and by providing opportunities for long-continued and close observation and experiment upon abundant and varied material. Not the least valuable factor of such laboratories is the stimulus of contact with other investigators engaged in different lines of research.

In addition to the morphological and embryological researches, which, for many years constituted the chief work done in biological stations, these stations have in recent years facilitated the rapid extensions which have taken place in the domain of experimental physiology and in the wide application of experimental methods to the casual analysis of biological phenomena, thus helping materially to place the science on a broader and more comprehensive basis. During the past decade the work of biological stations has been more fully appreciated in regard to economic and industrial affairs, as is witnessed by the foundation of so many new laboratories on the continent of Europe, and by the increasing use of their facilities in medical instruction, in researches in comparative physiology, and especially in connection with the modern development of fisheries research. In this last direction it becomes increasingly evident that scientific investigations are imperative if the harvest of the sea is to be fully reaped and its resources to be maintained unimpaired for the future. But these investigations, while, of course, directed largely to the solution of the problems presented by the fisheries, must of necessity be founded on the broader basis of general biological inquiry. Fresh-water stations are likewise doing a sound work in regard to the problems of pisciculture, restoring and improving the sanitary conditions and food resources of the streams and lakes with which they are associated.

But apart from all economic problems, important though they are, the purely scientific aspect of the work of these stations wholly justifies their existence and the claims they have upon the community, for, to quote again from Prof. Kofoid's report,

The biological station is a unique agency in biological research, indispensable in the equipment of a nation for the upbuilding of leaders in biological teaching, and in the development and expansion of the spirit of research.

NOTES.

A WARM tribute to the value of the scientific work carried through in the West Indies by the Imperial Department of Agriculture was paid by the Prime Minister, Mr. Asquith, in a speech at a banquet given by the West Indian Club on June 15. In the course of his remarks, Mr. Asquith said:—"I desire to refer for a moment with the warmest appreciation to the work of the Central Department of Agriculture. Established in 1898 at the cost of the Imperial Government, presided over with distinguished ability first by Sir Daniel Morris and now by his successor, Dr. Watts, the work of that department is universally and gratefully acknowledged by the planters to be largely responsible for the improved state of affairs in all branches of agriculture, and I believe—I speak with some experience—it would be difficult to find a case in which any analogous experiment made by the Home Government has attained such speedy and satisfactory results. The outlook is thus full of promise, and not the less so by reason of the fact that the Panama Canal is now approaching completion. The ultimate effects of that great enterprise are, of course, at present incalculable, but it can hardly be doubted that it will in the long run favourably influence the economic progress of the West Indies." It is seldom that such warm commendation is given by a Minister, but the work that has been done merits it fully. So long ago as 1888, the value of botanical federation in the West Indies was urged in these columns, and several articles appeared relating to it and the starting of experiment stations and other aids to the development of the colonies. It is gratifying to find that after all the years which have elapsed since then the results are regarded with such satisfaction, not only by the persons closely concerned with the West Indies, but also by statesmen in the mother country.

A MEETING was held at the Colonial Office on June 14 to discuss with representatives of the self-governing Dominions and States a scheme for imperial coordination in the prevention of the spread of disease in agriculture and horticulture, which it is proposed to organise in connection with the Colonial Entomological Research Committee. An official report states that Lord Cromer, chairman of the Entomological Research Committee, explained the proposals, the object of which is to establish a central organisation in London for the transmission of

information to the various parts of the Empire, thus enabling them to legislate against the introduction of certain insect pests with a greater knowledge of the facts than would otherwise be possible. After a discussion, in the course of which the representatives expressed their hearty approval of the scheme, the following resolution, proposed by the Premier of New South Wales and seconded by the Premier of Tasmania, was passed unanimously:—"That this meeting is of opinion that the proposal to obtain and disseminate information of a scientific and useful nature, tending to prevent the spread by insects of diseases both in animals and plants to various Dominions and States of the Empire would be highly advantageous, and that steps should be taken to obtain the adhesion of the Dominions and States interested in the matter."

We notice with deep regret the announcement of the death, on June 16, of Sir Rubert Boyce, F.R.S., Holt professor of pathology in the University of Liverpool, in his forty-ninth year.

The Duke of Connaught has consented to become honorary president of the Royal Geographical Society.

The annual conversazione of the Institution of Electrical Engineers will be held at the Natural History Museum, South Kensington, on Thursday, July 6.

The council of the Royal Society of Arts, with the approval of the president, the Duke of Connaught, has awarded the Albert medal of the society for the current year to the Hon. Charles A. Parsons, C.B., F.R.S., for his experimental researches into the laws governing the efficient action of steam in engines of the turbine type, and for his invention of the reaction type of steam turbine and its practical applications to the generation of electricity, the ventilation of mines and other large spaces, blast-furnace work, ship propulsion, and other important purposes. The beneficial results which have followed upon these inventions include a cheapening of the production of mechanical power, greater economy and speed for steamships, and the first successful solution of the problem of rotary engines, which long had baffled many other inventors.

As already announced, the twenty-second annual conference of the Museums Association will be held in Brighton on July 10–15 next under the presidency of Mr. H. M. Platnauer, who will deliver his address on the morning of July 11. The same evening Dr. F. A. Bather, F.R.S., will deliver a public lecture on "Open-air Folk-Museums." The mornings of July 12 and 13 will be devoted to the reading of papers. Numerous excursions and receptions have been arranged for the visitors. The association was founded in 1889 with the object of improving and extending the work and usefulness of museums, the word being used in its widest sense to include collections illustrating pure and applied art, archæology, technology, and the natural sciences. Originally confined to the institutions of Great Britain and Ireland, the association has been joined by leading museums of all types in every part of the world, and now includes members from most countries of the world.

An appeal has been made by the British Empire League for funds to secure the establishment of a solar observatory in Australia. The need for such an observatory is strongly felt by solar physicists. A cooperative scheme of research has been initiated between the great solar observatories of Europe, America, and India whereby the sun may be continuously observed throughout the whole of the twenty-four hours, but a gap exists between the two latter stations which would be filled by a solar observatory in Australia. Mr. Geoffrey Duffield, on behalf of men of science, has personally pressed this subject on politicians in the Commonwealth, and Mr. Deakin has promised 1500*l.* a year upkeep if the sum of 10,000*l.* is privately forthcoming. 4000*l.* has already been offered in money and apparatus, so that 6000*l.* is still required. The scientific world will be grateful to the British Empire League for bringing the matter before members of the league and others, thus giving them an opportunity to support a movement which, if successful, will complete the chain of solar observatories which circle the earth, and enable the international scheme to be carried into complete effect. Mr. C. Freeman Murray, secretary of the league, Norfolk House, Laurence Pountney Hill, London, E.C., will be glad to receive and acknowledge any subscriptions which may be sent to him towards this important project.

An extra meeting of the Chemical Society was held on Wednesday, June 14, when Prof. T. W. Richards, of Harvard University, delivered the Faraday lecture, entitled "The Fundamental Properties of the Elements." The president, Prof. Percy F. Frankland, in introducing the lecturer, stated that the Chemical Society had assembled to celebrate what was one of the most important festivals in the calendar of the society, namely, the delivery of the Faraday lecture and the presentation of the Faraday medal. The significance of the meeting would be most effectively realised by calling to mind the names of the following illustrious men who had acted as Faraday lecturers since the first lecture was delivered by Jean Baptiste André Dumas in 1869:—Stanislao Cannizzaro, 1872; August Wilhelm von Hofmann, 1875; Charles Adolphe Wurtz, 1879; Hermann Ludwig Ferdinand von Helmholtz, 1881; Dmitri Ivanovitsch Mendeléeff, 1889; Lord Rayleigh, 1895; Wilhelm Ostwald, 1904; Emil Fischer, 1907. To these eminent *savants* the society had now added another in the person of Prof. Richards, whose great work and whose great contributions to science, especially his determination of atomic weights and his experiments on the compressibility of the elements, are not only well known in this country, but throughout the whole chemical world. Prof. Richards then delivered the Faraday lecture, of which we hope to print an abridgment in a subsequent issue. At the conclusion of the lecture the president, in presenting the Faraday medal to Prof. Richards, spoke of the sincere appreciation and the deep regard which his colleagues in this country had for his work, and also for the great and enduring importance which was attributed to his scientific discoveries. The vote of thanks to the lecturer, which was proposed by Prof. W. Odling, seconded by Sir William Tilden, and supported by Prof. Harold B. Dixon, concluded the meeting.

Mr. W. Hough, curator of ethnology in the United States National Museum, has prepared a descriptive catalogue of the valuable ethnographical collections made by Mr. Hoffman Philip, Minister and Consul-General at Addis Abeba, the capital of the Emperor Menelik. Ethnographical material from Abyssinia is notably scanty, and this large collection is interesting on account of the survivals which it exhibits from the ancient culture of northern Africa, the neighbouring Asiatic continent, and eastern Europe.

MR. R. TORII, under the title of "Études anthropologiques, Les Aborigènes de Formose," contributes to the Journal of Science issued by the Imperial University of Tokyo an introductory account of the primitive races of the island. The present portion consists of a list of the tribes with their geographical distribution, and it is accompanied by a large collection of photographs illustrating their physical appearance, environment, and occupations. Anthropologists will await with interest the publication in the journal of further instalments of the results of Mr. Torii's careful survey of these little known races.

MUCH has been written about the North-West Frontier Province, once an integral part of the Punjab, and specially interesting in connection with the restless Pathan tribes and the diversity of its physical characteristics. The problems which face the officers who control the relations of the British Government with the races within and beyond our border are discussed by a distinguished political officer, Mr. W. R. H. Merk, in a paper read before the Royal Society of Arts on May 25, and published in the society's journal. The conclusion of the writer, supported by Lord Minto and generally concurred in by Sir Mortimer Durand, Sir T. Holdich, and other authorities who joined in the discussion, is that, though we may expect occasional trouble from these tribes, our frontier policy is gradually attaining its object, and that it is possible that in the future this belt of rugged mountain territory will be, not a source of anxiety, but a barrier against aggression and a substantial addition to the security of India.

THE report of the Otago University Museum for 1910 records the gift to that institution of the valuable collection of Maori ethnology made by the late Dr. Hocken, who died on May 17, 1910.

IN the May number of *The Ottawa Naturalist* Mr. Lambe describes the skull of a new species of the bear-like genus Arctotherium from the Pleistocene of the Yukon. The genus, which is in some degree intermediate between Ursus and the extinct Old World Hyænarctus, has not hitherto been known north of California, and has accordingly been regarded as a southern type. The discovery of *A. yukonense* is therefore of considerable importance, as indicative of the northern origin of these huge, big-headed bears, and thus of the probable genetic connection with Hyænarctus.

WE have received the first section of a work to be published by Messrs. Friendländer, of Berlin, under the title of "Nomenclator animalium generum et subgenerum," in two volumes, at the price of 5*l.* The section received is devoted to the Primates. The various names are arranged in generic order, without any reference to the species by which they are typified. When names have been misspelt, they are frequently quoted as if they were new terms proposed by those responsible for such errors, without any clue as to their real origin, as, for instance, in the case of Aulaxinus for Aulaxinuus.

THE discovery in the autumn of 1907 of mummified carcases of mammoths and rhinoceroses in the ozokerit deposits of the Starunia district of eastern Galicia gave rise to considerable interest at the time. The specimens were transferred to the museum at Lemberg, where the skin of the rhinoceros has been set up, and an illustrated account of both specimens, by Mr. E. L. Niezabitowski, has been published in the April number of the *Anzeiger d. Akad. d. Wissenschaften in Krakau*. The rhinoceros belongs to the woolly species (*Rhinoceros antiquitatis*), and so well is the head preserved, that the author has been enabled to compare it in detail with that of its nearest relative, the existing white rhinoceros of Africa. The species presenting the next nearest relationship appears to be the European Pleistocene *R. mercki*. The hair of the Starunia rhinoceros had disappeared.

IN *The British Medical Journal* for June 3 (p. 1310) Dr. Leonard Hill and Mr. Martin Flack publish a second note on the comparative nutritive value of white, standard, and whole-meal bread when used as food for rats. The experiments show still more conclusively than in their first note (see NATURE, May 11, p. 355) the deficiency of white bread as a food, and the better nutritive qualities of standard and whole-meal breads. The germ seems to contain adjuvant bodies whereby the tryptophane-containing portions of the proteins are split off in larger amount and more easily when it is present in the flour.

IN his annual report for the year 1910, recently issued, Dr. Herbert Williams, medical officer of health for the Port of London, describes the incidence of plague among the rats and the measures taken for plague destruction in the port. Plague has now appeared among the rats for three years in succession: in 1908 in the West India Dock during five weeks in August and September; in 1909 seven dead rats which were proved to have died of plague were found in the South-West India Dock; and in 1910 three dead plague rats were picked up in the Royal Albert Dock. Of 199 rats captured and examined last year, only three were plague-infected. Dr. Williams remarks that this occurrence of plague among the rats three years in succession indicates the need for special vigilance.

THE rhythmic character of the movement exhibited by the plasmodia of Myxomycetes is discussed by Dr. V. Vouk in the *Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften*, Vienna (vol. cxix., part viii.). The progressive and regressive flows together constitute a rhythmic period, which is found to be tolerably constant for the main streams of any given plasmodium. The period increases up to a certain point with the age and size of the plasmodium. Obviously mechanical stimuli upset the rhythmic flow.

THE frequent occurrence of localised hailstorms, generally of very short duration, as a typical phenomenon during late spring and summer in Missouri and Nebraska, prompted an investigation into the injury caused to forest trees, the results of which are communicated by Mr. F. J. Phillips in the Transactions of the Academy of Sciences (vol. xix., No. 3). Catalpa, sycamore, and mulberry suffered most both in the matter of defoliation and bark wounds. The soft nature of the bark on cotton wood and box elder was also apparent in the damage sustained. It is suggested that hail injury increases the development of *Polystictus versicolor* on Catalpa.

A NOTE on fungi collected in clay mines is communicated by Mr. P. Spaulding to the report of the Missouri Botanical Garden (1910). The greater number of the specimens were growing on the oak timbers used as supports. *Polystictus versicolor* and *Merulius lachrymans* were generally common, and *Merulius rubellus* was abundant in one mine. Stalked pendant forms of *Hydnum erinaceus* and *Schizophyllum commune* were also found. Only one fungus, *Fomes annosus*, was observed on the pine timbers, and *Coprinus atramentarius* was growing on the clay.

AN explanation of the differences observable in specimens of the common garden shrub, *Osmanthus Aquifolium*, is offered by Dr. O. Stapf in *The Kew Bulletin* (No. 4), as he is able to identify two plants, distinct both in foliage and flowers. The type of the original species has a leaf like the holly, and bears both hermaphrodite and staminate flowers. Another type, having leaves with shallower indentations, and for which only staminate flowers are known, fits in with a species segregated long ago as *Osmanthus Fortunei*. It has been suggested that the latter represents a hybrid between *O. Aquifolium* and *O. fragrans*; this opinion is supported by the characters, including the less hardy constitution, of *O. Fortunei*. Another item of horticultural interest is supplied by the note acknowledging the receipt of seeds of trees and shrubs collected in south-west China by Mr. Forrest. They include a number of rhododendrons, in connection with which the question arises whether any of them will supply a yellow-flowered hardy shrub so long desired.

THE systems of training and pruning fruit trees followed by the Japanese, as is the case with so many of their methods, are essentially different from those prevailing in European countries. According to the account by Prof. T. Ikeda, published in the Journal of the Royal Horticultural Society (vol. xxxvi., part iii.), a system—known as "tana"—of training the branches on overhead trellis-work is generally adopted for pears and vines, less often for plum and apple trees. The trellis is made of bamboos or wire fitted on wooden posts at a height of $5\frac{1}{2}$ feet and one to two feet apart; the pruning is very light, and is generally done in winter. Tana-training is said to offer advantages, notably in the matter of early fruit production and of protection from wind and rain storms. A more vigorous system of pruning is adopted in the case of Kaki trees, *Diospyros Kaki*, that appears to have arisen out of the practice of pulling the fruit with a portion of branch suitable for hanging it up to dry. The fruiting shoots are broken at the base, while the sterile shoots are left intact to produce spurs the next year.

WHAT is popularly known as "blackhead" in turkeys covers several different diseases, but one has been studied in some detail by Hadley and Amison, of the Rhode Island Agricultural Experiment Station, and traced to flagellated protozoa occurring in the cœcum. The organisms are identical with some previously described by Smith as *Amoeba meleagridis*; their development was studied, and found to resemble that of other parasitic flagellates which, at certain stages, have the habit of losing their flagella and becoming amœboid. They occur also in the English sparrow and other wild birds, several of which can act as hosts, and further they are found in game birds. So much damage is done that, in some districts, they constitute a severe menace to the poultry-raising industry.

SOME years ago Whitney and Means investigated the connection between the conductivity of a soil and the amount of saline matter present, and as a result of their experiments a method was elaborated whereby the percentage of soluble salts in "alkali" soils could be estimated in the field with sufficient accuracy for ordinary purposes and in a very short space of time. Thus a survey of a whole district could be made, and it was possible to ascertain the effects of irrigation, cultivation, &c., on the soluble salts of the soil. A bulletin has recently been issued by the United States Department of Agriculture giving the results of accumulated experience with the method. The writers, Messrs. R. O. E. Davis and H. Bryan, state that the method works well provided there is not too much organic matter present, and provided also carbonates are practically absent. In the former case it is better to drop the electrical method altogether, in the latter case the method can still be used, but a special set of tables is needed.

THE Canadian Department of Mines has sent us a volume, by Mr. F. Cirkel, entitled "Chrysotile-Asbestos, its Occurrence, Exploitation, Milling and Uses," which gives a very complete account of this extremely important Canadian industry. Asbestos is obtained from a relatively restricted area in the province of Quebec, but it has attained in a short time a most prominent position amongst the mineral products of Canada. The Canadian output at present is about 60,000 tons, forming about 80 per cent. of the total production of the whole world; it has practically doubled since 1904. The account now published, which is essentially a new edition of a previous report on the same subject and by the same author, issued in 1905, is a most exhaustive one, and deals very fully with all aspects of the asbestos industry, with the occurrence and distribution of the mineral, its mining and dressing, and with the subsequent manufacture of the prepared mineral into a large number of articles. Whilst, perhaps, more especially written from the commercial rather than the scientific point of view, it contains a quantity of valuable information not otherwise accessible, and should be of decided assistance to all who have to deal with asbestos either in the crude or in the manufactured state.

ON Monday, June 12, Dr. Arthur Neve, who has spent thirty years in Kashmir, lectured before the Royal Geographical Society on his journeys in the Himalayas and on some factors of Himalayan erosion. In Ladak erosion is at the present time not especially active, and the valleys are of easy gradient, but in Lower Baltistan and Gilgit rivers flow in deep gorges and have cut their way recently through immense accumulations of detritus. The rainfall is slight, and the dry, loose deposits, by their instability, are a source of considerable danger, which is greatly increased in the wet season, when vast landslips are common and rapidly alter the contour of the hillsides. Accounts were given of the damage caused by glaciers blocking up lines of drainage in such a way as occurred some years ago in the Saru valley. The lecturer's travels in the Karakorum range and the Nun Kun group in the Central Himalayas were referred to, and several points of doubtful topography were discussed. The subject of Himalayan erosion and topography were treated descriptively rather than analytically from experience gained in a long acquaintance with the region.

Le Radium for May contains a paper by M. de Broglie and L. Brizard in which their observations on the apparent radio-activity of sulphate of quinine are described. They find that the phenomena show neither of the characteristics of radio-activity—*i.e.* they are not atomic and are not independent of external influences. They have succeeded in tracing them to a thin layer of strongly ionised gas which surrounds the salt during hydration or dehydration, and they find that sulphate of chinchonine, which possesses the same phosphorescent properties as sulphate of quinine, shows the same effects. The search for other salts has not been successful. The mobility of the ions formed is of the order 1 centimetre per second in a field of 1 volt per centimetre, which shows that the ions are small. They may either diffuse slowly outwards from the layer in which they are formed or may be driven out more

quickly by an electric field. In the former case saturation currents can be obtained, in the latter the current increases indefinitely with the voltage applied. In either case the conductivity of the surrounding gas increases rapidly as its pressure is diminished.

Under the title of "First Report of the Bird Construction Committee," the Aëronautical Society of Great Britain has issued an attractive pamphlet, in which it is sought to summarise existing knowledge of the mechanical constants associated with the flight of birds. A special feature is the tabulated list of about 460 species of bird with numerical values of their wing dimensions, weights of their muscles, and similar data, compiled from the works of Harting, Marey, Moillard, Mullenhof, Legal and Reichel, and Winter. To the ornithologist, the list of Latin names with their equivalents in English, French, German, Italian, Spanish, and Russian will be exceedingly useful. Another pamphlet dealing with natural flight is Dr. Wolfgang Ritter's study of "The Flying Apparatus of the Blow-fly," published by the Smithsonian Institution (1911). For the first time in this connection, photography was used to delineate the structure of the wings and arrangement of the thoracic muscles, most of the illustrations being stereoscopic. Other figures give kymographic curves showing the movement of the wings, and serial photographs of the insect in the act of flight. Natural flight also figures in a pamphlet by Dr. Otto Wiener entitled "Vogelflug, Luftfahrt und Zukunft" (Leipzig: Johann Ambrosius Barth, 1911, pp. 60), based on the author's contributions to the *Deutsche Revue*. In addition, however, to sailing and other flight, the article deals with the influences of artificial flight in peace and war, its future effects on human progress, and other considerations of an equally general character.

OUR ASTRONOMICAL COLUMN.

The Eclipse of the Sun, April 17, 1912.—Next year's eclipse of the sun, although, under the best conditions, of very short duration, is arousing a great deal of interest owing to the proximity of the central line. It was at first suggested that a very brief totality might occur near Paris, but the slight uncertainty as to the moon's semidiameter makes this doubtful; probably it will be a very large annular eclipse there. According to the data of the *Connaissance des Temps* a six seconds' totality should occur in Spain, but according to those of *The Nautical Almanac* the eclipse will not become more than annular anywhere.

In the June number of *L'Astronomie* M. Landerer discusses the conditions for Spain, and, taking the moon's semidiameter as 15′ 31·62″, he finds that at one or two places in the peninsula an evanescent totality should occur. At El Barco (Orense) the eclipse path should have a diameter of 166 metres, and totality should last for 0·2s., so that an intending observer would have to make very sure of his position. Between El Barco and Penafiel (near Oporto) would probably prove a better station, the computed totality at the latter place being 0·4s. For Castandiello, a small village in the province of Oviedo, the computed magnitude is 0·9999, and the eclipse may easily prove total. All the places are shown on a map accompanying the article, and a special article dealing with the conditions for eclipse in France is promised in the next number.

The Changes on Jupiter, 1881–1909.—An important monograph of 180 pages discussing the features of Jupiter during the period 1881–1909 is contributed by Dr. O. Lohse to vol. xxi. of the *Publikationen des Astrophysikalischen Observatoriums zu Potsdam*, No. 62.

The observations of the various spots, bands, and other surface features of the planet are discussed individually, and the descriptions often illustrated by a sketch of the special feature made at the time of observation. Measures of the equatorial and polar diameters were frequently made with a filar micrometer, and are tabulated and discussed for each opposition. For the mean values Dr. Lohse obtains 38·343″ ± 0·059″ for the equatorial, and 36·031″ ± 0·044″ for the polar, diameter; the ratio expressing the amount of flattening is 1/16·584.

The changes in various features and many other interesting points are discussed, and the monograph concludes with twelve excellent plates, eleven reproducing drawings of the planet and the twelfth showing the normal joviographic longitudes of the Red Spot during the period 1879–1909.

Barnard's Comet, 1892 V.—The third return of Barnard's 1892 comet is due this year, and if the period lies between 6·23 and 6·52 years, as given by two of the three sets of elements prepared by M. J. Coniel, there is a chance of its being rediscovered.

To facilitate the search, M. Coniel publishes a comprehensive ephemeris in No. 4504 of the *Astronomische Nachrichten*, which is based on the assumption of a period equal to 6·37 years, and shows the places (for 1911) week by week from July 1 to the commencement of 1912.

The Motion of the Pole.—The provisional report of the results obtained by the International Latitude Service, for 1910, is published, as usual, by Prof. Th. Albrecht in No. 4504 of the *Astronomische Nachrichten*. The figure accompanying the paper shows that practically since 1906·1 the swing of the momentary, from the true, pole has been increasing; the curve for 1910·0–1911·0 encircles the previous spiral curve described since 1900·0. The x and y values (extrapolated) for 1911·0 are +0·002″ and −0·282″ respectively.

The Proper Motions of the Stars.—Several interesting conclusions are deduced by Dr. Oppenheim in a paper wherein he subjects to harmonic analysis the proper motions of the stars between declinations +38° and +65° given in the Greenwich new reduction of Groombridge's catalogue of circumpolar stars. He finds that the position of the stars into swarms along definitely directed "highways" is not finally established, and that their motions can be accounted for analytically by assuming a relative motion analogous to the geocentric paths of the minor planets, but he leaves the question of an ideal central body open (*Astronomische Nachrichten*, No. 4497).

Stellar Parallaxes.—More stellar parallaxes are given by Dr. Schlesinger in No. 4, vol. xxxiii., of *The Astrophysical Journal*. Seven stars are considered, and of these four have positive parallaxes greater than 0·1″. Among the latter, one of special interest is the well-known star Positiones Mediæ 2164, otherwise designated *Struve* 2398. The distance separating the components is now 17″, having increased nearly 5″ since the double was first measured by Struve in 1832. Recent measures show that the pair has a comparatively rapid orbital motion considering the great separation and the faintness of the components. Dr. Schlesinger finds the parallax to be +0·282″ ± 0·003″, and his results are so concordant, *inter se* and with independent determinations, that he considers that there are few stars the distances of which from us are known with so small a probable error.

Positions of Stars in the Huyghenian Region of the Orion Nebula.—As a Bulletin of the Philosophical Society (University of Virginia), vol. i., No. 4, Mr. Ralph E. Wilson publishes newly determined positions of a number of stars in the Huyghenian region of the Orion nebula. After reviewing the earlier work on the subject he gives his measures in detail; all the measures were referred finally to Bond's No. 628, but Nos. 558, 669, and 685 were also employed as fundamental stars. Six stars show what appears to be proper motion, which in the case of Bond's 612 and 618 amounts to 4″ or 5″ a century northwards. The motions of 622 and 636 can be explained by the supposition that they are physically connected with the trapezium and share its motion. In the cases of Nos. 686 and 688, the proper motions are affected by large proper motions, or Bond's positions are erroneous; observations in ten years' time would probably settle this point.

THE BRITISH SOLAR ECLIPSE EXPEDITION.[1]

T.S.S. "*Marama*,"
Pacific Ocean,
May 20, 1911.

MY last letter was very brief, as the ss. *Bouverie*, the steamer which ran on a coral reef and was subsequently got off, arrived unexpectedly at Vavau on her way to San Francisco. This meant that a mail could be sent by her, but only a short letter was written in consequence.

Although this letter is sent by the following mail to England, it happens that I am travelling in that particular mail steamer which is bound for Vancouver. We have therefore had a considerable time now to consider past events, and, incidentally, I have been down with a sharp attack of fever which I managed to pick up at Fiji; we are now three days off Honolulu, and I am convalescent.

Although during the first ten days of our stay at Vavau the weather conditions were all that could be desired for eclipse work, they gave way slowly to quite a different type; while rain had been the exception, it now became a daily occurrence, and not only did it rain, but it came down in torrents. This change of weather put quite a different complexion on our prospects. Nevertheless we worked and hoped for the best, but still the nearer the eclipse day approached the worse the weather became. On the day before the eclipse my notes regarding the weather are as follows:—"To-day would have been a bad day for the eclipse. There is a great amount of high cirrus which would have prevented good photographs from being secured, and the presence of low drifting cumuli would most probably have totally blotted out the sun for some period during totality. I expect the conditions to-morrow will be somewhat like Palma over again, but I hope the cloudy part will occur at third contact and not at second contact as it did there."

Luck was against us, however. Eclipse morning broke, and this was the cloudiest we have experienced. Cirro cumulus cloud in the form of waves extended over a considerable part of the sky, and low cumuli of various sizes were numerous. There was sufficient sun at intervals for all the instruments to be set and kept running, and I went round all the individual instruments and critically examined the definition of the solar images on the ground-glasses. Everything was most satisfactory.

I had arranged that all the working parties should be ashore at 7 a.m., and that the remainder should arrive half an hour later. The camp assumed a most business-like air, and everyone seemed glad that the day had at last arrived. I had taken the precaution to distribute parties as far apart as possible that could be distributed, and with this object I sent one party off early in the morning to take up their position on Talau Hill, 400 feet high and about three miles distant. This party consisted of observers for stars, shadow phenomena, and drawing the corona, and a small camera party. On another hill, 200 feet high and half a mile away, a second similarly constituted party was dispatched. A special party was also on board, and men placed at the mastheads.

Alas! with all these precautions no party saw the sun free from clouds. There is little doubt that, as the moon gradually covered the sun and a natural reduction of the air temperature took place, the tremendously moist atmosphere gradually condensed in the form of cloud, which became denser the nearer totality approached. Some minutes before second contact a very large black, dense cumulus with billowy tops came sweeping up from the eastward, and this cloud it was that practically sealed our doom. Onward it came, and just before second contact its outliers began to cover the sun and then totally eclipse it. The presence of the clouds made the image of the cusp very difficult to observe, as it was jumping up and down on the card. The cusp observer had eventually to give the signals from the chronometer alone.

Three whistles, two whistles, and one whistle were the signals to precede the order "go," and at "go" the whole camp began their combined effort. I fired off my first four instantaneous exposures, and then one of a few seconds, and then a long one. During this last I went out of my tent with opera-glasses and card and pencil to draw the corona, when, alas! I could not even see where the sun ought to be. The large ominous black cloud had completely blotted out the whole region. I returned to my tent very sad; at a later long exposure I emerged once more, and there was the silvery corona as rigid as an Indian order suspended in the sky. It was shorn of most of its beauty, for the cirrus cloud was very thick, and must have absorbed a great amount of light. There was no doubt about its form, however, for at a glance it represented the minimum type known as the wind vane.

FIG. 1.—Landing the Instruments.

Something extraordinary, however, seems to have happened. While the timekeeper shouted out twenty, *i.e.*

[1] Continued from p. 529.

FIG. 2.—In the early stages of the erection of the Instruments. View taken from a Cocoanut Tree.

FIG. 3.—A General View of the Eclipse Camp. Camera facing nearly West.

there are twenty seconds left, the sun burst through! The eclipse was over!

Being busy with my instrument at the beginning of totality, and not being able to see the sun because of the roof of my tent, I could not observe whether totality began with the word "go." A consultation with my *confrères* afterwards soon gave me the information I was seeking. The eclipse began fully twelve seconds before the word "go" was given, and finished twenty seconds before the word "stop" was shouted. This very considerable difference between calculation and observation seems at present unexplainable, but similar, or nearly similar, times were recorded by the other parties at Neiafu.

In addition to three chronometers, regular transit observations had been daily made with the transit that was set up on a concrete pillar in our camp. The ship's chronometers were also in very close agreement with those we brought out, so there could be no error of any magnitude regarding the time. This important matter will be cleared up when Mr. Brooks, who has the matter in hand, sends in his report on the subject.

The eclipse being over, I called my party together, and we gave three cheers for the captain, officers, and men of H.M.S. *Encounter* for the magnificent assistance they had rendered on the occasion of this eclipse. It was most disappointing that the weather had been so unfavourable, for had it been otherwise we should have gathered a wonderful harvest of valuable solar data.

While we were so hard dealt with at our station, the Australians at Neiafu, about a mile from us, suffered nearly the same experience. They watched the approach of the large cloud, and thought that it would affect them and not us—it affected both of us, however, with disastrous results. A hundred yards or so distant from the Australian camp was that of Mr. Worthington and his party. He seems to have been wonderfully lucky, for in spite of all the clouds about, a rift in them enabled him to secure some beautiful photographs of the corona, as good as the best photographs that have ever been taken during an eclipse. I have not seen the negatives myself, but everyone who has is most enthusiastic about them.

On development of the photographs of my party, the useful results are very meagre. No record at all was shown on the large films of the large grating spectrograph worked by Mr. McClean. On the 6-inch prismatic camera plates one plate may be very useful. This plate was closed at twenty seconds according to the eclipse clock, *i.e.* was closed about half a second after third contact. All the chromospheric large arcs are well shown, and a great number of short bright arcs, showing that a record of the chromosphere was secured. There is a certain amount of continuous spectrum shown on the plate, but the spectrum is rich in lines in the violet end. A plate exposed immediately after this gives a dark-line spectrum. Several of the coronographs show images of the corona sufficiently good to enable the general form of the corona to be deduced, but they all show too much cloud. The 4-inch 16-foot coronograph has perhaps the best record of the lower corona, and this is beautifully sharp and gives a very fine photograph of the large prominence, the most conspicuous object just before third contact.

FIG. 4.—The Captain and his two time callers at the Eclipse Clock.

The above practically sums up the results of the expedition from the astronomical side. In other directions we have positive results. Thus a fine series of observations made with the self-recording barograph, thermograph and hydrograph have been secured. A very complete collection of botanical specimens representing the wild flowers, ferns, &c., and numerous seeds, of the island will, I hope, prove useful.

An excellent collection of butterflies and moths representing most of the varieties has been made, and we are bringing home numerous pickled specimens of fish, centi-

pedes, lizards, ants, scorpions, &c. Geological specimens were not numerous, but what there were were secured. A large number of specimens of shells and different varieties of coral were also collected.

The day following eclipse day, a Sunday, it rained steadily from morning until night. The camp became a hopeless morass; every tent was saturated through and through, and most of the contents as well. Fortunately, packing up had been commenced directly totality, of the day before, had finished, and by the evening the greater portion of all the instruments were safely housed away in their packing-cases in the instrument tent. Fortunately, again, I had had the floor of this tent covered with thick rafters to keep the cases off the ground, and if it had not been for this precaution the cases would have been thoroughly soaked. The rain therefore did little damage. We filled as many barrels as we had with the water from the awnings, and this came in extremely useful for the dark-room during the subsequent days spent in developing and making copies.

I had two special boxes made on board the ship to carry the original negatives, and the copies and one box will go home with the rest of the packing-cases, while the second will be dispatched later by a different steamer to England.

On May 3 the ss. *Tofua* arrived at Vavau on her way to Sydney, and I boarded her to inquire from her captain what he had seen of the eclipse. Captain Halford had stopped his ship right on the central line, and they viewed the eclipse in a cloudless sky. Several drawings which were made on board were shown to me, and they all indicate similar appearances, namely, equatorial extensions and rifts at both poles. Shadow bands were very conspicuous, and a great number of stars were logged. The captain kindly had a copy of his observations made for me, as I wished to compare the times of his contacts with those observed by us.

In the evening the *Tofua* left with all the eclipse parties except those going by the *Encounter*.

The next morning the *Encounter* weighed anchor from the spot where she had remained so long. I think we were all very glad to get away. If we had had a successful eclipse we might have severed our connection with a pang of regret. There were no regrets. We had worked hard and been treated very badly, and some of us, myself included, hoped we should never see the spot again. Out of the little harbour we steamed, stealing away before the inhabitants were up. One by one we passed the thickly tree-covered islands, and at last we came to the open sea and the cooler air, leaving the pests of flies and mosquitoes behind us. Oh those flies and mosquitoes; they were the curse of the island!

The *Encounter* being now bound for Suva, Fiji, to coal, and land Mr. McClean and myself, our course was shaped for that island. In order to make all land by daylight, a six hours' stop was indulged in off Late Island. This island is on the western outskirts of the Tonga group, and is nothing but a large volcano. With difficulty a landing was made, and while one party, including myself, started out to climb to the crater, another party went to shoot pigeon and pig. Incidentally, I made a good botanical collection, and gathered numerous specimens of seeds. On our return to the shore the tide had gone down, and the pools in the lava were full of the most beautiful coral fish and snakes, weird in colour and shape, that one could desire. An exciting return to the boats ended quite a successful day's adventure. The next day was spent at sea, and we sighted Suva on Saturday morning (May 6). Being "Accession" Day, the ship was dressed as the anchor was let go.

Mr. McClean, Mr. Anderson and myself took up our quarters at this port to await our ship, the t.s.s. *Marama*, which was to take us to Honolulu. On May 11 H.M.S. *Encounter* steamed gracefully out of the harbour on her way to Sydney, and it was sad to see her go without us, for both officers and men had become quite endeared to us. However, it had to be, and we watched her until nothing more than smoke was visible.

At Suva there was little to be done, as it was very hot, but there were no flies and very few mosquitoes, so we might have been worse off. On May 13 we drove to Rewa, a distance of twelve miles, and then took a motor-boat up the fine river Rewa, the upper reaches of which are very beautiful. To me this trip was disastrous, for next day I was laid up with fever. On May 15 our steamer, the *Marama*, bound for Honolulu and Vancouver, arrived, and we boarded her and sailed the same evening. At the moment of writing (May 21) we are now two days off our destination, and we are indulging in the cool N.E. trades after the stillness of the doldrums.

After Honolulu we are bound for the States, where I hope to see first hand the chief American astronomical observatories. We are due in England about July 11, when we shall have completed a most interesting circuit of the earth. We shall have gained one day!

W. J. S. LOCKYER.

A NEW ROD OF AARON.

THE naturalist and the physiologist have been well acquainted for several years with the results achieved by Loeb, Delage and others, in the way of causing the eggs of various animals to develop by chemical and other purely physical means, apart altogether from the agency, direct or indirect, of the male animal; but these astonishing experiments are still very little known to workers in other sciences. Before directing attention, as is the object of this short note, to the last and perhaps the most startling of all such experiments, it may be worth while to say a few words on the general question.

The subject seems to fall under two heads, namely, artificial means of facilitating the action, or of widening the sphere of action, of the male element, and, secondly, means of dispensing with it altogether and of replacing it by some wholly artificial stimulus.

In Loeb's early experiments he showed that, while under normal conditions the eggs, for instance, of a sea-urchin could not be cross-fertilised by the sperm of a starfish, yet by simply rendering the surrounding sea water faintly alkaline, a new condition was established in which the sea-urchin's eggs were capable of fertilisation by the sperm-cells of any or every species of starfish, and by certain other alien species of echinoderms besides, while, at the same time, in this more alkaline sea water the sperm of the original sea-urchin had actually lost the power of fertilising the eggs of its own species.

More than five-and-twenty years ago it had been shown, by Tichomiroff and others, that the eggs of the silkworm could be caused to develop "parthenogenetically" by simple mechanical stimulation, such as brushing, or by chemical treatment, as with sulphuric acid. But these results attracted less notice than they should have done, partly, perhaps, because in other insects parthenogenesis, or the development of unfertilised eggs, was known to occur under natural conditions, as in the case of greenflies or plant-lice (Aphides), or in the case of the drone-progeny of the queen-bee.

Passing over various intermediate experiments, we come to those which Loeb published in 1904, in which he showed that, if the eggs of a sea-urchin be put into sea water to which has been added a little formic, acetic, butyric, or other fatty acid, and then after a minute or two be put back into ordinary sea water, they begin to show the initial changes characteristic of nuclear division. But if, on the other hand, they be transferred from the acidified sea water to sea water the concentration of which is increased by a suitable addition of common salt, then the whole cycle of development proceeds just as though normal fertilisation had taken place, and the highly complicated free-swimming larvæ are produced in unlimited numbers and in the same manner and at the same rate as in the ordinary course of sexual development; and if the experiment has not been carried further, to the complete post-larval development of the entire sea-urchin, it must be remembered that the artificial feeding and rearing of this and other marine animals beyond a certain stage, even from normal and fertilised eggs, is a matter of the very greatest difficulty. Precisely similar experiments have been successfully performed by various workers on marine worms and molluscs, and a few years ago Bataillon showed that even the eggs of the lamprey could be induced to segment by simply placing them in water of a certain

degree of salinity. It is impossible to discuss here the various theories of fertilisation to which these astonishing experiments have given rise.

But such phenomena appear, perhaps unreasonably, all the more astounding to us, as the animals experimented on are higher in the scale; and so we may look with renewed wonderment at a phenomenon which M. Bataillon has demonstrated in the frog, and M. Henneguy has repeated and confirmed.[1] Eggs were taken from the body of a female frog, under proper antiseptic precautions and with careful simultaneous "control" experiments. The eggs were placed in a little dish, and were then carefully pricked with a tiny needle of platinum or a sharp spicule of glass, after which they were covered with a layer of water sterilised by heat. In the hands of these physiologists, the little needle was as potent (or almost as potent) as Aaron's Rod. In about four hours the eggs began to develop, but while all of them passed through some initial stages, it was about one-fifth only that segmented in the normal way. At every stage the mortality was greater than in the case of ordinary fertilised eggs, but at length, out of a thousand eggs experimented on, one hundred and twenty hatched into tadpoles, and of these three were reared through parts of their metamorphosis. They did not actually turn into frogs, but died accidentally or for want of proper nourishment after the appearance of their legs, and after the oldest (about three months old) had all its four legs well developed and its tail already beginning to disappear; it was, in short, all but a perfect frog. As with St. Denis, when he walked a short distance with his head under his arm, "ce n'est que le premier pas qui coûte"; but these tadpoles, if they did not endure to the end, went a long distance on their way.

It is all but superfluous to add that the authors of these researches are men of high standing and reputation, skilled in all the precautions necessary for the carrying out of their experiments and for safeguarding them from all sources of accidental error. In short, we may have no doubt at all that what they assert they have actually performed—that they have demonstrated the artificial fertilisation of a vertebrate ovum by a simple mechanical stimulus, and that, so to speak, they have raised a hybrid between a needle and a frog! But here we are face to face with the double *rôle* which the male plays in the process of fertilisation, for, on one hand, it is his part to give the initial impulse or stimulus to the act of development, and on the other to convey to the offspring a share of his own hereditary qualities or characteristics. In these artificial experiments of parthenogenesis the two influences are dissociated. The former one is efficiently replaced by chemical or mechanical means, but the other drops out of sight altogether. For, as a French critic has remarked, "il ne peut être question d'hérédité du côté du père, car on ne voit pas très bien les jeunes grenouilles héritant des propriétés de leur épingle paternelle"!

D. W. T.

AGRICULTURAL RESEARCH IN CEYLON.[2]

THE staff of the Royal Botanic Gardens, Ceylon, show commendable activity in investigating the planters' problems that come under their notice. At frequent intervals issues are made of the Circulars and Agricultural Journal containing their papers, which will be found to bear comparison with any publications from other experiment stations. These papers show an obvious mastery of the situation, they are conceived in a scientific spirit, and exhibit none of the looseness characteristic of amateur investigations into agricultural questions. Tea and rubber naturally come in for a good share of attention, but other crops also present their problems, many of them of considerable interest and importance.

As usual in subtropical countries, most of the problems are connected with insect and fungoid pests, and half of the present batch of publications are from the mycologist, Mr. T. Petch. Five root diseases of tea caused by fungi are described. The commonest is caused by *Ustulina zonata*, Lév.; the dead tea roots show no external mycelium, but only a few inconspicuous black spots; if the cortex is removed, however, white fan-shaped patches of mycelium are found overlying the wood. The starting points of the disease are usually the dead stumps of Grevillea, which is grown among tea, and cut down either for firewood or when it has grown too large. Another common disease is caused by *Hymenochaete noxia*, Berk., a fungus that attacks numerous other plants. Here the mycelium is external to the root, and binds up a mass of sand, earth, and small stones, thus forming a crust 3 or 4 mm. thick; in the early stages the mycelium is brown, whence the name brown root disease has been given; later on, however, the whole turns black. It is the commonest root disease of Hevea in Ceylon, but does less damage than *Fomes semitostus*; unlike the latter, it does not spread through the soil, but only along the roots of trees; hence its progress is so slow that, as a rule, the first affected tree is dead before the neighbouring trees are attacked. Another root disease of Hevea, so far uncommon, is also described. It is caused by *Sphaerostilbe repens*, B. and Br., and is characterised by the black or red flattened strands running over the surface of the wood after the cortex is removed, there being no external mycelium. *Acacia decurrens*, which has been extensively planted as a wind-break for tea or for green manuring, and for more than thirty years seemed immune from disease, has now been found to suffer from two root diseases in addition to a "gummosis," the cause of which is not yet ascertained. An agaric, *Armillaria fuscipes*, causes one root disease, and *Fomes australis* the other. Another publication deals with canker in cacao and hevea. The latter plant does not usually suffer from canker when grown alone, but it is badly affected when grown in mixed plantations with cacao, which serves as a permanent source of infection. It is concluded that both canker and pod diseases are caused by *Phytophthora faberi*, Maubl.; complete examination was, however, made of the other fungi also present.

Mr. E. E. Green describes the extraordinary outbreak of snails, *Achatina fulica*, that has occurred in part of the island, and to which reference has already been made in these columns. This snail is large, its shell being about 4½ inches long, and weighs about 4 oz. It has only recently been introduced, but it has not effected nearly so much damage as might have been expected, because it feeds on human and cattle excreta; indeed, Mr. Green considers that, on the whole, it is doing more good than harm, and does not recommend any drastic attempts at extermination. Before long the natural enemies will keep it down.

Messrs. Kelway, Bamber, and R. H. Lock give a preliminary account of their studies on the effect of different intervals between successive tappings in Para rubber. A previous investigator, Parkin, obtained an increase of more than 600 per cent. of latex by increasing the frequency of tapping; Bamber and Lock, on the other hand, find no such marked wound response, although they advise frequent tappings from the practical point of view.

The official correspondence with regard to cotton-growing in Ceylon is also published. Dr. Willis does not think there is much future for the crop; other products yielding larger profits are not likely to be displaced. There is also a useful account of various samples of Cymbopogon grass oils prepared by Mr. Jowitt, of Bandarawela, and examined at the Imperial Institute.

ABSORPTION SPECTRA OF METALLIC SALTS.[1]

THE present volume is designed as a continuation of the work of Jones and Uhler and Jones and Anderson, and gives the results of a detailed study of the absorption spectra of salts of potassium, cobalt, nickel, copper, chromium, erbium, praseodymium, neodymium, and uranium, as affected by various chemical reagents and different temperatures. For the purpose of the discussion some 3000 solutions have been examined. The main points

[1] "A Study of Absorption Spectra." By H. C. Jones and W. W. Strong. Pp. ix+159+98 plates. (Washington, D.C.: The Carnegie Institution, 1910.

of investigation have been the effects of the addition of free acids and foreign salts on the absorption spectra. A notable result is the discovery of well-defined "solvent bands" for various substances, for example, water, alcohols, acetone, glycerol, which do not show any appreciable absorption of visible light.

In general it is shown that the *anions* of the various coloured salts play a much less important *rôle* in modifying the spectra than the solvent. Different salts of the same anion in the same solvent usually have the same absorption spectra. As, however, the absorption spectra of the powdered salts may be very different, it is evident that the solvent has an important part in the mechanism of absorption.

On the other hand, the absorption spectra of the same salt in different solvents are often very different; Jones and Anderson have ascribed this to the formation of *solvates*, more or less stable compounds of the salt and solvent. The persistence of solvent bands varies quite widely for the different solvents, appearing to be greatest for water and less for the alcohols.

Some of the uranous salts in the various solvents, water, alcohols, acetone, and glycerol, show characteristic bands very strongly. An attempt is being made to correlate many of these well-defined phenomena with the results of the Zeeman effect on similar variations of the salts and solutions, and it is considered that the results of such investigations may lead to a much clearer knowledge of the chemistry of compounds. In some cases it is possible to break up the absorption bands into very fine bands by chemical methods, as has been done with uranyl and uranous salts in acetone solutions, the most marked example being the action of hydrochloric acid on an acetone solution of uranous chloride.

A very noticeable result is the action of free acids on the corresponding uranyl salt, *e.g.* acetic acid on the acetate, nitric acid on the nitrate, &c. In most of these cases the presence of these foreign reagents causes the uranyl bands to become more intense, and, in most cases, narrower. The action of all except nitric acid is to cause the uranyl bands to be shifted towards the red. Nitric acid, on the contrary, produces large shifts towards the violet. A very important result of this analysis is that the absorption bands gradually shift as one salt of a metal is transformed into another by the addition of free acid. This is interpreted to mean that a series of intermediate products are formed, each with its characteristic absorption spectrum, although the chemical methods at present at our disposal do not enable us to isolate them.

It is also shown that rise in temperature causes the general absorption of any salt in water to increase, and the bands to broaden and become more intense.

The authors summarise the discussion as to the bearing of this work on the solvate theory of solution.

An excellent series of ninety-eight photographic reproductions of the spectra is included in the volume.

C. P. B.

THE ROYAL SOCIETY CONVERSAZIONE.

THE ladies' conversazione of the Royal Society was held at the rooms of the society in Burlington House on Wednesday, June 14. Many objects and experiments of scientific interest were on view, but most of them were described in our account of exhibits at the previous conversazione on May 10 (NATURE, May 18, p. 394). It is unnecessary, therefore, to refer to these again. Among other exhibits at last week's function were those described in the subjoined summary of the official catalogue.

The Director, Khedivial Observatory, Helwan, Egypt.—Photographs of Halley's comet, taken with the 30-inch Reynolds reflector by Mr. H. Knox Shaw. The photographs exhibited cover the period from April 16, 1910, to June 10, 1910. *Royal Astronomical Society.*—Photographs of the planet Mars, taken by Prof. E. E. Barnard with the 40-inch telescope of the Yerkes Observatory. The photographs of September 24, 1909, show the region of the Fastigium Aryn and Margaritifer Sinus, and those of September 28 the region of the Syrtis Major.

The Director, Royal Botanic Gardens, Kew.—(1) Collection of Euphorbias, showing mimetic resemblance. The following species of Euphorbia, selected from the collections at the Royal Botanic Gardens, Kew, show remarkable resemblance in habit to plants of other natural orders to which they are in no way related botanically. The species of Euphorbia, together with the plants they resemble, were exhibited side by side.

(1)	*Euphorbia Berthelotii*	*Cotyledon lineolare.*
(2)	,, *colletioides*	*Rhipsalis micrantha.*
(3)	,, *dendroides*	Willow twigs.
(4)	,, *hystrix*	*Cereus insularis.*
(5)	,, *Intisy*	Prunus twigs.
(6)	,, *polygona*	*Cereus polygonus.*
(7)	,, *Schimperiana*	*Ceropegia fusca.*
(8)	,, *Sipolisii*	*Vitis quadrangularis.*
(9)	,, *stapelioides*	*Stapelia micrantha.*
(10)	,, sp.	Pelargonium sp.
(11)	,, *Tirucalli*	*Senecio junceus.*
(12)	,, *xylophylloides*	*Epiphyllum truncatum.*

(2) *Ficus Krishnae. F. Krishnae*, a remarkable species most nearly allied to *F. bengalensis*, in which the leaves are cup-shaped, the inside of the cup being formed by the under surface of the leaf. *Mr. W. Fawcett.*—A parasitic flowering plant from Jamaica (*Scybalium jamaicense*, Schott and Endl.). This species is one of the Balanophoraceæ, a family of parasitic flowering plants growing on the roots of trees in tropical forests. They do not develop chlorophyll, and are therefore altogether dependent upon their host for sustenance. The seed contains an embryo of the simplest structure, having neither cotyledons nor radicle; it germinates in the soil, the embryo grows in length, thread-like, until it touches the root of a tree, and then penetrates it. When established on the root it forms a tuberous rhizome, from which flowering stems are produced. The flowers are very small, numerous, in heads on a stalk covered with scales—male and female flowers on distinct heads. This species is found in Jamaica, Cuba, and Hispaniola. Other species occur in Brazil and Colombia. *Mr. P. S. U. Pickering, F.R.S.*—Germination of seeds in heated soil. When soil is heated there is formed in it a substance toxic towards the germination of seeds and the growth of plants. Seeds germinate more slowly and in smaller proportions the higher the temperature of heating up to 250°. By exposure to air and moisture the toxic substance is destroyed. Plants grown rapidly in previously heated soil also show the presence of a toxic substance, but after this has become decomposed, such soil, owing to increased soluble contents and altered bacterial conditions, promotes plant growth.

Dr. G. H. Rodman.—A series of stereoscopic transparencies illustrating the life-history and minute structure of the stick insect (*Bacillus rossi*). Stick insects are natives of warm climates (India, Australia, the Malay Peninsula), but with care they may be reared in this country. They resemble, as their name suggests, portions of stick, and they afford an excellent example of mimicry. The various stages during the escape of the insects from their eggs are shown. The feet are provided with a pair of sharp hooks, by which they can cling to rough surfaces, and also with a pad or sucker, which enables them to get a foothold on perfectly smooth surfaces. The eye is a compound one, and faceted. They stand prominently out from the surface of the head, and are covered at will by the insect extending his forelegs directly forward in the long axis of his body. The skin is cast several times during the growth of the insect. It is shown that the antennæ and surface of the eyes share in the desquamation of the insect. *Dr. Francis Ward.*—(1) Photographs of fish life, as seen from below the surface of the water. (2) Photomicrographs of the growth of larval fish (plaice) taken from life. The photographs are taken in a pond specially constructed for the purpose. In one wall of the pond is a large open space which communicates with an observation chamber, and between this chamber and the water in the pond is a sheet of plate glass. Concealed in the chamber, the observer can watch the fish as they appear to each other in the water. In consequence of the darkness in the chamber and the light in the pond, the glass acts as a mirror, and the fish merely sees himself and his surroundings reflected, while the observer can plainly see into the pond. It is thus possible to observe a timid fish without disturbing him. In addition, an instantaneous

photograph can be taken at 1/250th of a second. *Dr. W. N. F. Woodland.*—Microscopic preparations and a model illustrating the mechanism employed in the production of the oxygen used to inflate the gas bladder of bony fishes. Most fishes employ oxygen (usually also nitrogen and carbon dioxide) for the inflation of the gas bladder (incorrectly termed "air" and "swim bladder") when this is present. The presence of oxygen is associated with the power of producing relatively rapid variations of the quantity of gas in the bladder, a power required in deep-water fishes which sink and rise, and so experience considerable changes in external pressure. A special gland, the oxygen gland ("gas gland"), and an equally important and very remarkable supplementary apparatus, the rete mirabile duplex, are developed in the bladder wall for the special purpose of producing the oxygen. The reason why oxygen is the gas employed for the inflation and deflation of the bladder is because of its abundance in the blood stream and the facility with which it is dissociated from (the red blood corpuscles undergoing disintegration for the purpose) and reassociated with the hæmoglobin of the blood.

Miss Dorothy Bate.—(1) Fossil remains of the peculiar goat-like animal *Myotragus balearicus*, Bate, from Majorca. (2) Photographs of the locality and caves in which the bones of Myotragus were found. Nothing is known of the habits or origin of this peculiar animal, which formerly inhabited Majorca in large numbers. Myotragus differs from all other goats, sheep, and their allies in having only two lower front teeth, which are very large and are modified to form a sharp chisel-edge; they grow continuously, like those of a gnawing animal such as the rat or rabbit. It is also remarkable for the shortness and stoutness of its metacarpals and metatarsals, the latter being usually united to the distal row of ankle bones. *Dr. C. W. Andrews, F.R.S.*—Remains of Tertiary mammals from near Lake Victoria Nyanza, British East Africa. The specimens shown are the first remains of Tertiary mammals from Central Africa. They are portions of the lower jaw with teeth, and a calcaneum of a small species of Dinotherium, which is very similar to *Dinotherium cuvieri* from the Lower and Middle Miocene of France. The age of the African beds is not yet definitely known, since it is possible that Dinotherium may have survived in Central Africa long after it had become extinct elsewhere. The specimens were obtained through Mr. C. W. Hobley, C.M.G., Commissioner of Mines. *Mr. G. C. Crick.*—Models of shells of extinct cephalopods. The models represent the shells of three cephalopods which lived in the Silurian seas and possessed chambered shells like that of the living pearly nautilus, but differed therefrom, among other characters, in the contracted form of the aperture of the body-chamber. *Mr. C. Forster-Cooper.*—Part of a collection of fossil mammals from the Lower Miocene beds of Dera Bugti, Baluchistan. (1) Jaw of a specialised type of primitive Rhinoceros; (2) separate lower incisor of primitive Rhinoceros; (3) portion of cranium of primitive Rhinoceros; (4) upper molar tooth of primitive Rhinoceros; (5) astragalus of primitive Rhinoceros; (6) mandible of Aceratherium, sp.; (7) teeth of mastodon, sp.; (8) upper teeth of Rhinoceros; (9) upper and lower teeth of an Anthracothere; (10) portion of a mandible of an anthracothere.

Nubian Archaeological Survey.—Objects found in the area to be submerged on the raising of the Aswan Dam. (Exhibited by the late Director-General of the Survey Department of Egypt, Captain H. G. Lyons, F.R.S., and the present Director-General, Mr. E. M. Dowson, on behalf of the Egyptian Government.) (1) Decorated pottery and other objects of the early dynastic period in Nubia (Dynasties I. and II. in Egypt, *circa* B.C. 3000), at which date Nubia was occupied by the Egyptian race. The hand-made pottery differs from that of the same period in Egypt in form and decoration, possibly owing to the geographical position of Nubia and to the rarity of stone vessels, the manufacture of which appears to have checked the development of fine hand-made pottery for funerary purposes in Egypt. (2) Decorative pottery and other objects illustrative of the non-Egyptian culture of the race (C group) which occupied Nubia from about the close of the old kingdom until it was expelled or absorbed by the military expeditions of the twelfth dynasty and the Egyptian colonies of the early new Empire. The incised pottery and steatopygous dolls show marked analogies with similar objects of the pre-dynastic Egyptian period of nearly 2000 years before.

Mr. Albert Bruce-Joy.—Bronze statue of the late Lord Kelvin by Mr. Albert Bruce-Joy, to be placed in Belfast. The likeness represents Lord Kelvin as he appeared about twenty years ago. The statue will ultimately be placed on a granite pedestal.

SHELL-FISH AND THEIR RELATION TO DISEASE.[1]

THE connection between the consumption of edible shell-fish (molluscs) and certain diseases, in particular typhoid or enteric fever, has in recent years attracted the attention of epidemiologists, and several valuable contributions on the subject have been published in this country. In 1894 Dr. Bulstrode reported to the Local Government Board on "Oyster Culture in Relation to Disease," in which he concluded that there remains "much to be done before the public can consume oysters, bought promiscuously, with a reasonable degree of safety." The danger of oysters was again brought home to the public by the outbreaks of enteric fever following banquets at Winchester and at Southampton in 1902, on which Dr. Bulstrode also reported.

Cockles and mussels have likewise been implicated in the dissemination of enteric fever in and about London and elsewhere.

The matter has assumed such importance that a further report on the subject by Dr. Bulstrode has been communicated to the Local Government Board, and brings up to date and extends our knowledge of the relationship between the consumption of shell-fish *other than oysters* and the occurrence of disease among those consuming the shell-fish. The molluscs of chief importance are cockles and mussels, and the beds are found all round our coasts, particularly in the estuaries of rivers, which are frequently liable to sewage pollution; but a part of the supply is obtained from abroad, America and Holland chiefly. In the report, the distribution of the shell-fish is shown on maps, and also the relation of the beds to the neighbouring sewer outfalls. The possibility of contamination is critically surveyed from a consideration of all the local factors, for the proximity or otherwise of a sewage outfall to a bed does not necessarily imply contamination or purity respectively; much may depend, for instance, on tidal conditions, on the absence of water at low tide, on the period at which the sewage is run out, &c. Again, even if the shell-fish beds themselves are remote from sources of pollution, the shell-fish may be brought to polluted waters for cleansing or storing, and several examples are given of this in the report. Bacteriological investigations have been excluded from the report, because it was considered that the topographical test would, on the whole, afford the least conflicting evidence.

Although shell-fish such as cockles are cooked before use, the "cooking" is often a very perfunctory affair, and by no means sterilises. At Leigh-on-Sea, however, owing to definite proof of the conveyance of enteric fever by the fish, the cockle merchants have provided forms of sterilisers or autoclaves in which the fish are exposed to steam under pressure. In the coppers in which the cockles are ordinarily boiled, while the bottom layers may be sterilised, the upper layers very often certainly are not.

The epidemiological evidence connecting the consumption of shell-fish with the subsequent occurrence of enteric fever or gastro-enteritis is detailed in chapters vi.–x. of the report. While in numerous instances it has been possible to connect the consumption of shell-fish with a subsequent direct outbreak of enteric or gastro-enteritis, it is more difficult to connect a part of the ordinary and sporadic incidence of these diseases with the general con-

[1] Report on Shell-fish other than Oysters in relation to Disease. By Dr. H. Timbrell Bulstrode. Pp. viii+243. Supplement in continuation of the Report of the Medical Officer. Thirty-ninth Annual Report of the Local Government Board, 1909–10; (London: Wyman and Sons, Ltd.; Edinburgh: Oliver and Boyd, Dublin: E. Ponsonby, 1911.) Price 8s.

sumption of shell-fish. The evidence marshalled by Dr. Bulstrode for this connection must, however, go a long way to dispel any doubt, if such exist, of its reality. The evidence, of course, is largely indirect, and comprises such details as these: the greater incidence of enteric among those who eat shell-fish than among those who do not; diminished incidence of enteric coinciding with diminution in the amount of sewage emptying into estuaries, &c.; the "cooking" of shell-fish diminishing the incidence of disease; reduction in enteric fever prevalence coinciding with limitation of the consumption of shell-fish; and (sometimes) seasonal variations in the shell-fish supply coinciding with seasonal variations in disease.

Finally, one of the most important parts of the subject, the administrative control of contaminated shell-fish, is dealt with. The difficulties in this direction are very great. Ineffective efforts at legislation have been made, and, failing success, the authorities concerned have fallen back on the publicity secured by local posters, &c., which, of course, affects the sale of wholesome, as well as of unwholesome, shell-fish. The Fishmongers' Company and several corporations have done excellent work, and one or two local Acts have been obtained (*e.g.* by the Corporation of Blackburn in 1908) to deal with the matter, but otherwise practically no control, in a sanitary sense, has been exercised over the beds, laying, and cleansing and storing places. Probably the local application, as required of the powers contained in the Public Health (Regulations as to Food) Act, 1907, would generally suffice.

The whole report is a very valuable one, and should arouse public attention to the necessity for taking definite action to deal with the subject of the contamination of shell-fish. The report is prefaced by a lucid introduction by Dr. Newsholme, the Board's medical officer, from which we have drawn freely in writing the above.

R. T. H.

THE CHEMISTRY OF MUMMIFICATION.

MR. A. LUCAS has rendered a great service to all who are interested in the customs of the ancient Egyptians and in the history of the methods adopted for the preservation of the body by collecting into one convenient volume the results of his investigations concerning the "Preservative Materials used by the Ancient Egyptians in Embalming," which has been issued as Survey Department Paper No. 12 (Cairo: National Printing Department, 1911).

More than seventy years ago Dr. Pettigrew published an exhaustive account of the chemistry of mummies, so far as this was possible at that time, and he had the assistance of Michael Faraday in his investigations. Since then the whole subject of mummification had fallen into the hands of archæologists, who invented a curious alchemy of their own for the purpose of interpreting the accounts of Egyptian embalming given by the ancient Greek writers; but during the last ten years this era of sensationalism has received its quietus, and a serious attempt has been made to elucidate by recognised scientific means the nature of the methods of mummification.

Recent investigators have had the immense advantage of having many hundreds of mummies of known age and provenance for every unknown mummy that came into Pettigrew's hands; and the enormous strides in chemical knowledge that the last seventy years have witnessed have made it possible to obtain much more information from the material than was possible before. Most of the embalming materials thus rescued have been analysed by Prof. W. A. Schmidt, of the Cairo School of Medicine, and Mr. Lucas, analyst to the Egyptian Survey Department, and the results of their work have been published in various scientific journals published in Egypt and Europe. Mr. Lucas has collected all this scattered information and added to it in this valuable report. He has also given an extensive bibliography, which, though not quite complete, will be of very real service to archæologists, who in the past have been at a loss to obtain accurate information upon such matters as are discussed in this work.

AN IMPERIAL BUREAU OF ANTHROPOLOGY.

WE print below a memorial relating to the formation of an Imperial Bureau of Anthropology, received from the Royal Anthropological Institute. The memorial was sent a few days ago to the secretary of the conference, to Mr. Asquith and each of the other Prime Ministers, and to the Colonial Secretary. Though the matter did not appear on the agenda of the Imperial Conference, we learn that the individual members of the conference are cognisant of the facts, and one or two are desirous of obtaining more information. We trust it will be possible for some action to be taken on the lines suggested by the memorial.

Memorial on the Establishment of an Imperial Bureau of Anthropology presented to the Imperial Conference by the Royal Anthropological Institute.

The Council of the Royal Anthropological Institute desires to submit the following facts for your consideration:—

(1) An important and an integral portion of the problem of Empire is that which is concerned with the relations of the Imperial race with dependent peoples whose history, religion, social structure, and habits of life and thought are far removed from ours.

(2) The social characteristics of the dependent races are being profoundly modified by contact with our civilisation, and experience has shown that habits of life and thought, the products of long ages, have a tendency to disappear under modern conditions.

(3) The council urges, also, that on administrative grounds an exact and an intimate knowledge of the mental attitudes and modes of life of these races is essential to those whose duty it is to govern them.

(4) As the body representing the premier scientific institution in Great Britain whose object it is to promote the organised study of mankind, the council is much concerned with the inevitable loss to science consequent on the extension of our civilisation; but the manners and customs of many semi-savage tribes in the Empire still survive, and are worth the serious attention of the scientific anthropologist. It urges, therefore, that the resources of modern science should be thoroughly and systematically employed in order to record those customs which are of such value and interest to the student of anthropology.

(5) Another important problem of Empire is the physical improvement or deterioration of all the races of the Empire. This can only be ascertained by periodic measurement of children and adults. It is obvious that this work must be controlled from a single centre in order to secure uniformity.

(6) The council desires to point out that the scientific study of anthropology at the universities has made great and marked progress in late years, a gratifying fact which is due in no small measure to the efforts and example of distinguished fellows of the Royal Anthropological Institute.

(7) The number of trained investigators is steadily increasing, and every year sees an advance in the accuracy and thoroughness of the methods of anthropological investigation.

(8) While it is the duty of the universities to organise the study of anthropology, it is the task of the Royal Anthropological Institute to coordinate all branches of that study by the exercise of functions in regard to it analogous to those performed for science in general by the Royal Society.

(9) In these circumstances the Council of the Royal Anthropological Institute seeks the support, moral and financial, of your Governments for a scheme to establish in London, in association with the institute, an Imperial Bureau of Anthropology, in order to secure the systematic investigation by scientific methods, according to a uniform plan, of the anthropology of the dependent and independent races within the British Empire.

(10) The council recognises that this project can be carried to success only if local cooperation and support be freely accorded to it. The methods and procedure of investigation very often must be adapted to local necessities of which the investigator on the spot is alone competent to judge. But it is clearly desirable that within limits there should be uniformity of method for the sake of the com-

parison and collation of the results garnered in so many parts of the Empire.

(11) The council therefore proposes (*a*) that there should be established in London an Imperial Bureau of Anthropology; (*b*) that the bureau should be managed by a committee constituted of the Council of the Royal Anthropological Institute, and containing representatives of the Governments of the British Dominions, of the India and Colonial Offices, and of those Universities in Great Britain, in India and the Colonies and Dependencies of the Empire where anthropology is systematically studied.

(12) The council further proposes that in each of the British Dominions, in India and in the Crown Colonies, there should be established local committees on which the local university or universities and scientific associations should be represented: that these committees should maintain close touch with active workers, superintend the collection of anthropological data in accordance with the plans and methods formulated by the Central Committee and transmit them to the Imperial Bureau, where they would be collated, printed, and issued from time to time in suitable form.

(13) Too much cannot be said as to the importance from a scientific standpoint of such a scheme. The council thinks it is justified in urging that from the aspect of practical utility such a bureau would render most valuable service for many years to come to all who are engaged in the task of spreading civilisation, whether as servants of the Empire, as traders, or as missionaries and travellers.

(14) The council therefore asks for financial assistance to enable it to provide and equip the bureau with a well-trained and competent staff, and to publish as may be necessary the information collected by local committees with funds at their disposal, to enable them to employ trained investigators when desirable.

(15) The council estimates that for the first five years the cost of maintaining and equipping such a bureau would be

	Staff	Maintenance and Publication	Equipment	Total
	£	£	£	£
1st year ...	300	100	200	600
2nd year ...	300	150	50	500
3rd year ...	400	200	50	650
4th year ...	500	250	50	800
5th year ...	500	250	50	800

(16) The Council recognises the value and importance of the work which has already been accomplished by Government aid in Canada, Australia, India, in Southern Nigeria, Ceylon, and the Anglo-Egyptian Sudan, and desires very earnestly that this work should be carried on with greater continuity over a wider area in accordance with a uniform plan by standard methods of investigation which should be laid down by the Royal Anthropological Institute, the only scientific body which is entitled by its standing to speak with authority on such matters.

A. P. MAUDSLAY, *President*.
J. GRAY, *Hon. Treasurer*.
T. A. JOYCE, *Hon. Secretary*.
(*For the Council of the Royal Anthropological Institute*.)

TECHNICAL EDUCATION AND INDUSTRIES.[1]

THE widefelt need for drastic improvements in our systems of education makes the present period a critical one. We are on the verge of important changes which will probably be made by the Board of Education in its rules and regulations, and this naturally makes the present an anxious time to us as teachers. In addition, we are threatened with what may almost be called a revolt of the ratepayer, who is often far from realising fully the intimate relationship between industrial progress and technical education. Though this subject has been discussed almost *ad nauseam*, I propose to put before you some striking figures derived from the recently published Census of Production, of 1907.

The following tabular statement gives details of net output, number of salaried persons and wage-earners employed, and the net output per head of the nine leading industries already published in the summaries of the census, coal mining being omitted, as this is of a very different character from the other industries. The net output represents the value added to the raw material during the processes of manufacture. For purposes of comparison, I have added the percentages of salaried persons and wage-earners respectively in each industry. A glance at the table at once reveals the important fact that the net output per head broadly rises throughout with an increase of the percentage of salaried persons. Although this conclusion is derived from a comparison of different industries, we are probably safe in assuming that it will hold good in a similar way when applied to different branches of one and the same industry. This suggests that, within certain limits, the employment of a large number of skilled technologists will develop the industry into higher forms, which is accompanied by an increase of productivity. This must in course of time react on the prosperity of the country as a whole, and determine its position in the industrial struggle between the nations of the world.

SUMMARY FROM CENSUS OF PRODUCTION, 1907.

TRADE.	Net Annual Output.	Number of Persons Employed.			Percentage of Persons Employed.		Net Annual Output per head.
		Salaries.	Wages.	Total.	Salaries.	Wages.	
	£						
1. Engineering Factories (including Electric. Eng.)	49,425,000	33,384	416,924	455,561	7·3	92·7	108

Scientific Research in Industry.

Beaconsfield is credited with having once stated that the chemical trade of a country is a barometer of its prosperity, a statement for which we see there is some justifi-

[1] From the Presidential Address delivered before the Association of Teachers in Technical Institutions at the Southport Conference, June 5, by Mr. Barker North.

cation, considering that it heads the list in net output per head.

There are many problems that are awaiting solution, but these will only be solved by scientific methods applied by the technologist trained in research.

Although in 1907 we were employing, as compared with other English industries, a relatively high percentage of salaried persons in the chemical industries, a large proportion of whom would be technical chemists, it is when we inquire into the type of chemist employed that we find a remarkable difference from the practice adopted in Germany. In England, the work of our chemists is almost entirely of a more or less routine character, whereas the astounding number of research chemists employed forms a distinguishing feature of the German chemical industry. The suggestion recently made that we are incapable in this country of producing technological organic chemists, trained in research methods, is an absurd one; the fact is that the manufacturer, requiring an immediate turnover for his capital, does not, as a general rule, encourage the training of such men by demanding their assistance in the works. His policy, however, is a short-sighted one, as the following contrast of the chemical trades of England and Germany will show the valuable results accruing from the German method.

In 1907 the gross value of the output of the chemical trade in the United Kingdom was $23\frac{1}{2}$ millions sterling, and of this amount a little more than one-third of a million represents the total value of the coal-tar dyestuffs. Germany in 1909 produced aniline colours alone equal to 15 millions sterling in value, approximately two-thirds of the whole of our chemical trade. The imports of coal-tar dyes into England in 1909 increased by 16 per cent., and in 1910 by 10 per cent. The irony of the whole situation is that we celebrated, a few years ago, the jubilee of Perkins's epoch-making discovery of the first aniline dyestuff.

Ten years ago, practically all the indigo put on the market was of natural origin and supplied by British possessions, but certain German firms set out to capture the indigo market by the production of artificial. indigo. In spite of the statement that the natural product possesses certain intrinsic valuable properties not possessed by the artificial variety, and despite the attempts of the English Government to bolster up the Indian indigo trade, in ten years the annual value of indigo imported into this country from India has fallen from a million sterling to less than 50,000*l*. Germany in 1909 exported to Asia alone, the home of the natural indigo, indigotin to the value of 1,900,000*l*. This again is now being followed up by the production of vat dyes, many of them products derived from artificial indigo. These colours being extremely fast, in many cases even to bleaching agents, may yet revolutionise our cotton-dyeing industry. We have not only lost our indigo trade, but in these developments our colour manufacturers are again allowing the German firms to forge ahead.

This forward movement is not confined to the colour trade alone, for the adoption of new processes of manufacture often reacts advantageously on older processes, creating an increasing demand for other products, notably in the heavy chemical trade. At one time Lancashire produced practically all the sulphuric acid of the world; some ten years ago about one million tons were said to be manufactured annually principally in this part of the country, whereas, according to the recent census, the total amount manufactured in the United Kingdom in 1907 was 473,000 tons. This is largely due to the commercial development in Germany and other countries of the "contact process" for the manufacture of sulphuric acid, the initiation of which is principally due to the demands created by the dyestuff industries. It is again interesting to note that the first patent for this process was taken out by Dr. Squires, an English chemist, though the process has been converted into a commercial success in other countries.

This is typical of the advancement and development which has been such a marked feature of the chemical trade of other countries. Examples might be multiplied to prove that in England we are engaged to a large extent in tinkering up the old processes of manufacture, whilst other countries avail themselves of new lines of thought and experiment. The great German industrial concerns, knowing the value of the scientific expert, will often wait for years for the final results of researches which they realise may ultimately revolutionise an industry, or may provide entirely new industries.

Germany has developed a scheme of practical education of the masses which will provide her industries with an army of well-trained workers, and at the same time she has developed to the highest pitch the scientific training of original technologists. It may be that we require more Dreadnoughts, but no number of battleships will prevent our being left far behind in the race of industrial progress if we continue to rest self-satisfied on the laurels of the past.

The more one inquires into the various suggestions that have been made for England's failure to take the lead in industrial developments, the more one is driven to the conclusion that lack of the spirit of organisation and system in both industrial and educational matters is the root of the evil.

In discussing reforms that are necessary in the work of our technical schools and universities, we have to recognise clearly that provision must be made for two distinct types of students, namely, (1) the rank and file of the industrial army; (2) the officers, who will have to organise and direct the work of the rank and file. The ideal principle which should govern the whole system is that the second type should be evolved from the first by means of natural selection. In the earlier years, the training of the two types may therefore be identical, and can be efficiently carried out by part-time instruction in technical schools, as far as possible in the daytime. With regard to higher technical work, this cannot be adequately dealt with in evening classes. We have a unique system of evening classes in this country, doing undoubtedly far better technical work than most people realise, but this system will have to be developed even further if we are to keep pace with the improvements which are bound to follow the increasing application of science to industry.

Higher technological instruction is at the present time given in some six or seven universities, a few university colleges, and many technical colleges and schools.

With respect to our day technical institutions, the following points may be urged in connection with the higher instruction given by them at present:—

(1) The students are too young at entry, and coming mostly direct from secondary schools at the age of fifteen or sixteen, during the first two years they are not old enough to appreciate the necessity for serious study, and have little sense of responsibility.

(2) The student when he has completed his three or four years' training is still without any practical experience such as is gained as an employee in a works. Through lack of this practical experience, he has often an inflated opinion of his own ability and immediate industrial value.

(3) It is only the occasional man who displays the ability requisite for the highest technological positions. Only a comparatively small percentage of those entering the day technical institutions finally display that initiative which is required in the trained technologist. The greater number are only suitable as routine men for second-rate positions, and would receive a more suitable training by entering works and attending evening classes. The explanation for this is that the day students are at present not being chosen by the process of natural selection.

(4) There are too many institutions at the present time all attempting the highest form of technical training in numerous branches, resulting under the existing conditions of selection and supply in small classes and in the unnecessary duplication of expensive equipment for the most advanced work.

(5) The small number of students in each institution does not justify the engagement of the numerous staff of specialists really necessary for the highest form of technological training.

All these defects will be remedied by drafting the most promising of evening students systematically into day courses, and by concentrating them for the highest class of work in specialised institutions, each of which could then afford the necessary elaborate equipment and specialist staff.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

On July 15 the King will lay the foundation stone of the new Welsh National Library at Aberystwyth.

Dr. Shand, of the Royal Scottish Museum, Edinburgh, has been appointed by the council of Victoria College, Stellenbosch, South Africa, to the recently instituted chair of geology.

It is proposed to start in September next, at the Horticultural College, Swanley, Kent, a year's course in natural history for intending teachers of nature study and gardening. The course is designed to give students an insight into field work in natural history based on sound laboratory instruction, and enable them to impart their knowledge to others in simple and intelligible language. The work will be thoroughly practical, and students will be shown how to prepare their own material and construct any necessary apparatus. The course will extend over one session of three terms, thus giving opportunities for field work in all seasons.

Prof. W. A. Herdman, F.R.S., will hold a vacation course on oceanography at the Port Erin Biological Station in September this year, probably in the two weeks following the meeting of the British Association. The exact dates and further particulars will be announced shortly. The practical work of the course will, as last year, be conducted by Dr. W. J. Dakin (as zoologist) and Dr. H. E. Roaf (as physiologist). Prof. Herdman's new steam-yacht *Runa*, which is being fitted up for oceanographical work, will by that time have returned from her contemplated plankton cruise in the Hebrides, and will be available for demonstrations of apparatus and method on board in Port Erin Bay.

The second volume of the 1910 report of the U.S. Commissioner of Education shows that 494 of the institutions of higher learning which report to the Bureau at Washington admit men students, 352 admit men and women, and 108 women only. The report includes much interesting information as to the property and income of the various colleges and universities. We notice that the 494 colleges admitting men students have libraries valued at 3,850,000*l.* The value of their scientific apparatus, machinery, and furniture is given as 6,550,000*l.*; of their grounds, 3,538,000*l.*; and of their buildings, 42,300,000*l.* The productive funds of these institutions amount to 51,875,000*l.* Their income for 1910 reached 16,088,000*l.*, of which 2,320,000 was from productive funds. From the same source much can be learnt concerning the growth of secondary education in the United States. For twenty years the rate of increase in the number of secondary-school pupils has been greater than the rate of increase in population. In 1890 the number of secondary-school pupils was 367,003, or 5900 to the million of population; in 1900 the number was 719,241, or 9500 to the million; and in 1910 it was 1,131,466, or 12,300 to the million. The per cent. of increase in population since 1890 has been nearly 47, while the per cent. of increase in secondary-school pupils has been 208.

SOCIETIES AND ACADEMIES.

London.

Royal Meteorological Society, June 14.—Dr. H. N. Dickson, president, in the chair.—Dr. C. **Chree**: Discussion of the barograph records kept by the late Mr. P. Bell at Castle O'er, Dumfriesshire, during the seven years 1902–8. The records show a well-marked principal maximum and minimum at 10 p.m. and 5 a.m. respectively. Every single year agrees in this except 1908, which puts the maximum at 7 a.m. The existence of a secondary maximum and minimum is unmistakable, but while the hour of occurrence of the former is clearly 11 a.m., that of the latter is less distinct. It seems to be 4 p.m., but a longer series of observations would have been necessary to confirm this.—Spencer C. **Russell**: Experiments carried out at Epsom during the last two years in order to obtain a permanent record of the variations in the size of raindrops as and when they occurred. The first method employed was the exposure of a number of ruled slates divided into ¼-inch sections, and gently brushed over with an even coating of oil. This was not altogether satisfactory, as during heavy rain the drops impinged upon the slate with such force as to become broken up into a series of drops composed of one large and a number of small ones. The most satisfactory results, however, have been given by the use of plaster of Paris. Mr. Russell exhibited to the meeting a number of these raindrop models. He stated that the sizes of the drops which he had already collected were:—7 of 6 mm., 44 of 5 mm., 73 of 4 mm., 222 of 3 mm., 257 of 2 mm., 175 of 1 mm., and 107 of less than 1 mm.—A. J. **Makower**, Dr. W. **Makower**, W. M. **Gregory**, and H. **Robinson**: Experiments carried out at Ditcham Park to investigate the electrical state of the air at different heights above the ground by means of kites and balloons.

Dublin.

Royal Irish Academy, June 12.—Rev. Dr. Mahaffy, president, in the chair.—R. Lloyd **Praeger**: Phanerogamia and Pteridophyta. Part I. Dispersal and distribution. (Clare Island Survey.) In connection with the study of the vegetation of Clare Island, particular attention was paid to the questions of the origin and the age of the flora. The question as to whether the flora could have immigrated across the existing strait which separates it from the mainland was decided in the negative, on the grounds, among others, of its variety and complexity in relation to that of the mainland, the equal abundance of species with or without dispersion devices, and the non-applicability in this case of certain usually potent methods of dispersal. The influence of man upon the flora was also dealt with fully.

New South Wales.

Linnean Society, March 29.—Mr. C. Hedley, president, in the chair.—C. **Hedley**: Presidential address, a study of marginal drainage. Previous to the present cycle, it is believed by geologists that a peneplain extended from New Guinea in the north to Tasmania in the south. Probably this peneplain extended eastwards beyond the limit of the present coast, and was continued seawards by a broad continental shelf. The theory is advanced that the present cycle commenced by the sinking of the ocean-floor, and by pressure upon the border of the continent. In the zone of compression folding ensued, by which the continental shelf was depressed and the coastal range elevated simultaneously. Where the margin of the shelf approaches the coast, so does the divide. From this it is inferred that a broad shelf serves as a buttress to that portion of the continent that lies behind it. Sheltered by this buttress, radial rivers persist as relics from the peneplain epoch. To show that the continental shelf is still being diminished, an instance is furnished by Captain Sharp of how the shelf has retreated from five to ten miles within forty years near Break Sea Spit. A feature of many rivers of our Pacific slope is that, for part of their course, they run in valleys parallel to the shore. Then they are apt to break away and run direct to the sea. Of where and what were the rivers of the preceding cycle, the peneplain times, there is no record. It is obvious that no peneplain could have carried such crooked rivers as the Clarence or the Shoalhaven. Of necessity the peneplain rivers were longer, slower, and straighter than these. How were those peneplain rivers succeeded by an entirely diverse scheme of drainage? The explanation offered is that the crooked rivers lie in a zone of compression; that movements from the pressure-trough threw the coastal area into irregular folds; that these broke and caught the radial rivers, which, turning aside, flowed along their furrows; then at once denudation played on elevation. At every opportunity the river burst through the obstacle which held it back from the shortest way to the sea. Finally, the old channel, chopped in lengths by cross-streams, appears as an empty river-bed. Every stage in this performance is illustrated by the rivers of New South Wales. It is clear that as these great meridional valleys, marginal to the coast, are undergoing rapid dis-

integration by the ordinary agents of denudation, that they cannot have endured such attack for long. Consequently these valleys themselves are geologically recent.—Ordinary meeting, Mr. W. W. Froggatt in the chair.—*Papers read:* D. **McAlpine**: Description of a new smut in a new genus of grass.—T. Harvey **Johnston**: (1) The entozoa of Monotremata and Australian Marsupialia, No. ii.; (2) new species of avian cestodes.

April 26.—Mr. W. W. Froggatt, president, in the chair. —Dr. J. M. **Petrie**: The *rôle* of nitrogen in plant metabolism, parts iii.–v. (iii.) The distribution of nitrogen in the seeds of *Acacia pycnantha*. The seeds contain 4·51 per cent of N in various forms. The changes in the solubility of the protein are examined in various stages of partial neutralisation. A study of the action of various protein precipitants is made. Quantitative precipitation by alcohol of increasing strength brings out a differentiation of the N values, and shows the presence of at least two different proteins. The protein-free solution contains (1) substances which easily set free ammonia when distilled; (2) compounds which liberate ammonia only when hydrolysed with dilute acids; (3) compounds which are only decomposed by boiling with strong acids for prolonged periods; (4) basic compounds. (iv.) The nitrogen of ripening seeds. Experiments on the wild tare, *Vicia sativa*. The seeds, as ripening progresses, gain in protein and also in non-protein N compounds, the mature seeds containing the largest amount of each. The view that the proteins are formed at the expense of non-protein N compounds is not supported. All ripe seeds examined contain non-protein N, which remains unaltered throughout the dormant state. A series of experiments on *V. faba* showed that when the seeds are left enclosed in the isolated pods, a transference of material takes place from the pods to the seeds. This results in an increase in total N and protein N, and a small increase in non-protein N. The seed-protein could only have been augmented by the addition of protein or protein derivatives, and the only possible source is the pods. (v.) The occurrence of potassium nitrate in plants. The occurrence of an unusually large amount of potassium nitrate in the leaves of *Solandra grandiflora*, 2·01 per cent. of the plant dried at 100° C., is recorded.—R. J. **Tillyard**: Studies in the life-histories of Australian Odonata. No. 4. Further notes on the life-history of *Petalura gigantea*, Leach. The account of the life-history of *P. gigantea* is completed. The living nymph, hitherto undiscovered, was found in a swamp at Medlow, Blue Mountains. These larvæ appear to be at least two years in reaching maturity.—E. W. **Ferguson**: The Amycteridæ of the Voyage de l'*Astrolabe*, 1835. The author has had the opportunity of examining Boisduval's types of ten species, from Coll. Dejean, out of a total of nineteen described, the descriptions of the remaining nine being sufficiently full for satisfactory recognition.—W. W. **Froggatt**: Description of a new lac-coccid (genus Tachardia) from New South Wales.

VICTORIA.

Royal Society, April 13.—Mr. Walcott in the chair.— J. **Shephard**: A list of Victorian rotifers, with description of two new species and the males of two species. H. H. Anderson and the author published a Victorian list in 1892. *Brachionus lyratus*, n.sp., and *B. dichotomus*, n.sp., and males of *Lacinularia reticulata* and *L. elliptica* are described.—A. J. **Ewart**: Fruiting of "Blackfellow's Bread" (*Polyporus Mylittae*, Cooke). Sporophores do not form without the stimulus of light.

May 11.—Prof. Skeats in the chair.—W. Baldwin **Spencer** and R. H. **Walcott**: The origin of cuts on bones of Australian extinct marsupials. Bones from localities in Victoria, New South Wales, and South Australia have cuts and marks on them into which the teeth of Thylacoleo will fit, thus confirming its carnivorous habit.—Jean **White**: Bitter-pit in apples. Results of one season's work are given. Several diseases are confounded under the name; the one investigated is caused by spraying with lead arsenate.

CAPE TOWN.

DYNAMICAL METEOROLOGY AND HYDROGRAPHY.

Dynamic Meteorology and Hydrography. By Prof. V. Bjerknes and different collaborators. Pp. 146+36A+30B+22C. (Washington, D.C.: Carnegie Institution, 1910.)

IN a lecture delivered at University College in May, 1910, Prof. Bjerknes outlined the methods, described characteristically as rational, by which he hoped to utilise synchronous meteorological observations for a more purely scientific purpose than the preparation of daily forecasts. The present work is the first instalment of a treatise prepared, in collaboration with Dr. J. W. Sandström, with such investigations in view, and is intended to present in an ordered and rational form the principles and development of meteorology and hydrography viewed from the point of view of a mathematical physicist. Bjerknes has realised the fact that economy of thought and labour are essential to advance in meteorological and hydrographic investigation, and although his book bears little actual resemblance to Lagrange's "Mécanique Analytique," we cannot help calling to mind that classical masterpiece of scientific economy in reading this volume.

The existing chaos in meteorological units has led Bjerknes, among others, to the conclusion that a thorough reform in this respect will go far towards making meteorological progress possible through the practical application of more advanced mathematical treatment than is at present customary. He begins therefore by introducing as suitable units for meteorological purposes the metre, the metric ton, or 10^6 grams, and the second, and calls this briefly the m.t.s. system. The metre and the ton are chosen on the ground that the centimetre and the gram are too small as units of length and mass for practical applications, in much the same way as the c.g.s. electrical units are in general unsuitable for the practical engineer. The atmosphere, however, resembles a thin plate, and although the vertical dimensions and motions are relatively small, they are nevertheless important. No combination of units will be appropriate for all cases, and Bjerknes himself departs in some cases from the rational derived units which follow from his scheme. It seems doubtful therefore if it is a wise plan to run the risk of discouraging the reader at the outset by the formal introduction of new units.

The first two chapters are introductory in character, and deal with the units used in the work and with gravity and the corresponding scalar, gravity potential. The unit of gravity potential on the m.t.s. system is called the dynamic decimetre, because it is equal to the work done in lifting unit mass against gravity through a height which is approximately equal to a decimetre. For practical application, however, the dynamic metre is taken, and this unit is fundamental in Bjerknes's work. Its great advantage is that the distance to which it corresponds agrees sufficiently closely with the metre, to make it suitable for expressing approximately *geometric* heights, and points at the same distance in dynamic metres from the earth's surface (sea-level) are on the same level surface of gravity. Bjerknes even makes out a case for publishing the results of geodetic determinations of "height" in dynamic metres, just as in a later chapter he emphasises the need for giving the corresponding values of pressure and temperature in the publication of the results of upper-air observations, instead of height and temperature, the quantities more frequently adopted at present.

Some care is needed to prevent confusion in connection with dynamic decimetres and metres. These are units of work and are invariable, but the heights, with which they correspond, vary with the locality inversely as the value of gravity.

The m.t.s. unit of pressure is the centibar, but here again it is found convenient to take as the practical unit the bar or the megadyne per square centimetre, and the graduation of the barometer in "millibars" is advocated. It seems necessary to proceed cautiously in this connection. It is proper and scientific to express atmospheric pressure in terms of the megadyne per square centimetre or the bar, and it is legitimate to take advantage of any practical device which will enable this to be done as easily as possible; but in using the mercury barometer we are primarily measuring a distance, and equal increments of height do not correspond with equal increments of pressure at different places, or under different conditions at the same place. Meteorologists ought to beware of adding another incongruity to the list of those which they ridicule frequently in a good-humoured way when they have become accustomed to the feeling that long usage has made the bonds too strong to be broken.

Chapter iii. deals with the specific volume and density of air and sea-water. Owing to the fact that the amount of water-vapour present in the atmosphere is a variable quantity, the "constant," R, in the equation $pv=RT$ is variable also, and this constitutes a real difficulty in the discussion of atmospheric changes. Bjerknes reduces the difficulty very considerably by adopting the artifice of keeping R constant throughout, and using in the equation, not the actual temperature T, but the virtual temperature τ, which is the temperature at which dry air would have the same density as the air under consideration. By another ingenious device he makes seven small tables for obtaining the density of sea-water from the temperature, salinity and pressure cover the same range as a quarter of a million pages of straightforward tabulation.

The next two chapters are concerned with the principles of hydrostatics and their application to the atmosphere in the case of constant temperature gradient and for adiabatic equilibrium. They contain an instructive set of diagrams showing for the same scale of height (measured in dynamic metres) the pressure, density, and specific volume of the atmosphere at different levels for the four cases, homogeneous atmosphere, dry atmosphere in adiabatic equilibrium, atmosphere with constant vertical

gradient of temperature $0{\cdot}5°$ C. per 100 m., and isothermal atmosphere. Thus it is interesting to observe that at 20,000 m., for example, the pressures expressed in millibars are in the four cases 0, 10, 42, 79 respectively.

Chapter vi. is devoted to a consideration of the problem of determining the heights at given pressures or the pressures at given heights when the virtual temperatures at given pressures or at given heights are known. The method developed is applied to particular cases in which the observed quantities have been found from the records obtained by means of registering balloons. In calculating the height at which a given isobaric surface is to be found, the distances between consecutive isobaric surfaces are taken directly from the tables, so that the single process gives the entire representation of the field of pressure and mass. The ease and simplicity of the method suggest that meteorologists may find it preferable in their synchronous charts to represent the heights at which a standard isobaric surface is to be found instead of the pressures at a standard level. In chapter vii. such charts are drawn for different isobaric surfaces by using the results of the international ascents of registering balloons. Profile diagrams are also drawn showing the section, by a vertical plane, of the isobaric and isosteric (constant specific volume) surfaces, and of the equipotential and isopycnic (constant density) surfaces. In the equilibrium state no two of these surfaces intersect, and the number of tubes made by their intersections in actual cases is a measure of the departure from the equilibrium condition. This method of viewing the distribution is very suggestive, and deserves further development and application.

Chapters viii. and ix. are hydrographic counterparts of chapters vi. and vii., and complete the formal development presented in this volume, the remaining eighty pages being devoted to the tables necessary for the application of Bjerknes's methods. They will be found of great use in the discussion of the atmosphere as a fluid in three dimensions. They differ in some respects from the tables constructed five years ago by Sandström, and they cover a wider field. There are slight differences in the values for the distance between consecutive isobaric surfaces, which are no doubt due to the revision of Sandström's results.

The impression produced by a study of Bjerknes's book is that it does not contain new discoveries or throw much fresh light on individual atmospheric phenomena, but it presents what is fundamental in our knowledge of the physics of the atmosphere in a new way, and makes possible the application of methods which have hitherto been disregarded, because of the immense labour involved in dealing with even a single case. The temptation to pad the work with examples has been successfully resisted, and the cases discussed are confined to what is strictly necessary in the scheme of development.

The observations in the upper air obtained by means of kites and balloons have hitherto been little used in the synoptic representation of atmospheric conditions, and in the investigation of the dynamical problems which a three-dimensional knowledge was expected to elucidate. They have indeed achieved much in giving us definite knowledge in place of erroneous hypotheses, but ambitious minds naturally wish to turn them to practical use in daily forecasting. Laborious investigation is an essential preliminary to such an application, and Bjerknes, with his large, enthusiastic spirit, has taken up this work in a way which ought to secure him the active support of professional meteorologists. The book is excellently printed, and its form and style produce a sense of pleasure and satisfaction. There is an old rule about leaving the preface of a book until the remainder is completed. Apparently Bjerknes is taking this rule so literally that he is reserving the introduction, as well as the index, until the issue of the final volume.

E. GOLD.

THE JEWS.

The Jews: a Study of Race and Environment. By M. Fishberg. Pp. xix+598. (London and Felling-on-Tyne: Walter Scott Publishing Co., Ltd., 1911.) Price 6*s*.

IN order to elucidate the problem whether the Jews constitute a race or simply a nation, Mr. Fishberg discusses at considerable length certain physical characters, with the following results. Stature is not homogeneous among the Jews in every country, and its limits of variation are almost as large as are observed in European races generally; further, where the indigenous population is tall the Jews are also tall, and the reverse. It is also evident that the shortness of their stature can be attributed only to a slight extent to the influence of environment or to occupation. Jewish skulls are extremely rare in museums; indeed, there do not appear to be any data whatever for the ancient Hebrews; the cranial index of five skulls of the second century, found in Rome, varies from 75·1 to 83·4; of twelve skulls found in Basel in a cemetery dating from the thirteenth and fourteenth centuries two were dolichocephalic, while the remainder were brachycephalic, the total average being 84·6. The same variability occurs in other finds, but the skulls of most of the Sephardim—or Spanish and Portuguese Jews—are dolichocephalic.

Among the existing population it is found that in countries where the indigenous population is narrow-headed, as in Africa and Arabia, the Jews are dolichocephalic, and where broad-headedness prevails, as in Russia, Poland, and Hungary, the Jews are brachycephalic. The ancient Hebrews must have been either of the one type or the other, or a mixed race originally; the former alternative implies that for most of the Jews miscegenation must have occurred in later times. Although predominantly dark, fair Jews are found everywhere; even among the Sephardim, it appears that the blond type oscillates between 5 and 16 per cent., and between 25 and 50 per cent. are of the mixed types according to the country of birth. The suggestion that the blondness is a product of climatic conditions can be eliminated as worthless, as blond Jews occur everywhere. The combination of tall stature, blond-

ness, and dolichocephaly is not observed among the European Jews, but they have other physical traits of their non-Jewish neighbours.

Prof. F. von Luschan believes that the blond Jews of antiquity may have been the result of intermarriage with the fair "Amorites," but the bulk of the blondness, according to Fishberg, must have been acquired later by intermarriage with non-Jews. He also shows that the predominant type of Jewish nose is straight, nearly 60 per cent., the aquiline being only about 14 per cent. The character of the nostrils, to which Joseph Jacobs directed attention, is characteristic only of the latter type of nose, which von Luschan says should be termed Armenoid and not Jewish or Semitic. It is very commonly asserted that owing to social and religious causes the Jews have retained their "racial purity." Putting aside the dark Jews of India and Abyssinia, among whom proselytising has taken place, we read that in Gaul, Spain, Italy, and Hungary the Jews owned slaves, and records show that the Church has at various times taken measures to prevent them from converting their Christian slaves to their own faith; finally, the Church was compelled to forbid them to own slaves altogether. The descendants of white slaves have been fused with the rest of the Jews, and to-day, after several generations of liberty, they can be no longer recognised; but other causes have contributed to miscegenation. Fishberg supports the statement of Gumplowitcz that "the type or physiognomical character of a folk or social group is not anthropological but social"; he adds, "Mainly for this reason most of the Jews in eastern Europe, who are anthropologically of various types, deceive the casual observer into believing that they all present physiognomical homogeneity."

These conclusions, which he believes to be justified, dissipate the exalted notion of the "Chosen People," who claim that they can trace back their ancestry to their patriarch and progenitor Abraham, as well as the pseudo-scientific theory of the Anti-Semites of a "Jewish race," which is entirely alien in Europe, and incapable of assimilating European standards of morals and fair play. From all the historical evidence available, it appears that the Synagogue and the Church are both powerless to prevent intermarriage between Jews and Christians unless the State comes to their rescue. Such marriages are increasingly taking place; thus there is every indication that the social isolation of the Jew is coming to an end, and that in the near future all the real and alleged differences between Jews and Christians will completely disappear in progressive communities.

The author gives interesting information concerning the marriage-rate, birth-rate, and infant mortality among the Jews, and their pathological characteristics are discussed at length. There are practically no differences between Jews and Christians as regards the incidence of typhoid fever, scarlet fever, measles, diphtheria, &c. The so-called "tenacity of life" of the Jews is mainly dependent upon the great care Jewish mothers take of their children; they nearly always nurse them at the breast, and Jewesses only rarely go to work in factories after marriage. Their lesser liability to consumption is remarkable, perhaps because, being better adapted to city life and overcrowding by a long sojourn in the Ghetto, and by a process of natural selection, there were eliminated most of those who were predisposed to tuberculosis. The only pathological processes which are more frequent among Jews are the derangements of the nervous system.

"The Jew is the most nervous, and, in so far, the most modern of men. He is by the very nature of his diseases the forerunner, as it were, of his contemporaries, preceding them on that perilous path upon which society is urged by the excesses of its intellectual and emotional life, and by the increasing spur of competition."

Many other aspects of Jewish life are dealt with in this interesting and valuable study, such as the social, economic, and political conditions of the Jews. With regard to their future as a people—for we are no longer justified in speaking of a Jewish race—the author evidently subscribes to Ruppin's statement that "orthodoxy and poverty, assimilation and prosperity, are almost synonymous terms with the Jews."

A. C. HADDON.

ALCOHOLIC FERMENTATION.

Alcoholic Fermentation. By Dr. A. Harden, F.R.S. Pp. ix+128. (London: Longmans, Green, and Co., 1911.) Price 4s. net.

THE appearance of Dr. Harden's "Alcoholic Fermentation" will be warmly welcomed by those engaged in studying problems connected with yeast and the production of alcohol. Dr. Harden's own contributions to the question of alcoholic fermentation are so well known that one expects and finds in this small volume a good up-to-date general survey of the subject. The material is divided up into eight chapters, of which the first is devoted to historical introduction, whilst the next four deal with the properties of zymase and the theories which have been developed since Buchner's fundamental discovery of the dependence of fermentation on enzymes rather than on necessarily living organisms.

In dealing with the accelerating effects of phosphates, arsenates, and arsenites on the course of fermentation, Dr. Harden compares the ideas of von Lebedew and Iwanoff with his own conception of the constitution and function of the "hexosephosphate," which he formulates as the salt of a hexose-diphosphoric acid, whilst Iwanoff regards the substance as a triose-phosphoric acid, $C_3H_5O_2(PO_4H_2)$. Perhaps the strongest evidence in favour of the hexose-diphosphoric acid formula is afforded by the observation of Harden and Young, that when hydrolysed, fructose, as well as phosphoric acid is produced. The significance of the phosphate derivatives is such that one must welcome the synthetic production of phosphoric ester-acids of sugars and allied compounds now being effected by Contardi and Neuberg.

Some interest attaches to Neuberg and Pollak's synthesis of salts of monophosphoric acids of sucrose and glucose, as they have been isolated in analysable condition, and, though not of glucoside type, need to be hydrolysed before undergoing fermentation with yeast. In the case of the hexose-phosphate of alco-

holic fermentation, probably the aldehyde-group participates in the formation of the ester-acid. Dr. Harden remarks (p. 46),

> "the identity of the products from glucose, mannose, and fructose may be explained by regarding the acid as a derivative of the enolic form common to these three sugars, or *by supposing that portions of two sugar molecules may be concerned in its production.*"

The "equation of alcoholic fermentation,"

$$2C_6H_{12}O_6 + 2PO_4HR_2 = 2CO_2 + 2C_2H_6O + 2H_2O + C_6H_{10}O_4(PO_4R_2)_2,$$

whilst recording the experimental facts, scarcely affords an explanation of the formation of alcohol, as it is not obvious why, when one of two glucose molecules forms hexose-phosphate, the other should yield carbon dioxide and ethyl alcohol. Perhaps the part of the above quotation which the reviewer has put in italics furnishes a clue.

Chapter iv., dealing with Harden and Young's discovery of the coenzyme of yeast-juice and its remarkable properties, is of considerable interest, and the possibility of this containing the phosphate group referred to, though it is admitted that experiments have so far yielded only negative results. The next chapter is devoted to the action of inhibiting and accelerating agents on the enzymes of yeast-juice, whilst in chapter vi. the by-products of alcoholic fermentation are dealt with. The results of F. Ehrlich's brilliant work on the production of higher alcohols are clearly expounded, and production of aldehydes and glycerol referred to. It is a matter of interest that only living yeast appears to be capable of producing alcohols from the amino-acids, and even then only does so in presence of fermentable sugar. The discovery of zymase has furthered the solution of the fermentation problem, but the stability of the amino-acids in the absence of the living organism, and the superiority of yeast itself over preparations of its enzymes in effecting the conversion of hexoses into alcohol and carbon dioxide need further explanation.

The chemical changes involved in fermentation are dealt with in chapter vii., and the various explanations put forward at different times are recorded; the reader cannot fail to be struck with the small measure of success which has so far attended these efforts.

Chapter viii., on the "Mechanism of Fermentation," is rather condensed in comparison with the rest of the work; here, however, one departs somewhat from the biochemical aspect of the problem which has been treated by Dr. Harden in so successful a manner. J. T. H.

A CRITIC IN GEOLOGY.

L'Évolution des Théories géologiques. By Prof. S. Meunier. Pp. 366. (Paris: F. Alcan, 1911.) Price 3.50 francs.

THIS is one of the most useful works that Prof. Stanislas Meunier has given to his geological colleagues, and at the same time it will be appreciated by the general reader. The latter, however, must be constantly on his guard, lest he cry out, "A hit, a very palpable hit," every time that Prof. Meunier tilts against the theories of to-day. In an introduction intended to show the inexactitude of the works of nature when compared with the demands of mathematics, the author seems to include in the same order of things the forms of basalt columns and those of crystallised minerals; he rightly points out the irregularity of the former, but says of man (p. 12),

> "à la place des formes toujours variées des objets naturels, il a inventé les formes géométriques . . . tetraèdre, cube, rhomboèdre . . . auxquels il rapporte les objets véritables."

Prof. Meunier doubts the conclusions of the chemist when he remarks, "De même, à la place des composés naturels, il à inventé des composés définis; oxydes, acides, sels," &c. All this is harmless Meunierism to the trained geologist, and will be taken in good part, like the author's rejection of the reality of the Ice age; and it is undoubtedly good for us to have the erroneous conclusions arrived at in the past by the "unanimity of geologists" pointed out as a warning for our later age.

The history of geological thought exhibits to us a science more cumbered by theory in its earlier stages than it is at the present day, and Prof. Meunier does well to begin with cosmogony, tracing the study from Moses to Sir George Darwin. The form of the earth and the nature of its interior are then discussed, with references in the main to French authors. But in succeeding chapters the literature of the world is freely drawn on, and is often criticised as freely. The chapter on mountain building is of special interest, though a more regular chronological arrangement would have aided the reader. The author hails with complete approval the views of Suess on horsts, and of Schardt and Termier on horizontal overfolds, and justice is done (p. 99) to Reyer's theory of gravitational sliding.

The chapter on earthquakes is still more injured by lack of systematic arrangement, and cannot be regarded as complete. In that on metamorphic theories we should have liked to find the names of Scrope and Darwin, both of whom had such clear views on foliated rocks; but Hutton, Lossen, Lehmann, and Michel Lévy are similarly passed over, and the chapter is a brief essay rather than a history. Rivers and glaciers are more adequately dealt with. The chapter on the latter concludes (p. 282) with the following amazing statement as to the striated pebbles found in boulder clays:—

> "Or il est maintenant démontré que les stries . . . ne sont aucunement d'origine glaciaire et qu'elles dérivent entièrement du phénomène d'érosion réalisé dans la masse des éboulis par l'infiltration des eaux de pluie."

Has Prof. Meunier ever consulted an agriculturist as to the penetration of boulder-clay by rain, or has he seen the scratched blocks in a modern glacial deposit, newly revealed from Arctic ice? He continues the discussion when dealing with "théories sédimentaires," and asserts firmly (p. 301) that "pratiquement les glaciers ne strient pas de galets." French tourist steamers now penetrate the fjords of Spitsbergen, and Prof. Meunier should certainly ask one of these to land

him on the arid shores, strewn with striated boulders, of Tempel Bay or Cora Island.

The transport of boulders and striation of rock-floors by ice are, of course, fully admitted, and we have interesting references to Playfair, Perraudin, and de Charpentier. A short account of the origins of sedimentary rocks follows, in which, by a slip, fresh-water shell-limestones become included under "roches argileuses." This part of the book may be regarded as consisting of somewhat scattered notes, all of which have an interest for the professed geologist, but which do not systematically express the growth of geological opinion.

The absence of an index is astonishing. Perhaps the publisher quailed before the proper names, which are very imperfectly corrected in the text. We have Leibniz, Hitchkock and Hitchcok, Mayer-Aymar, Uscher, Revenier, Spalanzani, Moris Davis, d'Aubuisson de Voisin, and Deshays. One or two dates seem erroneous by about a century.

G. A. J. C.

LEAD SMELTING.

The Metallurgy of Lead. By H. F. Collins. Edited by Sir W. C. Roberts-Austin, K.C.B., F.R.S. Second edition, thoroughly revised and enlarged. Pp. xx+538. (London: C. Griffin and Co., Ltd., 1910.) Price 21*s.* net.

We welcome a revised and enlarged edition of this useful work, as the progress of metallurgy is now so rapid and great improvements have been made in smelting during the last decade. A too brief reference has been made to the physical properties of lead and that of its alloys, and much recent work has been overlooked, probably due to the aim of the author in making the work chiefly a compendium of information on lead smelting, which is here brought well up to date. Ore roasting has received the attention it deserves, and we are glad to find that pot roasting is clearly described, and the chemical reactions occurring in this novel process fully discussed, since a correct knowledge of the chemical changes that occur in any process often leads to advancement and discoveries. Useful data are given as to costs in the various modifications developed from the Huntingdon-Heberlein process.

The most suitable fuel for a given ore is here rightly considered, as well as the proper amount to be used in each case. But the twyer ratio and twyer efficiency are also of great significance, and it is a pity more attention has not been given to the pressure and volume of air supplied to each furnace.

The principles of blast-furnace lead smelting are clearly expressed, as the method of dealing with each constituent, according to its quantity, is essential for economic working. It is also equally important that the proper flux should be applied in order to produce the most suitable slag and to obtain the maximum quantity of metal. This is dealt with in a plain and lucid manner. A comprehensive description of modern furnaces with plentiful illustrations is a good feature in this edition, the parts being described in considerable detail. The important subject of water-jackets receives due attention as more refractory ores have now to be dealt with, necessitating greater height of jacket than formerly. It is shown that with increase of size of furnaces and amount of output larger fore-hearths are required and greater facilities for separating matter and slag. The treatment and disposal of slag are also given due prominence. Formerly the production of matte was considered a necessary evil, but it is now esteemed a desirable thing, since the lead is better reduced and the slag more free from lead and silver.

The various products of lead smelting are amply described, as well as the methods adopted for dealing with them at different works.

In chapter xi. examples of lead smelting in the chief European and American works form the subject of narration, and the following chapter deals with costs and losses.

As all lead ores carry silver and sometimes gold, it often becomes more profitable to work for their extraction than that of the lead itself. The author devotes about 100 pages to a consideration of this important subject. A valuable part of this section is the description of the methods of separating gold from zinc crusts.

In chapter xix. works assaying and analytical methods are dealt with.

In the following chapter the difficult subject of treatment of zinc-lead sulphides is considered, and various methods of separation discussed.

The last chapter deals with flotation processes, which have in recent years assumed great importance.

We consider this work a valuable contribution to the metallurgy of lead, in which so much new matter has been introduced, and it can be confidently recommended as a trustworthy guide to anyone who is interested in the subject.

THE TRISECTION OF AN ANGLE.

The Trisection of the Angle by Plane Geometry: Verified by Trigonometry with Concrete Examples. By Dr. J. Whiteford. Pp. 169. (Greenock: J. McKelire and Sons, Ltd.; Edinburgh and Glasgow: J. Menzies and Co., Ltd.; Cambridge: Bowes and Bowes, 1911.)

The *Paralogistes pseudomathematicus* has become so rare, or possibly so shy, that it is a real pleasure to find that the species is not extinct. Alack! that De Morgan is not with us, to do justice to this latest attempt at solving one of the three famous problems that have been proved to be beyond the power of Euclidean constructions. The curious thing is that the author, in his introduction, gives two long quotations from De Morgan, in which he states the conditions of the problem with the utmost precision, except that he does not explicitly say that the trisection must be performed by a finite number of operations. It is here that Dr. Whiteford has come to grief, for his method is nothing more or less than successive approximations, each of which involves a Euclidean construction. It is only fair to add that the author is no vulgar paradoxer, and that his method, as an approximation, is sound, and leads to accurate values with a comparatively small number of

trials; thus in his examples he works to seven places of decimals, and we have not noticed a case in which more than seven trials are required. The one, unfortunately fatal, objection, is that he has ignored the conditions of the problem; it is as though the value of π were found from the perimeter of a regular polygon of 2^n sides. By taking n large enough, we can get by Euclidean construction a value as near π as we please; but it is needless to say that this is not what is meant by "squaring the circle" with rule and compass.

Dr. Whiteford's method is sufficiently ingenious to deserve a brief description. Let AP be an arc of a circle, of which AOB, COD are perpendicular diameters; then if through P a line PQRS be drawn cutting the circle in R, and the diameters CD, AB in Q, S, so that QS=AB, then the angle ROB is one-third of the angle AOP. This theorem was known to the Greeks, and, in fact, led to the invention of the conchoid of Nicomedes as an auxiliary curve for the trisection of the angle. If we take Q anywhere on CD and produce PQ to S, making QS=AB, the locus of S is a conchoid, and its intersection with AB gives the solution of the problem. Now Dr. Whiteford gives a construction for a point on AB, which is in no case very far from S, and thence obtains a sequence of points which have S for their limiting point. After translating his construction into trigonometry, he gives fifty-one worked-out examples, so variously distributed over the quadrant as to leave no doubt that his sequence does actually converge in every case, though, as might be expected, he makes no attempt to prove this fact.

It is easy to draw the obvious moral that it is waste of time to attack a mathematical problem without completely understanding what the problem is. However, this is perhaps ungracious; let us rather conclude by admitting that Dr. Whiteford has added one more to the fairly numerous approximate solutions of this celebrated problem. G. B. M.

LILIENTHAL'S WORK ON AVIATION.

Birdflight as the Basis of Aviation: a Contribution towards a System of Aviation, Compiled from the Results of Numerous Experiments made by O. and G. Lilienthal. By Otto Lilienthal. With a biographical introduction and addendum by Gustav Lilienthal. Translated from the second edition by A. W. Isenthal. Pp. xxiv+142+viii plates. (London: Longmans, Green, and Co., 1911.) Price 9*s*. net.

THE interest of this book lies chiefly in the biographical part. The two Lilienthals, born in the town of Anklam, were from childhood devoted to mechanics, and also to natural history. Otto gained practical knowledge as a mechanic in the works of Schuarlzkopf in Berlin, while his brother was educated as an architect. Watching the flight of the storks which abounded about their home seems to have given them their first taste for the problems which afterwards occupied so much of their attention.

One curious passage (p. 103) is here quoted. After a picturesque description of the storks following the harvesters to pick up field mice and such "small deer," and a reference to the high regard in which the birds are held by the farmers, we read:—

"Thus it is not to be wondered at if the farmers, above whose homesteads these birds with a span of two metres hold great flight meetings every year, evince great interest in the art of flight, though they do not wish it to be known, fearing ridicule. Nevertheless, from no other trade or profession have so many inquiries for light engines—for a secret purpose—reached the author, as from farmers."

The theoretical part of the book is not of any great value, and some of the diagrams (notably those on pp. 45 and 56, of the flow of a stream past an obstacle) are very far from representing the actual facts.

Lilienthal seems to have attached great importance to curved, as against plane, and flapping, as against fixed wings. Flapping wings are really the more efficient of the two, but not for the reasons given.

Difficulties of mechanical construction have hitherto prevented their adequate trial on a large scale, but it would be too much to say that they are impracticable.

The merit of the curved wing section now generally in use is not that it gives an increased lift or efficiency, but that the efficiency does not vary so rapidly with the change of inclination to the air current as happens when the surfaces are planes.

It is seldom that the enthusiasm, mechanical ability, knowledge, and money necessary for experiments in a new field are found in the possession of one and the same individual. Lilienthal had the two first, but was hampered as regards the others. This book, however, which is well translated, should be read as giving a very interesting account of the work of a typical "inventor" of the best class.

A. MALLOCK.

OUR BOOK SHELF.

A Systematic Handbook of Volumetric Analysis; or, the Quantitative Determination of Chemical Substances by Measure, Applied to Liquids, Solids, and Gases. By F. Sutton. Tenth edition. Revised throughout, with numerous additions, by W. L. Sutton and A. E. Johnson. Pp. xiv+621. (London: J. and A. Churchill, 1911.) Price 21*s*. net.

A BOOK that has been the standard text-book on its subject for nearly fifty years, and continues to enjoy that position, calls for little remark as edition after edition is issued. Every student of chemistry knows, or ought to know, his "Sutton," as he knows his "Fresenius," and it would therefore be superfluous to attempt to describe its character and scope. The author, being now eighty years old, has placed the preparation of this tenth edition entirely in the hands of the two editors named in the title. There seems to be every evidence that the editors have done their work thoroughly and judiciously. They say that a good deal of obsolete matter has been deleted, and we naturally turned to some of those classical methods that have served so well in the past, such as Bunsen's method of gas analysis, and have been almost wholly replaced, rather than superseded, by processes that are more suitable for technical work. But the

old method of making and graduating, as well as calibrating, gas burettes is retained, though the apparatus for graduating and etching them would probably be regarded as curiosities in a modern laboratory.

By means of a new setting, and a rather smaller though quite clear type for some paragraphs and sections, space has been economised, and the volume, with all its added matter, is practically of the same size as the last edition. The deletions have in no sense altered the character of the book as giving full practical instructions, but in some cases, where a suggested modification is of comparatively little importance, or an application of a process is of very restricted use, the editors give only a short statement and refer to the original description by the author. In many cases they have taken advantage of the assistance of experts who have had exceptional experience of various methods. All factors and numerical details have been recalculated according to the latest "International Atomic Weights." The section on weights and measures has been rewritten, using the data adopted at the National Physical Laboratory.

In short, the editors appear to have spared no trouble to maintain if they could not enhance the reputation of the book, and thus to merit the gratitude that the aged author expresses in his preface, and, we may add, the thanks of all those who are interested in the subject with which it deals.

The Influence of Strong, Prevalent, Rain-bearing Winds on the Prevalence of Phthisis. By Dr. W. Gordon. Pp. xiv+108. (London: H. K. Lewis, 1910.) Price 7*s*. 6*d*. net.

FOR many years Dr. Gordon, in a series of papers, has brought before the medical profession evidence that strong rain-bearing winds have a very definite influence on the prevalence of phthisis. He has now collected these papers, and, in a work bearing the above title, gives a complete account of his observations. He maintains, as a result of these observations, that in any situation exposed to rain-bearing winds, whether it be over a wide region or merely the side of a street, the mortality from pulmonary phthisis is high. He works this out specially for Devonshire, but takes Exeter streets at one extreme and the civilised world at the other, always coming to the same conclusion. In all this, however, he does not, by any means, ignore other factors, especially "soil" and poverty. Our author points out that this high mortality from consumption is not due merely to a depression of vitality, for it is found that the general death-rate is not affected in the same way as is the phthisical death-rate. Moreover, he is satisfied that the action of the rain-bearing wind is exerted directly on the person exposed to it and not indirectly, "either through closure of doors and windows against the wind or by it driving wet into the walls of the houses."

It is, of course, difficult to test the accuracy of Dr. Gordon's observations, but his figures certainly seem to prove that, taking female death-rates as offering a safer basis of inquiry, in the rural districts of Devonshire, swept by rain-laden winds, the mortality is higher than in those where the winds are dry. Dr. Gordon, not shirking the numerous criticisms that have been directed against his conclusions, has certainly made out a very strong case for the accuracy of his hypothesis. As dealing with one of the side-issues of the tuberculosis question, as opening up a new field of inquiry, and as affording a guide to those in search of places to which consumptives may be sent, although it is not designed for that special purpose, this work will be of very considerable value. The coloured charts on which the statistics are both based and recorded are exquisitely drawn and reproduced. We congratulate Dr. Gordon on the completeness of his work.

Die Naturwissenschaften in ihrer Entwicklung und in ihrem Zusammenhange. By Friedrich Dannemann. Erster Band, Von den Aufängen bis zum Wiederaufleben der Wissenschaften. Pp. viii+374. Leipzig: Wilhelm Engelmann, 1910.) Price 9 marks.

THIS is the first of four volumes designed to give a connected history of the development of all the sciences, with especial regard to their connection with each other. It deals with the earliest records of geometrical and arithmetical learning among the Egyptians and the Sumerian conquerors of Mesopotamia; proceeds to the Greeks from Thales to Aristotle; sketches the development of science in the Greek colonies, the two periods of Alexandrian learning, the Arabian era, and the decline of the Middle Ages; and finally describes the revival of learning in the fifteenth century.

In dealing with Babylon, the author makes some telling extracts from the Nippur tablets, which date back to between 2200 and 1350 B.C., to show that a decimal system of notation is used in the cuneiform inscriptions, without, however, the use of the zero circle, which was introduced by the Indians, and brought to Europe by the Arabs.

In a work like this one misses a description of the Egyptian orientations of temples and pyramids with regard to particular stars. The recent Cretan discoveries are not included, and Chinese observations are only briefly touched upon. But the book is written in a very entertaining style, and as it is plentifully supplied with references, it forms a useful guide-book through the historic development of the sciences.

A Course of Plane Geometry for Advanced Students. Part II. By C. V. Durell. Pp. xiv+358. (London: Macmillan and Co., Ltd., 1910.) Price 7*s*. 6*d*. net.

THE first part of this work, on the straight line and circle, has already been reviewed. The present volume, which treats of conics, shows the same merits of clearness, conciseness, and good judgment. For example, there is a fairly complete account of involution, which is by far the most powerful instrument for developing the properties of conics; and, in order to avoid, on one hand, a lack of rigour, and on the other a difficult theory, the author has frankly based his treatment on an algebraic foundation. Other chapters deal with homography in general, reciprocation and projection; there is even a brief outline of practical solid geometry, though this is too sketchy to be of much use. There are various historical notes, excellent diagrams, and a vast collection of exercises; altogether Mr. Durell's book may be recommended as a trustworthy, practical, and interesting text-book.

M.

The Phase Rule and its Applications. By Dr. Alex. Findlay. Third edition. Pp. xvi+356. (London: Longmans, Green, and Co., 1911.) Price 6*s*.

THE first edition of Dr. Findlay's book was reviewed in these columns on April 21, 1904 (vol lxix., p. 579), and the arrangement and general character of the work remain much the same as they were. In the second edition numerous additions were made to bring the information up to date, and though no changes of a fundamental nature have been made in the present edition, paragraphs have been added where necessary on the results of recent researches. In addition to this, the whole book has been subjected to careful revision.

LETTERS TO THE EDITOR.

New Use for Eucalyptus.

THE following extract from a private letter deserves a wider publicity :—

W. T. THISELTON-DYER.

You may perhaps remember the work published in 1902 from this institution on "Eucalypts and their Essential Oils." Prior to this the eucalyptus oil industry was in a chaotic state in Australia, the New South Wales article being almost unmarketable. By working out the species on a basis as laid down in the work (*supra*)—that is, a natural one—many new products were discovered, such as geraniol, the active principle in the otto of roses; a dextro- and a lævo-turpentine corresponding to the American and French respectively; many eucalyptol oils (medicinal), in addition to those previously known; citral, from which ionone, the artificial perfume of violets, is made; citronellal, corresponding with the product obtained from the lemon grass of India; eudesmin and other products of unknown economic value at present.

The British pharmacopœia laid it down that no eucalyptus oil should be sold unless it contained not less than 50 per cent. eucalyptol, but such did not hold good for Australia; consequently *any* oils were sold for therapeutic purposes.

But recently, through our instrumentality, the Health Board has passed a regulation that the B.P. standard should obtain here; consequently there has been a "slump" in the oils thus disqualified, and so these became worthless. Naturally the distillers were very much put out with us, and some travelled so far as Victoria and Queensland to interview us and discuss the matter. But the hands of the clock could not be put back.

The now discarded oils have been classified by the chemist as phellandrene oils, and the particular gum trees yield them in larger quantity than any other oils, and the desideratum was to find an industrial avenue for their utilisation. Well, this is how it has come about. There are at certain large mining centres here millions of tons of "tailings," containing particles of minerals very finely divided, and the trouble in the past has been to extract these profitably, and many methods and patents have been adopted, but none satisfactorily.

At Broken Hill, our greatest mining centre, chemical investigation has been carried on for some time, and a complete series of essential oils of our own extraction and true to botanical names was forwarded for trial. The result was that the phellandrene oils yielded from 86 to 90 per cent. concentrates, the highest of any oil experimented with! Here indeed was a market. The demand for these particular oils has at once enormously increased; hundreds of tons are required, for the method will be introduced into U.S.A., Canada, Queensland, and through all Australia, South Africa, and wherever the industry obtains.

Its utilisation is the essence of cheapness, and the information on a sample that I brought from Broken Hill myself reads as follows:—Zinc concentrates; about Zn 47 per cent., Pb 10 per cent., Ag 15 oz.; recovered by eucalyptus oil ½ lb. per ton of concentrates.

When we started out on our research on eucalypts we little thought that the oil would play so important a part in mining. RICH. T. BAKER.

Technological Museum, Sydney, April 7.

The Date of the Discovery of the Capillaries.

THE discovery of the capillary blood-vessels being an event of such supreme importance in biology, it is highly desirable that the date of it should be accurately ascertained. It so happens that it is known for certain it was made in the year 1660 by Marcello Malpighi in the city of Bologna, and yet nearly every author gives the date of this discovery as 1661.

The latest statement of 1661 is in Prof. Miall's delightful little book "The History of Biology," in which in the useful chronological table we find :—

"1661. Passage of blood through capillaries observed by Malpighi." As justifying this date, he would doubtless point to the note at the head of the table:—("The date of a discovery is the date of its first publication when that is known.")

Now while in many cases this principle may be not only a convenient one, but the only one capable of application, yet in certain cases it is a principle not to be followed at all.

These cases are those in which we have evidence regarding both the date of a discovery and the date of its being made known.

For instance, the date of the *discovery* of the circulation of the blood by William Harvey is certainly earlier than 1628, the date of its publication.

We have the evidence of Harvey's own lecture notes, dated 1616, that he knew of the circulation and was teaching it at least twelve years before he published it. Only when we cannot find the true date of a discovery should we fall back on the date of its publication.

Now the discovery of the existence of the invisible capillaries was a very great thing, and it seems a pity that we should get into the habit of assigning it to one year later than it actually was made.

Sir Michael Foster's account in his "Lectures on the History of Physiology" is clearness itself. Speaking of Malpighi, we read:—"Here" (Bologna) "he resumed office as a Professor of Medicine, and in spite of domestic troubles and anxieties, pursued his researches to such good effect that he was able in the next year, 1660, to announce privately to Borelli his discovery of the structure of the lung, an account of which was published in the year following."

The published account alluded to is his "De pulmonibus observationes anatomicæ," which, after the manner of the time, is in the form of two letters to his friend G. A. Borelli, at Pisa.

In the second epistle he describes the circulation in the herniated lung of the living frog. He heads the description with these words, "Magnum certum opus oculis video"—"I see with my eyes a great, certain thing," not, as always translated, "a certain great thing," which is much feebler and not a true translation.

1660, then, and *not* 1661, was the date of the discovery of the blood-capillaries, within only three years of the death of Harvey in 1657. Harvey made their existence a logical necessity; Malpighi made it a histological certainty. As we still speak of the "rete mirabile Malpighii"—for no lapse of time can ever make that rete less wonderful—we might as well take the trouble to assign the discovery of it to its correct date, 1660. D. FRASER HARRIS.

The University, Birmingham, June 19.

The Osmotic Pressure of Colloidal Salts.

CONGO red and similar salts in aqueous solution cannot diffuse through an ordinary dialysing membrane. When the osmotic pressure is directly measured by an osmometer it is found to be about that which the kinetic theory would ascribe to the salt present if the molecules were completely un-ionised.

The solutions, on the other hand, are good conductors of electricity, and the specific molecular conductivity of the solutions employed is that of a solute 60 to 70 per cent. of the molecules of which are dissociated. There is thus, as Bayliss has pointed out,[1] an apparent conflict between the results obtained by different experimental methods.

Congo red is the sodium salt of a complex organic acid. Its ions, therefore, are of very unequal size, and as the membranes employed in the osmometer are permeable to

[1] Paper read at the meeting of the Biochemical Society, May 4.

ordinary salts, they may be assumed to be permeable to the sodium ion, while holding back the much larger organic ion. On the other hand, it is found in actual experiments that the sodium ion does not escape from the osmometer.

Many collateral results show that the membrane does not *mechanically* directly constrain the sodium ion from diffusing. Thus a membrane, even when deeply impregnated with congo red, will permit the passage of sodium sulphate. Biltz and von Vegesack,[1] in order to explain the results, assume that the sodium ion of congo red, because it can diffuse through the membrane (and in spite of the fact that it actually does not do so), therefore contributes nothing to the osmotic pressure. I find myself quite unable to accept this view.

Osmotic pressure is a measure of the total constraint imposed on the system solution and pure solvent by a membrane. To the organic ions, owing probably to their size, the membrane offers what may be called a mechanical constraint. The sodium ions, on which the membrane exerts no such direct mechanical constraint, do not escape, because they are held back by the electrostatic attraction of the negatively charged organic ions. When equilibrium is reached, the electrostatic pull inwards must balance the osmotic pressure, which tends to drive the sodium ions outwards. The total pressure borne by the membrane, therefore, is the sum of the osmotic pressure of undissociated molecules, of the organic ions, and of the sodium ions held back by their attraction to the organic ions.

On this view, the osmotic forces would produce at the membrane an average orientation of plus and minus ions, which should appear as a contact potential difference between the solution and the solvent. The magnitude of the electromotive force can be calculated in several ways, of which the simplest is as follows.

If E be the potential difference of the quasi-condenser formed by the ions, P the osmotic pressure, and c the concentration of the dissociated salt in gr. equivalents per c.cm., then the osmotic force acting outwards on one gr. equivalent of ions is $\frac{1}{c}\frac{dP}{dx}$, and the electrostatic pull inwards is $\frac{dE}{dx}q$, where q is the charge on one gr. equivalent. Since these balance one another, we have

$$\frac{dE}{dx}=\frac{1}{cq}\frac{dP}{dx},$$

putting $c=P/RT$ we have

$$\frac{dE}{dx}=\frac{RT}{qP}\frac{dP}{dx},$$

which on integration gives

$$E=\frac{RT}{q}\log\frac{P_2}{P_1}.$$

This expression differs from Nernst's well-known equation only in the absence of the terms representing the rate of diffusion of the ions.

From what is known of colloidal solutions, it is possible that, except at a high dilution, some of the positive electricity might be carried by complexes too large to penetrate the membrane. These would contribute either nothing at all, or something less than the amount given by an equal number of sodium ions, to the potential difference. Their presence, therefore, would cause the calculated values to exceed the observed values.

W. B. HARDY.

The Fox and the Fleas.

In reference to the letters of Prof. Hughes in NATURE of March 23 and April 13, and his query as to whether the device adopted by foxes for divesting themselves of fleas is "instinctive," may I be permitted to give some particulars of a similar practice which has been observed in this country?

Foxes were introduced into Victoria from England in the early days of the colony, and are now plentiful even in the neighbourhood of Melbourne. Mr. P. R. H. St. John, of the Botanic Gardens, tells me that, whilst botanising or shooting in the neighbourhood of Point Cook during the 'eighties, he has on at least a score of occasions seen foxes enter the water with apparently the same object as the fox observed by Mr. Day.

Point Cook is situated on the west shore of Port Phillip Bay, and is about twenty miles from Melbourne. The surrounding country, being marshy, covered with saltbush, and of little agricultural value, was practically uninhabited, and a favourite hunting-ground for naturalists.

The procedure adopted by the fox was to retreat slowly into the shallow water (the beach being very level at that spot) until only the head was visible, and then it would disappear completely and rise to the surface about a yard away, and, leaving the water with a bound, the fox would rapidly reach the shore, shake itself like a dog, and make off into the bush. The time occupied by the whole operation, which was only attempted when the water was quite calm, would be about three or four minutes.

Mr. St. John, though never closer than about fifty yards, did not think that the foxes he observed held any wool or fur in their mouth (there were no sheep grazing in the locality), but he and his father, and various friends who accompanied him, had come to the conclusion that the object must have been to rid themselves of the fleas which were always to be found on those specimens which they shot.

It will be noticed that this manœuvre differs materially from that of the English foxes in that no wool or fur was used. This would suggest less call on the reasoning power of the fox, but on the other hand the deficiency was made up for by a final complete submersion and (there being no current) a side movement and a rapid escape from the water to dodge the dislodged and probably floating fleas.

The proverbial cunning of the race is surely to be seen in this adaptation of method to the conditions to be found on an uninhabited coast.

HEBER GREEN.

Agricultural Chemistry Laboratory, The University of Melbourne, May 23.

Chemistry at the Forthcoming Meeting of the British Association.

MAY I direct attention to the following features in the provisional programme of Section B (Chemistry) at the British Association meeting in Portsmouth, beginning on August 30 under the presidency of Sir William Ramsay?

(*a*) Joint discussion with the section of agriculture on the part played by enzymes in the economy of plants and animals.

(*b*) Discussion on colloids (opened by Prof. Freundlich, Leipzig, with a contribution on the theory of colloids).

(*c*) Discussion on indicators and colour.

Many foreign chemists intend to be present—amongst others, Profs. Ostwald and Freundlich (Germany), Wegscheider (Austria), Gautier, Haller (France), Clarke, Barus (America), Righi (Italy), Pettersen, Euler (Sweden), Birkeland (Norway), Zeeman, Cohen (Holland)—and it is to be hoped that there will be a numerous attendance of British chemists to do honour to these and other distinguished guests.

JAMES WALKER.
(*President, Section B.*)

Edinburgh, June 24.

Breath Figures.

LORD RAYLEIGH'S communication on breath figures (NATURE, May 25, p. 416) puts me in mind of an experiment—if I may call it so—we made when we were children. After breathing on a window-pane we wrote our names on the glass with the point of a finger. Now after having waited until the moist deposit had disappeared, and again breathing on the glass, the written characters became quite legible.

This seems quite to agree with Lord Rayleigh's explanation, grease on the fingers causing the phenomenon.

Delft, June 6.

J. W. GILTAY.

THE SCOTTISH SURVEY MEMOIRS.[1]

THESE three memoirs mark an important change in the publications of the Scottish Geological Survey. The maps are now colour printed instead of being hand-coloured. This is an improvement for which all Scotch geologists will be profoundly grateful. The cost of the hand-coloured maps at their present outrageous prices is prohibitive to most private students. The solid and drift editions of the Blair Atholl sheet, for example, cost *2l. 7s. 6d.*, and these precious maps may be ruined by a single day's use in the field in wet weather. Moreover, however carefully these hand-coloured maps may be revised they are always liable to suspicion, and occasional errors and omissions are inevitable. The colour-printed maps are in every respect a great improvement. They are cheap, the colours are clear and fixed, and the geologist is no longer perplexed by patches which are uncoloured or of which the colour is doubtful. A useful innovation on two of the new maps is a series of vertical and transverse geological sections, which add greatly to their usefulness. One disadvantage of the Scottish maps compared with the new English series is their unwieldy size; they measure about two feet by two feet five inches, which is inconveniently large. This, however, is a detail which any purchaser of a map can remedy for himself, and will not detract from the congratulations of Scotch geologists to the officials of the Survey on having secured the boon of colour printing.

The three memoirs deal with two very different branches of Scottish geology. Sheet No. 71 comprises the districts around the Sleat of Skye. To the west it includes the eastern part of the Cainozoic volcanic series of Skye, with the gabbros of Blaven and the granophyre of Lord Macdonald's Forest; the eastern part of the sheet is occupied by the Archæan rocks, while a strip of Torridon sandstone with the southern end of the great thrust-planes of north-western Scotland traverse the middle of the map. The memoir on this district has been awaited with much interest, for many of the problems with which it deals are of wide importance. The area includes the well-known Archæan limestones to the east of Glenelg; it shows exceptionally well the relations between the Moine and Lewisian gneisses, and north of Glenelg Bay there is an interesting contact between the Torridon sandstone and the Moine gneiss.

The memoir marks one very important advance in the history of the Scottish Archæan geology. It has

FIG. 1.—Intrusive Sheet of Teschenite, with Upper Old Red Sandstone in the Foreground, Salisbury Craigs, Arthur's Seat, Edinburgh. From "The Geology of the Neighbourhood of Edinburgh."

[1] The Geology of Glenelg, Lochalsh and South-East part of Skye. (Explanation of one-inch map 71.) By Dr. B. N. Peach, F.R.S., and others. With contributions by G. Barrow and others. Pp. x+206 and map. Price 3*s*. 6*d*. Memoirs of the Geological Survey, Scotland.

The Geology of the Neighbourhood of Edinburgh. (Sheet 32, with part of 31.) By Dr. B. N. Peach, F.R.S., and others. Contributions by Dr. J. Horne, F.R.S. and others, and Petrological Chapters by Dr. J. S. Flett. Second edition. Pp. xii+445+xii plates and map. Price 7*s*. 6*d*.

The Geology of East Lothian, including parts of the Counties of Edinburgh and Berwick. (Explanation of sheet 33, with parts of 34 and 41.) Second edition. Revised and re-written by C. T. Clough and others. With contributions on the Silurian Tableland by Dr. B. N. Peach, F.R.S., and Dr. J. Horne, F.R.S. Pp. x+266+xii plates and map. Price 4*s*. 6*d*. (Edinburgh: W. and A. K. Johnston, Ltd.; London: H.M. Stationery Office, Edward Stanford, and T. Fisher Unwin; Dublin: Hodges, Figgis and Co., 1910.)

been a widespread belief that the Moine gneiss is the metamorphosed eastern representative of the Torridon sandstone, a view supported by the high authority of Dr. Peach. The memoir does not accept that view, and leaves the decision somewhat uncertain. The Moine series is described on the map as of uncertain age, but it is placed below the Torridonian, from which it is separated by a series of igneous rocks, and it is placed just above the Lewisian. The guarded statements in the text and the association of the Moines in the explanation of the map with the Lewisians rather than the Torridonians, both suggest that the final conclusion of the Survey inclines strongly to the view that the Moines are pre-Torridonian. The relations between the Moine and the Lewisian gneisses is another problem on which there is a strong difference of opinion, and the neighbourhood of Glenelg yields important evidence on this question. The subject is carefully discussed in the text, and the conclusion is adopted that the Moines are a younger series, resting unconformably on the Lewisian, the junction being marked in places by a basal conglomerate.

The problems dealt with in this memoir are of unusual variety, for the area includes a wide band of the Torridonian, the Cambrian limestones with their interesting metamorphic structures south of Broadford in Skye, a varied series of Mesozoic rocks, ranging from the Trias to the Upper Cretaceous, and the eastern part of the famous Cainozoic volcanic series of central Skye.

The two other memoirs are both new editions, and describe better known and more accessible areas. The memoir on sheet 32 is issued as a new edition of "The Geology of Edinburgh." This edition is necessarily enlarged, and is now a work of 450 pages with twelve excellent plates, a coloured map of Arthur's Seat, and other illustrations. The new edition contains many important alterations, for its predecessor was issued fifty years ago. The subject of most general interest in this sheet is the ancient volcano of Arthur's Seat. The work of the Survey has confirmed many of the conclusions of Sir A. Geikie, especially his explanation of the basic lavas of Calton Hill as a part of the volcanic platform of Arthur's Seat, which has been faulted westward. Prof. Bonney's separation of the sill of Salisbury Crags, now identified as teschenite, from the other igneous rocks is accepted, and Prof. Judd's theory that the volcanic rocks of Arthur's Seat all belong to one series of eruptions is fully established. The sedimentary rocks have also undergone great changes; the Craigmillar sandstones that underlie the volcanic rocks, are transferred to the Old Red Sandstone, a view first suggested by Goodchild, who held that their lithological characters were inconsistent with the climatic conditions that prevailed in the area during Carboniferous times. This argument has now been established by Dr. Traquair's identification of some fossil fish remains which were first found by Dr. Peach.

FIG. 2.—Typical Dry Valley joining Spott Burn, above Spott. From "The Geology of East Lothian."

The geology of the country to the west of Edinburgh has undergone even greater changes. When that part of the sheet was mapped in 1859 there was no oil shale mining in the district; the discovery of the West Lothian oil shales and the development of the mineral oil industry has all happened since the first edition was issued. There is also much fresh

evidence as to the coal supply of the area, and the memoir quotes the estimate of Dr. Dixon and Mr. John Gemmell that, at the present rate of consumption, there is sufficient coal in seams of one foot or more in thickness to last for another two thousand years.

The Edinburgh area is rich in fossils, and the interesting palæontological sketch and the tables by Dr. Lee are among the most useful contributions in the volume. There is a detailed bibliography by Mr. Tait. One remarkable omission from the literature of the areas is the absence of reference in any of the Survey memoirs to Bertrand's papers on the structure of the Scottish oil shale.

The third memoir deals with the geology of East Lothian, the district to the east of Edinburgh. Its geology includes part of the Silurian tableland of the Southern Uplands, of which the account is mainly taken from Peach and Horne's monograph on the Silurian rocks of Scotland. At the eastern foot of the Silurians is a wide plain of upper Old Red Sandstone, including at the base conglomerates containing such large boulders that Sir Andrew Ramsay regarded them as of Glacial origin. No support to this view has been obtained, and there is much more probability in Goodchild's view that the sandstones of the upper part of this system are a desert formation stained by the infiltration of iron from some once overlying beds of New Red Sandstone. The largest part of this sheet is occupied by rocks including two varied igneous series; the first consists of the lavas of the Calciferous sandstone series, and their associated necks, including trachytes, banakites, and mugearites, and the rare hornblende trachy-dolerites —to use that misleading term—known as kulaites. Bass rock is a neck belonging to this division, and the exposure of some fresher samples from it enables its rock to be identified as a phonolite-trachyte. The second igneous series includes the quartz-diabase, teschenite, and essexite, intrusive into the Carboniferous limestone series. The lowlands contain a varied series of Glacial deposits and some dry valleys described by Prof. Kendall and Mr. Bailey, cut during the recession of the ice (see Fig. 2).

Mr. Bailey contributes an interesting summary of the history of the scenery, and shows there is good reason to believe that the Midland Valley of Scotland originated as a true rift-valley, and that the scenery, though greatly modified during Glacial times, is mainly due to pre-Glacial denudation.

The areas described in these publications are of especial importance in Scottish geology owing to their varied problems, and the Geological Survey is to be congratulated on these valuable maps and memoirs, with the large amount of new evidence now so well placed at the public disposal. J. W. G.

PHYSIOLOGICAL APPLICATIONS OF RADIOGRAPHY.

It is a matter of common knowledge that the introduction of X-ray examinations of patients was a boon and a blessing both to patients and surgeons. The localisation of foreign metallic objects, such as bullets and needles, and the exploration of fractured bones and disorganised or dislocated joints, have been thus rendered both easy and certain.

It may not, however, be so generally known that it is also possible to render visible the movements of certain internal organs, which are sufficiently opaque to cast their shadow on the photographic plate or the fluorescent screen; it need scarcely be pointed out that in this way much more accurate information can be obtained of the movements of the heart and diaphragm than what was previously inferred from the examination of the cadaver, or the inspection of the exposed parts in anæsthetised animals.

Notable among the recent achievements in this direction are researches which have for their object the investigation of the digestive canal. Cannon's work in the Harvard laboratory a few years ago showed that in animals the journey of a meal mixed with bismuth salts can be followed with a nicety never before experienced. Valuable as this pioneer work was, it is comparatively unimportant from the human and practical point of view, when compared with the investigations which, by similar means, are possible in man. Here Dr. Hertz and his colleagues at Guy's Hospital have done yeoman service; and Dr. Hertz has embodied the bulk of his work in a very readable volume, entitled "Constipation and Allied Disorders" (London: Hodder and Stoughton, 1909). It is possible to administer to human beings sufficiently large doses of bismuth carbonate (2 to 6 ounces) without any detriment either to digestive processes or to the well-being of the subject of the experiment. Without going into the details of the time occupied in the various parts of the alimentary tract, and the nature of the peristalsis which is the cause of the downward progress of the food, it will be sufficient to say that we now possess trustworthy data on these and many other points, and the events from swallowing onward to defæcation have been examined and registered.

We have been led into these references by a reprint now before us by Dr. A. C. Jordan, who holds the office of Medical Radiographer to Guy's Hospital. It is entitled "Radiographic Demonstration of Lane's Ileal Kink," and this, to the non-medical reader, will not convey much. When man adopted the upright posture, the advantages he gained were, to a certain extent, counterbalanced by some disadvantages and a liability to certain troubles. One of these is that the abdominal viscera either drop, or tend to drop. The stomach, for example, has its greater curvature in the pelvis when a man stands upright, and the transverse colon (a part of the large intestine) hangs in a great loop, the middle of which accompanies the stomach into the pelvis. Mr. Arbuthnot Lane has shown that Nature attempts to diminish these changes of position of the viscera by the formation of adhesions, which form supplementary mesenteries to hold them up. But this attempt at a remedy is not entirely adequate, and kinks in the bowel may be produced, which lead to obstruction, giving rise to pain, to many days' delay in the passage of food, and severe constitutional changes, due to the absorption of toxic materials from the intestine. A part of the intestine called the ileum is particularly apt to be kinked in this way, and its surgical treatment will relieve the patient of all symptoms. A bismuth meal and subsequent radiographic examination will reveal the situation of the kink, and so the surgeon knows exactly where to cut down, and the patient has only to suffer from a comparatively small abdominal wound.

We may take such work as an admirable example of the practical and beneficent application of the X-ray method to structures which are neither bones nor foreign objects such as bullets. The members of the Guy's Hospital staff responsible for these results are to be heartily congratulated on the outcome of their researches, and the public at large owe them a deep debt of gratitude in addition.

SIR RUBERT BOYCE, F.R.S.

THE news of the premature death of Sir Rubert Boyce, at the age of forty-eight, will come as a shock to many, not only at home, but throughout the tropical world. A bare record of his scientific work would give but little idea of what his achievements really were. His rare abilities were of a practical nature, and took shape eventually in the initiation and organisation of manifold activities. He was educated in London, Heidelberg, and Paris, and after taking his medical degree in 1889 he devoted himself to research work, mainly on the pathology of the nervous system, under Sir Victor Horsley, at University College, and in 1893 was appointed professor of pathology at the then University College, Liverpool. Soon afterwards he was asked to take up the position of bacteriologist to the city of Liverpool, which he held until his death.

In 1902 Sir Rubert Boyce was elected a Fellow of the Royal Society. He was a member of the Royal Commission on Sewage Disposal, and for a period of five years he supervised the researches conducted for the Commission at Liverpool. In 1904 he was appointed a member of the Royal Commission on Tuberculosis, and on the day of his death he was to have signed the final report of the Commission.

During these years his powers of organisation were being put into practice, and to mention one project only, his part in the transformation of University College into the University of Liverpool is a well-known fact. While this and many other achievements—for in each he took a most active part—represent an amount of work and energy that can only be appreciated by those who know the manifold difficulties and the dead weight of opposition that has to be removed before such objects can be successfully carried through, yet they were still to be followed by even greater things.

Sir Rubert Boyce had established a close relationship, often indeed a warm friendship, with those other great organisers who mould the destiny of the great commercial world of Liverpool. He was never tired of telling the commercial community that science was not merely an academic pursuit, but was intimately connected with the carrying on of their business. Whilst he preached that science was not merely an academic pursuit, his practice was a proof of it. One of the most remarkable and devoted of his friendships was with one of the most striking of the great personalities of Liverpool—the late Sir Alfred Jones. Sir Alfred himself was a man of great practical organising genius, and the great organising powers of Sir Rubert Royce now found their full scope in association with this untiring orginator of ideas. It was in 1898 that he, together with Sir Alfred Jones, founded the Liverpool School of Tropical Medicine, which rapidly became known throughout the whole world, both scientific and non-scientific, for its work. Now also at his initiative commenced that remarkable series of expeditions which, apart from their scientific side, fired the imagination of all residents in the tropics.

Tropical medicine was forced on the ear of the public, and their help and that of the governors in the tropical dependencies was enlisted, in securing that the conditions in the tropics should be improved. The improvement in the last ten years has been great, but the work has really only begun. Sir Ronald Ross had at this time been conducting his anti-malarial campaign, but there was more to be done, and Sir Rubert, not content with having founded a great school, himself actually went into the field to see matters at first hand.

In 1905 an outbreak of yellow fever occurred at New Orleans. He quickly availed himself of the opportunity, offered by the American authorities, to take part in the campaign. He then laid the foundation of that experience which was to bear fruit later. At the same time, at the request of the British Government, he visited British Honduras, where also yellow fever had broken out. In 1906 the first symptoms of the illness that eventually proved fatal occurred. In 1909 again, at the request of the Government, he visited the West Indian Islands to investigate yellow fever, and in 1910 he made his last expedition to West Africa, where an epidemic of yellow fever had occurred.

Not content simply with official reports of these expeditions, he determined to impress the importance of these subjects, of which yellow fever was only one, on the public. The result was in two short years three popular works, "Mosquito or Man," "Health Progress and Administration in the West Indies," and "Yellow Fever and its Prevention," stating in clear and forcible language the bearing of scientific results on the health and prosperity of the community. The success of these works was immediate, and the name of Sir Rubert Boyce became a household work to every European in the tropics. But even this was not enough; he must do something to remedy the state of affairs revealed, and the formation of the Bureau of Yellow Fever at Liverpool marks the last of his many practical works. It is as a great scientific organiser that Sir Rubert Boyce will take his place, and when the history of tropical medicine comes to be written, his will be a foremost and revered name.

In tropical medicine it may well be said that he found the passion of his life. The founding of the school may be regarded as the culminating effort of his practical genius, but his actual experience of tropical medicine in the field, in his visits to the tropics, so impressed his imagination that it is impossible to think he ever would have forsaken it; and, very shortly before his death, which he knew might take him at any moment, he declared that his one desire in life was to do some work to alleviate the condition of those who lived in the tropics. His methods came as a sharp electrical shock to those accustomed to more sedate ways. Financial difficulties seemed to present to him no obstacle, once he had seen that the end was desirable; his unrivalled success in collecting funds from the most unpromising quarters was well known, and he will be sorely missed not least by those who suffered gladly in this way at his hands.

His care and thought for those who worked with him were often unsuspected, but those who did their work thoroughly found that they were not forgotten in the race, and there are many in various parts of the world who can testify to his generous help.

His many activities often aroused keen antagonisms, and to many perhaps his personal qualities were quite unknown. But those who knew him in his private life, who had enjoyed his hospitality, or had further had the privilege of his friendship, found in him a warm, generous, and noble spirit.

J. W. W. S.

SCIENCE AND CORONATION HONOURS.

OWING to the necessity of going to press earlier than usual last week no reference was made to the list of Coronation honours. There is, however, little to record; for though the list is very long, the services which men of science render to the State are but scantily represented in it. From a national point of view this disregard of scientific work must be considered as unenlightened policy. A title does not

usually add much to the distinction of the man of science upon whom it is conferred, but it indicates that the State regards his work as worthy of public honour and encouragement. No greater services can be rendered to the nation than those represented by contributions to natural knowledge, but judging from the list of honours they are least esteemed. The reason is probably that men of science of distinguished eminence are as unknown in the political world as most of the names in the list are unknown outside particular circles. It is apparently necessary to apply science to some art or profession before the State can understand its value. Many members of the medical profession are rightly included in the honours list, and we offer all of them our congratulations. Education also receives some recognition. We notice in the list the names of the following Fellows of the Royal Society:—

Dr. W. Osler, Regius professor of medicine in the University of Oxford, has been made a baronet; Dr. A. J. Evans, honorary keeper of the Ashmolean Museum, has been knighted; the Hon. C. A. Parsons, C.B., has been promoted to K.C.B., and the same title has been conferred upon Major Ronald Ross, professor of tropical medicine in the University of Liverpool, Vice-Admiral A. M. Field, lately hydrographer of the Navy, and Prof. J. A. Ewing, director of naval education. Mr. R. E. Froude, superintendent of the Admiralty Experimental Works; and Prof. A. W. Reinold, late professor of physics in the Royal Naval College, Greenwich, and Colonel H. C. L. Holden, superintendent, Royal Gun and Carriage Factories, Woolwich Arsenal, have been created C.B.'s. Dr. J. Rose Bradford, secretary of the Royal Society, has been appointed a K.C.M.G.

Omitting representatives of medicine in its various branches, other names familiar to many of our readers are:—

Sir John Rhys (Privy Councillor); Sir Boverton Redwood (Baronetcy); Dr. A. W. W. Dale, Vice-Chancellor of the University of Liverpool, Mr. G. H. Ryan, president of the Institute of Actuaries, Dr. J. E. Sandys, Public Orator in the University of Cambridge, and Prof. R. P. Wright, lately professor of agriculture and principal of the West of Scotland Agricultural College (Knighthoods); Prof. M. E. Sadler, professor of education, University of Manchester (C.B.); Dr. R. A. Falconer, president of the University of Toronto, Mr. H. N. Ridley, Director of Gardens and Forests, Straits Settlements, and Dr. T. Zammit, Government analyst, Public Health Department, Malta (C.M.G.'s).

NOTES.

It is now an open secret that the intentions of Parliament for the investigation and cultivation of the local fisheries are being greatly delayed by the apparent reluctance of the Board of Agriculture and Fisheries to cooperate with the Development Fund Commissioners. Questions asked in the House of Commons during the last few months have elicited replies which show that a carefully drafted application, made more than a year ago, by the Lancashire and Western Counties Fisheries Committee, containing definite proposals for the improvement of the local fisheries, has not yet been submitted to the commissioners. On June 20 Sir E. Strachey, replying to Mr. N. Buxton and Mr. Whitehouse, assured the House of Commons that the Board is not neglecting the fisheries. It has applied to the Development Fund Commissioners for a loan of 50,000*l.*, and an annual grant of 8000*l.* for the purpose of coast patrol vessels. It is also asking for a sum of money to enable a special commission to investigate the condition of the inshore fisheries. The secretary to the Board should also have stated that, during the last nine years, two Departmental Committees have made exhaustive reports with regard to the inshore fisheries, and that the Board has now full control of the staff, funds, and resources for fishery investigation enjoyed by the Marine Biological Association until about a year ago. Further, it was not made clear that the subjects mentioned by Mr. Buxton—the investigation of the shell-fisheries and the pollution of tidal waters, the scientific investigation of the territorial water fisheries, and the organisation of the research societies—have all been considered by the fishery committees wherever these things are important enough to require consideration. The urgent need of the present time is that the Development Commissioners should assist the local committees in the prosecution of investigation and cultivation of the inshore fisheries.

The annual report of the Society for the Astronomical Study of Ancient Stone Monuments, Cornwall Branch, shows increasing membership and funds. The report consists mainly of a paper read by Mr. Henry Thomas, one of the secretaries, reviewing observations made at Boscawen-un, Tregaseal, Wendron, and Boskednan circles. In each case the typical circle "does not constitute or comprise in itself a system, but that it is rather the centre of a system, and that the number of stone monuments and barrows which stand at various distances and in various directions, but all within sight of the circle, were not erected and constructed in those positions by mere accident" is "one thing about which there can be no division in our opinions." The circles are never exactly alike, and it seems that not one of those examined is a true circle. It is confessed that no rule has been found to explain the varying distances between the stones in a circle. The apparent irregularity suggests the direction in which a rule might be found, namely, testing the astronomical use of each stone from all available view-points. The next meeting of the society is announced to be held at Rosemoddress Circle, St. Buryan, on June 30.

The late Prof. His, of Leipzig, conceived the idea of establishing in each country a central institute which should have for its chief aim the organisation and the coordination of biological research in its own territory, and serve as a means of cooperation with similar institutions in other countries. In other words, his far-reaching scheme implied the establishment of a regular organised army to attack the problems of living matter, which are being assailed at present only by the wasteful methods of guerilla warfare. During the last decade this proposal has been put to a practical test in the United States and Europe (excepting Great Britain) by the establishment, or the recognition, of certain institutions as centres for coordinating researches upon the brain, under the direction of the "Brain Commission" of the International Association of Academies. The success already attained in this domain of biology has encouraged others to follow in the footsteps of the neurologists. During Whit-week a conference was held in the zoological laboratory of the University of Utrecht for the purpose of founding an International Embryological Institute. Austria, Belgium, England, France, Germany, and Holland were represented at the meeting by workers in the domain of vertebrate embryology; and letters were received from Switzerland and the United States in support of the scheme adumbrated by the conveners of the meeting. Prof. R. Bonnet, of Bonn, was elected first president of the institute, and it was decided that the first aims of the new institution should be (1) the collection of complete series of well-preserved embryos of every mammalian order, and (2) a more intimate cooperation between embryologists, for the purpose of attaining a uniformity in nomenclature and the solution of the special difficulties in this field of investigation.

THE German Emperor has conferred the Order of the Crown, Second Class, upon Sir Ernest Shackleton.

DR. SVEN HEDIN has been elected a correspondant of the Paris Academy of Sciences in the section of geography and navigation.

THE death is announced, in his fifty-fifth year, of Dr. E. B. Voorhees, the director since 1896 of the New Jersey Agricultural College experiment station, and the president, since 1901, of the New Jersey State Board of Agriculture. He had written and lectured extensively on agricultural chemistry and allied subjects.

AT the meeting of the Association Internationale de l'Institut Marey held on June 6th, the resignation of Prof. Kronecker as president was received. The members of the association elected Prof. Charles Richet as president, and Dr. Augustus D. Waller as vice-president. The Institut Marey is under the patronage of the Associated Academies. It is situated in the Parc des Princes, Boulogne-sur-Seine, Paris, and contains laboratories, library, and living rooms for the accommodation of workers. The acting director is Dr. Lucien Bull.

THE Royal Institute of British Architects has awarded the King's gold medal for the promotion of architecture to Dr. W. Dörpfeld, director of the German Archæological Institute, Athens. Owing to Dr. Dörpfeld's serious illness, he was unable to receive the medal in person at the meeting of the institute on June 26, and he has had to abandon his projected visit to this country, in the course of which he was to receive an honorary degree at Cambridge, and speak at a special meeting of the Hellenic Society on July 4.

THE President of the Local Government Board has authorised the following special researches to be paid for out of the annual grant voted by Parliament in aid of scientific investigations concerning the causes and processes of disease:—(1) A research into the causes of premature arterial degeneration in man, by Dr. F. W. Andrewes; (2) an inquiry by Dr. J. H. Thursfield into the causes of death in measles; (3) a comparison by Prof. Nuttall, F.R.S., of the number and kind of fleas found on rats; (4) a continuation by Dr. C. J. Lewis of his investigation into the degree of prevalence and the characteristics of micro-organisms known as non-lactose fermenters in the alimentary canal of infants; (5) an investigation into the same subject by Dr. D. M. Alexander; (6) an inquiry by Dr. Graham Smith into the incidence of non-lactose fermenters in flies in normal surroundings and in surroundings associated with epidemic diarrhœa; (7) a study by Dr. F. A. Bainbridge of the anærobic bacteria in the alimentary canal of infants; (8) an investigation by Dr. Graham Smith into the possibility of pathogenic micro-organisms being taken up by the larva and subsequently distributed by the fly.

THE council of the Royal Society of Arts has decided to make the following awards in connection with the prize offered for the best portable apparatus or appliance for enabling men to undertake rescue work in mines or other places where the air is noxious:—a gold medal to Mr. H. A. Fleuss, for the apparatus submitted by Messrs. Siebe, Gorman and Co.; a gold medal to Mr. W. E. Garforth, in recognition of his efforts to perfect and to secure the adoption of rescue apparatus in mines; a silver medal for the "Draeger" apparatus submitted by Mr. Richard Jacobson; a silver medal for the "Meco" apparatus submitted by the Mining Engineering Company. Of the apparatus submitted to the committee appointed to report upon the subject, four depended on the supply of compressed oxygen, one on the provision of air evaporated from liquid air, and one on the production of oxygen from "oxylith." The principal points of difference, apart from the fundamental principles on which the apparatus are constructed, appear in the comparative lightness and convenience of carriage, and in the arrangements for enabling the wearer to breathe either by the use of a helmet or by means of mouthpieces of various construction. The committee does not consider that the liquid-air apparatus sent in is as yet sufficiently perfect to justify its adoption in preference to the older systems, under which oxygen is supplied from a receptacle containing the gas in a state of compression.

THE annual report of the committee of the Research Defence Society is a record of good work accomplished during the past year. The total number of members and associates, which was about 3360 a year ago, is now about 4600, showing an increase of 1240, as against an increase of 840 in the previous year. There are now twenty-five branches, and this number is expected to be increased in the autumn. Since June of last year more than ninety addresses or lantern-lectures connected with the society have been given in different parts of the kingdom. The following pamphlets and leaflets have also been published:—(1) report of annual general meeting, 1910; (2) Malta fever; (3) sleeping sickness; (4) experiments on dogs; (5) In Memoriam, Louis Pasteur; (6) the facts of the case; (7) experiments during 1909; (8) humanity and science, by the Bishop of Ely; (9) plague in India, by Colonel Bannerman; (10) friends of animals, by Major Marjoribanks; (11) a question of ethics, by Major Marjoribanks; (12) the case presented by the anti-vivisectionists, by Prof. Schäfer. The quantity of literature distributed has greatly increased during the year. Five hundred copies of Colonel Bannerman's pamphlet have just been supplied to the Government of Eastern Bengal and Assam. The total number of pamphlets and leaflets distributed during the year was more than 150,000. A book is in the press giving a full account of the evidence before the Royal Commission. Of course, with all this increase of work, there has been a considerable increase of expenditure, and the committee earnestly appeals to all members and associates of the society to enlist their friends, and thus to extend still further the society's useful work. The honorary secretary, to whom in great measure the success of the society is due, is Mr. Stephen Paget, 21 Ladbroke Square, W.

IN No. 5 of vol. v. of *The American Museums' Journal*, Prof. H. F. Osborn gives an account of an important extension of the American Museum of Natural History, New York, which is to be undertaken shortly. This is nothing less than the erection of a new eastern façade, similar in general character to the southern façade, but somewhat simpler in design. It will contain a second main entrance to the building. When this addition is completed, it will permit of the installation of an extensive ethnographical and also a zoological series arranged geographically. It is also contemplated to arrange a gallery illustrative of the sequence of human evolution; while eventually it is intended that astronomy, geography, and oceanography should be included in the exhibition series.

THE Museo Nacional of Buenos Ayres publishes in vol. xx. of its *Annales* two papers by M. Florentino Ameghino, one entitled "Observations au sujet des notes

du Dr. Mochi sur le paléoanthropologie Argentine," the second, "L'Age des formations sédimentaires tertiares de l'Argentine en relation avec l'antiquité de l'homme." In the first, while admitting Dr. Mochi's services to the cause of prehistoric archæology, the writer, whose paper is fully illustrated by drawings of skulls, conducts a lively criticism of Dr. Mochi's views. This is renewed in the second paper, in which he arrives at the conclusion that the presence of Archtotherium in the quaternary deposits of North America furnishes an additional proof of the immense antiquity of the Pampean and other ancient formations in Argentina, which contain the *débris* of animals of the same group.

In the study of the native languages of the American continent, Mr. A. L. Kroeber, in a paper entitled "Phonetic Constituents of the Native Languages of California," contributed to vol. x. of the publications on American archæology and ethnology of the University of California, has opened up new ground. Hitherto some of the most valuable grammatical study of these tongues has been conducted by ethnologists untrained in phonology. Recently, however, the principles and methods of phonetic research established by European scholars have been applied to the languages of the American Indians, and in this paper the results, already promising, are discussed. This investigation will, it is hoped, not only assist in the study of those Californian dialects which have not been as yet examined, but will help to solve the fundamental problem, whether the linguistic families of America possess any underlying or general features peculiar to themselves as a class.

The Somerset Archæological and Natural History Society has resumed work on the Meare Lake village, under the control of Messrs. A. Bulleid and H. St. George Gray. Besides various late-Celtic relics similar to those already discovered, Mound 7 has produced a class of objects hitherto not found elsewhere, including a number of worked and polished shoulder-bones of animals, the blade-bones being in some cases ornamented in the dot-and-circle pattern. Kimmeridge shale is rather plentiful for a substance imported from Dorset. Little bronze has so far been found, the objects including finger-rings, an awl, and a rivet. Some much-corroded iron objects, such as a knife and chisel, have been unearthed. Human remains are scarce, only two pieces of skull-bone having been found. Pottery is plentiful, and of a type differing in design from that found at the Glastonbury Lake village. As is evident from the number of bones of various kinds, the people occupying this site lived largely on meat. They possessed an ox and horse of a small type, a large variety of dog, and remains of the beaver and otter have been discovered. The relics which have been up to this time found are open to inspection at a temporary museum on the site, whence later on they will be removed to the County Museum at Taunton Castle.

The Edinburgh Medical Journal for June (vi., No. 6) is a centenary number dedicated to the memory of Sir James Y. Simpson, "to whose genius and benevolence the world owes the blessings derived from the use of chloroform for the relief of suffering." It includes a number of portraits and other illustrations, and articles on his life and work by his daughter, Miss Eve Simpson, Sir Alexander Simpson, Sir Halliday Croom, Dr. Berry Hart, and others. Not only did he introduce chloroform, but in addition the uterine sound, mechanical dilatation of the cervix uteri, and various obstetric and gynæcological operations. He was a great and lovable man, and also engaged in the pursuit of many archæological problems.

Livingstone College, Leyton, E., was founded in order to give elementary medical training to missionary workers, and judging by the matter contained in the Coronation number of its year-book, just issued, appears to be admirably fulfilling its functions. Among the achievements of old students may be noted the action of the Rev. E. W. T. Greenshield, who rescued the entire shipwrecked crew of a Dutch whaler in which he was sailing, and for this he has been decorated by the Queen of Holland; whilst in Assam an old student, a missionary of the Baptist Missionary Society, has discovered a new mosquito, henceforth to be known as the *Culex pettigrewii*.

Hides and skins coming from some parts of the world, *e.g.* Siberia, China, Persia, and Asia Minor, are liable to be infected with anthrax, and those handling them are liable to infection. Many methods have been suggested for treating the skins so as to destroy the anthrax spores without damaging the material, but none is satisfactory. In a valuable report to the Leathersellers' Company, Dr. Constant Ponder discusses the incidence of anthrax amongst those engaged in the hide, skin, and leather industries, and has investigated various processes proposed for the sterilisation of anthrax spores. Among these, a process recently introduced by Mr. Seymour-Jones has been tested. It consists in soaking the skins for twenty-four hours in a solution containing 1 per cent. of formic acid and 1 in 5000 of mercuric chloride, after which the skins are treated with a strong brine solution. The method has no deleterious action, the skins can be perfectly tanned afterwards, and it is generally efficient in destroying anthrax spores. Probably a slightly increased amount of mercuric chloride would be an advantage.

After a long period of quiescence, plague has once more appeared among the rats in the Port of London. As mentioned in a note in Nature of June 22 (p. 562), plague-infected rats have been found for three years in succession in the port, viz. in the West India, the South-West India, and the Royal Albert, Docks. The present site of the infection is a wharf on the banks of the Thames at Wapping, less than a mile from the Tower Bridge. Twelve dead rats were found at this wharf, of which four at least were plague-infected. The existence of plague in wharves and warehouses, which are not inhabited at night, may be regarded with comparative equanimity so long as it does not spread to the rats in the plexus of mean streets which lie behind. The real cause for anxiety is the steadily widening area over which plague-infected rats have now been found. The fact that no cases of human plague have lately been recorded in England is not of much significance, because the period for human infection is only now commencing, coinciding as it does with the increase of the rat-fleas. A writer in *The Times* of June 17 in an able article thus summarises the occurrence:—"While the recurrence in the Port of London of an infection which has been already noted in three successive years can be regarded without excitement, it has its serious aspects. It cannot be too strongly urged that the mere presence of plague in England among rats, in however limited a form, may become a matter of sinister importance. If the Wapping outbreak marks a slowly widening circle of infection, it would be in exact accord with Indian experience, for plague has sometimes taken months, or even years, to pass through the rats of a single village. So long as the rats are infected, there must always be some danger to mankind."

The second number of vol. iv. of the Journal of the Federated Malay States Museums contains four papers, by

Mr. C. B. Kloss and other naturalists, on local mammals and birds.

WE have to acknowledge the receipt of the report of the Field Museum of Natural History, Chicago, for 1910, in which it is stated that a steady development of that institution is in progress, with a continued increase of its utility as an educating centre. A marked extension took place during the year in the anthropological department. The report contains several illustrations, among which attention may be directed to a photograph of a group of three gorillas recently added to the exhibition series.

POULTRY-BREEDERS should be interested in an article on the inheritance of fecundity in domesticated fowls, contributed by Dr. Raymond Pearl to the June number of *The American Naturalist*. The article is so full of technicalities that it is difficult to give a summary of the conclusions intelligible to the ordinary reader. The author is however, of opinion that different degrees of fecundity are inherited by fowls, although it is extremely difficult, if not impossible, to isolate and develop a strain with great egg-laying capacity. It is further stated that the inheritance is probably in complete "accord with Johannsen's concept of genotypes." It may be added that the "genotype," or "pure line theory," is discussed in a second article in the same issue by Dr. J. A. Harris, who is disposed to doubt its validity.

VOL. xiii. of the *Rapports et Procès-Verbaux* of the International Council for the Exploration of the Sea contains the administrative report of the eighth year (1909–10) of the international cooperation and the proceedings of the ninth meeting of the council, which was held in Copenhagen in September, 1910. Special interest attaches to the presence at this meeting as guests of the Deputy-Commissioner of Fisheries for the United States of America, Dr. Hugh M. Smith, and the Inspector-General of Fisheries for France, M. Fabre Domergue. It would be of the very greatest value to the success of the investigations if the area to be explored could be extended to the waters of the North Atlantic, with the cooperation of the French and American Governments. The reports, which are appended to the proceedings of the meeting, are of considerable importance, although the general report on plaice fisheries, which it is hoped will bring to a head much of the most important work which has been carried out in connection with the investigations, is not yet available. Dr. Hoek gives a summary account of the quantitative distribution of the eggs and larvæ of the gadoids in the North Sea, and Prof. D'Arcy Thompson furnishes a second report on the later stages of these fishes. The flat fishes are similarly treated by Dr. Ehrenbaum and Dr. A. T. Masterman.

THE REV. HILDERIC FRIEND has reported to the director of Kew Gardens the discovery of two new annelids in earth received from Peru. The first is an Enchytræid, *Fridericia peruviana*, Friend, the other being a new species of Trigaster. It differs from the known species in its small dimensions, as well as in the position of the gizzards, the hearts, and the intestine, and is named *Trigaster minima*, Friend. This worm has the gizzards in segments 9, 10, 11, the principal hearts are in 12–15, and the intestine begins in 19, while the length is 15 mm., as compared with 250 mm. in *Trigaster lankesteri*, Benham.

IN NATURE of May 11 (p. 356) attention was directed to the proposal of the Bombay Natural History Society to start an investigation into the mammals of British India. Mr. N. Annandale writes from Calcutta to point out that a real zoological survey, in which the more obscure groups of animals (which have no less scientific value than the mammals) were included, would cost a great deal more than 2000*l*., for which an appeal was made, although preliminary work has been done as regards certain groups. He refers to Colonel Alcock's recent memoir on the fresh-water crabs, which it is hoped will be followed shortly by others on different groups of terrestrial and aquatic organisms.

IN *The Journal of Economic Biology* (vol. vi., No. 2) Mr. E. E. Green presents an enumeration of several species of Coccidæ, with diagnoses of those new to science, collected on rubber plants in Ceylon. *Lecanium viride* was the most important found on *Hevea brasiliensis*, but as it occurred chiefly on young trees it was amenable to treatment by spraying. A new species, *Inglisia castilloae*, was perhaps the most dangerous, as it spread from the Castilloa to tea shrubs in the vicinity, but it did not attack the closely adjacent Hevea trees. Another of the new species is a lac insect that spread thickly on a Landolphia vine. A second item of interest to entomologists is supplied by the article in which Mr. H. Maxwell-Lefroy offers advice on the training of British entomologists, with special reference to students prepared to take service in British colonies or possessions. He insists particularly on the desirability of infusing a more "economic" character into the student's training.

THE interesting account of his botanical expedition to Lower Siam communicated by Mr. H. N. Ridley is continued in *The Gardener's Chronicle* (June 17 and 24). Many new or remarkable plants were collected near Kanga, in the province of Perlis. Three species of Holarrhena, small apocynaceous shrubs, a Dischidia, and a dwarf Lastræa are new to science; *Cycas siamensis*, characterised by its curved white stems, and a swollen-stemmed balsam, *Impatiens mirabilis*, were particularly striking as they grew on the limestone hills, and the orchid *Dendrobium crumentatum*, which flowers simultaneously over a whole area, was observed on its flowering day. Further north, near Setul, several Australian types were discovered, the most remarkable being a new species of Thysanotus, a liliaceous genus confined to Australia except for one Philippine species. The author concludes that the boundary between the Malayan and Burmese flora is unusually distinct, and lies near the town of Alorstar in Kedah.

A PRELIMINARY study of the flora on different grass plots, with the object of ascertaining whether a botanical criterion of their value as pasture lands can be evolved, is reported in the Scientific Bulletin (No. 2) of the Royal Agricultural College, Cirencester. A complete catalogue of species was first compiled, and then the species were arranged under the three groups of grasses, Leguminosæ, and general plants according to their relative abundance. Data were thereby obtained for a comparison of the proportion of valuable grasses and leguminous plants to the less valuable and worthless species. Thus it was found that where the bottom grasses were luxuriant only nineteen species in all were recorded, whereas the total number of species exceeded fifty on the poor lands. Also generalisations are deduced from the growth of allied species; thus *Bromus erectus* was strongest on the dry oolitic soil, while *Holcus lanatus* predominated on wet areas.

IN an interesting report on the "Barometer in Jamaica," Mr. Maxwell Hall discusses the determination of the differences of height between pairs of stations in Jamaica from meteorological observations, and he calculates certain tables for use in the application to this problem of a form of Laplace's formula slightly different from that usually

adopted. Mr. Hall finds differences in the values obtained for the height according to the time of day and the season of the year at which the observations of pressure, temperature, and humidity are made. The values are generally larger near midday and in summer than at other times and seasons, a result not altogether surprising. The temperature enters into the determination of height through the expression $\int_{z_1}^{z_2} \frac{dz}{T}$, and there is clearly room for error if this is taken to be $(z_2-z_1)/T_M$ where $T_M = \frac{1}{2}(T_1+T_2)$ and T_1, T_2 are the temperatures at the lower and upper stations respectively. Mr. Hall elaborates an empirical method for correcting the value of T_M obtained in this way, in order to eradicate the differences found. In this connection it may be mentioned that recent determinations of heights in the Tyrol have furnished results closely agreeing with the values obtained by levelling. In these cases, however, mean values were used, and an intermediate station was available. Mr. Hall uses the value 60,159 feet in the hypsometric formula, instead of 60,369 feet, the value adopted in the International Tables, but does not state his reason for preferring the smaller value.

IN *The Electrician* for June 9, Dr. R. Beattie describes a method of determining the coefficients in the Fourier series for a curve, which should extend the use of such series amongst those who have not had a mechanical analyser at command and have been unwilling to go through the laborious process of determining the coefficients arithmetically. It will be remembered that the latter process consists in measuring the ordinates of the curve at regular intervals, multiplying these by the sines or cosines of certain angles, and taking the mean of the products. Dr. Beattie's suggestion is to measure the ordinates on scales graduated so as to read the products direct, and thus reduce the work to addition. Once the necessary scales are available the method will, we anticipate, be used extensively.

THE Department of Commerce and Labour, Coast and Geodetic Survey, Washington, has issued a volume of "Directions for Magnetic Measurements," by Mr. Daniel L. Hazard, of the Division of Terrestrial Magnetism. This extends to 131 pages, and contains instructions for the absolute observation of the magnetic elements with instruments of the various types used by the Coast and Geodetic Survey. The instruments are described with illustrations, and there is a discussion of the determination of the several constants. This is followed by a series of "directions for operating a magnetic observatory," which includes an account of Eschenhagen magnetographs and the methods of standardising the curves. At the end there are a series of tables intended to assist in the reduction of the absolute observations, which include some particulars of the diurnal inequalities recorded at the observatories belonging to the Coast and Geodetic Survey.

THE U.S. Coast and Geodetic Survey's "Results of Magnetic Observations made . . . between July 1, 1909, and June 30, 1910," gives in about seventy pages an account of a year's work in terrestrial magnetism in the United States. Observations were made at 241 stations, including a number previously occupied, so that numerous secular change data were obtained. A good many magnetic observations were also made at sea by the Survey's vessels. Two-thirds of the space is devoted to descriptions of the stations occupied. The situation of some of these seems a little unusual. Several, for instance, are in cemeteries, the exact site being marked by small pillars dated and lettered U.S.C. and G.S., the coordinates of which in some cases are given in terms of the distances from adjacent tombstones. If the absence of iron can be relied on, and sentiment does not count, it cannot be denied that a good deal can be said in favour of the practice, but one rather wonders how it strikes the average unscientific American.

THE June issue of *Terrestrial Magnetism and Atmospheric Electricity* contains particulars of comparisons of magnetic instruments made by observers of the Carnegie Institution, Washington, between 1905 and 1910, at a number of stations in North and South America, Asia, Australia, and Europe. It also gives voluminous lists of data which the editor, Dr. Bauer, has received from a number of observatories in response to a request for information as to the exact times of commencement of fifteen magnetic disturbances which occurred between 1906 and 1909. The object is to settle a controversy which took place recently in the columns of NATURE as to the rate of propagation of these disturbances round the earth. A further list of data is to appear in the next number of the magazine. The discussion by Dr. Bauer will be awaited with interest. In a reference to the meeting of the International Meteorological Committee, held last September in Berlin, the removal of atmospheric electricity from the domain of the Commission on Terrestrial Magnetism is adversely criticised. A reference to the "passing of the Kew Magnetic Observatory" leads to the statement that "the testing and standardising of magnetic instruments is shortly to be turned over to the National Physical Laboratory." This seems rather in want of explanation.

A CORRESPONDENT asks where he could obtain a portable and very sensitive instrument with which to measure the acceleration of gravity. In reply to the inquiry, Dr. C. Chree has been good enough to provide the following information :—"The determination of *absolute* values of g (acceleration of gravity) with high precision is an attempt very rarely made. For a good many years past relative determinations have almost all been made with half-second pendulums. The half-second pendulums originally obtained for the Indian Survey, which were swung at Kew in 1903, are described in Major Lenox Conyngham's paper on the subject (Roy. Soc. Proc., vol. lxxviii., 1906, p. 241) as 'made by E. Schneider, of Vienna, after Col. von Sterneck's design.' He also says: 'The clock belonging to the apparatus was constructed by Strasser and Rohde, of Glashütte; its pendulum, made by Riefler, of Munich, is of invar.' At the present moment Prof. Helmert, of Potsdam, is considered the leading authority on the subject. Of late years pendulums of invar have been tried at Potsdam, as temperature uncertainties in the field are amongst the most troublesome. The usual procedure is to swing the pendulums at a base station—*e.g.* the observatory at Potsdam—where g is supposed to be known, and thence to deduce its value at any other place where the pendulums are subsequently swung."

MESSRS. CASSELL AND CO., LTD., have commenced a reissue of Mr. W. F. Kirby's well-known "Butterflies and Moths of Europe," to be completed in thirty-two weekly parts. Part i. appeared on May 25.

THE Admiralty has ordered from Messrs. Newton and Co., of 3 Fleet Street, London, ten sets of X-ray apparatus to be supplied to the new battleships for service afloat. We understand that these will make altogether thirty complete installations that this firm alone has recently supplied to the ships of the Royal Navy.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR JULY:—

July 2. 18h. 0m. The Sun in Apogee.
" 22h. 0m. Jupiter stationary.
3. 13h. 0m. Mercury in superior conjunction with the Sun.
4. 21h. 21m. Jupiter in conjunction with the Moon (Jupiter 0° 58′ N.).
7. 4h. 0m. Venus at greatest elongation, 45° 29′ E.
8. 2h. 10m. Mercury in conjunction with Neptune (Mercury 2 19′ N.).
11. 18h. 19m. Uranus in conjunction with the Moon (Uranus 4° 28′ N.).
14. 9h. 0m. Neptune in conjunction with the Sun.
19. 7h. 31m. Mars in conjunction with the Moon (Mars 2° 0′ S.).
20. 11h. 11m. Saturn in conjunction with the Moon (Saturn 3° 33′ S.).
" 18h. 0m. Uranus at opposition to the Sun.
24. 14h. 42m. Neptune in conjunction with the Moon (Neptune 5° 29′ S.).
26. 20h. 0m. Mercury in conjunction with the Moon (Mercury 4° 6′ S.).
28. 9h. 18m. Venus in conjunction with the Moon (Venus 5° 47′ S.).
29. 2h. 0m. Mercury in conjunction with α Leonis (α Leonis 0° 9′ S.).
" 13h. 0m. Jupiter at quadrature to the Sun.

REDISCOVERY OF WOLF'S COMET.—A telegram from the Kiel Centralstelle announces the rediscovery of Wolf's comet, by Prof. Max Wolf, on June 19. The position of the comet at 12h. 4·9m. (Königstuhl M.T.) was

R.A. = 18h. 46m. 16s., dec. = 13° 28′ N.,

and its magnitude was 15. The position is about 15m. west of ζ Aquilæ. According to the continuation of the ephemeris published by M. Kamensky in No. 4505 of the *Astronomische Nachrichten*, the comet will move in a north-westerly direction until July 15, when it will turn south again. Its calculated magnitude for July, September, and October is about 12·2, but from the observation the actual magnitude is, at present, somewhat fainter than the calculated.

MARS.—Observations of Mars were commenced at the Juvisy Observatory during the clear mornings of April, and several well-known features were seen. The south polar cap was seen to be surrounded by a dark belt, which certainly had the appearance of an objective phenomenon. Mare Sirenum was seen on April 24 as a diffuse spot descending from the polar cap and fading gradually towards the bright limb of the planet. The central region to the north was seen to have the accustomed yellowish-orange hue, and Titan was vaguely, but surely, seen. These observations when the apparent diameter of the planet was only 6″ show that useful observations will be possible considerably before the opposition, which takes place on November 25. The account of these early observations, in the June number of *L'Astronomie*, is illustrated by a drawing made by M. Quénisset at 16h. 20m. on April 24.

In *La Nature* (No. 1986, June 17) Dr. Mascart has an interesting illustrated article, in which he discusses the present state of the vexed question concerning the reality of the Martian canals. The general result is that the question is, as yet, by no means decided, but there is a hope that the laboratory experiments being carried on by MM. Chapeau and Danjon may do something to elucidate this difficult question further.

THE PROBLEM OF THE SOLAR MOTION.—Continuing the discussion with Prof. Comstock concerning the proper motions of faint stars, Dr. H. E. Lau publishes some interesting results, accruing from the Copenhagen measures of the Engelhardt stars, in No. 4502 of the *Astronomische Nachrichten*.

He finds that the mean proper motion of tenth-magnitude stars is 3″ per century at the most, and that it is smaller in the Milky Way than outside it. For the position of the apex he obtains A = 290°, D = +44°, and finds that the proper motions of tenth-magnitude stars indicate a greater R.A. and declination than those of the brighter stars, but the reality of this difference is still doubtful. A reduction of the measures shows that the mean parallax of these stars of the tenth magnitude lies between two and three thousandths of a second of arc, and that the error of Newcomb's precession constant does not exceed 0·1″ per century.

THE FORMS OF SPIRAL NEBULÆ.—The forms of spiral nebulæ is a matter of moment in any investigation concerning cosmical evolution, and any attempt to find some general law which these early systems follow is therefore of interest. Such a research is described by Herr Von E. v. d. Pahlen in No. 4503 of the *Astronomische Nachrichten*.

The author has studied photographs of many spiral nebulæ taken at the Lick and the Isaac Roberts Observatories, and has attempted to find general equations to their curves. Among other nebulæ, he has considered M. 33, Trianguli, M. 74, Piscium, and M. 51, Canum Venatici. In each case an Archimedian spiral was tried, but it was found that a logarithmic spiral could be found which better fitted the chief branches of the observed spirals. The agreement of the calculated and observed curves is shown by a number of graphs, and all are satisfactory except the second branch of M. 51, in which there appear several discordances. The paper also discusses the probable generation of such curves as are observed in these objects.

THE SPECTROSCOPIC BINARY *o* PERSEI.—*o* Persei is of special interest as a spectroscopic binary because, as occurs in one or two other cases, the calcium lines H and K do not appear to participate in the general variations of the radial velocity. In discussing the Allegheny observations of this star, Mr. F. C. Jordan pointed out that his value for the velocity of the centre of the system did not agree with the one obtained earlier by Vogel from the Potsdam observations, and suggested the possibility of a systematic personal error in the latter.

To clear up this point, Dr. Ludendorff has made new measures of the spectra, and finds that, although there is a marked difference between Vogel's measures and his own, yet it remains probable that the difference between Jordan and Vogel is to some extent real; possibly a third, as yet unconfirmed, body is included in the system. As the spectrum of *o* Persei is difficult to measure, further investigations will have to be made to settle this interesting point (*Astronomische Nachrichten*, No. 4500).

THE COAL-DUST QUESTION IN THE UNITED STATES AND IN AUSTRIA.[1]

THE first explosion that seems to have attracted attention to coal dust in the United States occurred at Pocahontas mine in 1884. Very little attention was paid to the subject for some years afterwards, until explosions began to occur in the western region "in shallow mines in which firedamp had never been found before the explosions, and was not found after them." Although the majority of these were not of a serious character, they gave rise to much uneasiness; but when what might be called the *black* year of 1907, with a death-roll of "1148 men killed by mine explosions," had run its course, uneasiness gave way to consternation. In 1908 Congress "made an appropriation" for the investigation of mine explosions, which became available on July 1; the United States Geological Survey was entrusted with the work, and an experimental station, which had, in the interim, been erected at Pittsburg, was officially opened on December 3 of the same year.

Experiments which, in the bulletin before us, are described as a preliminary series, have been made with the object of determining "the quantity or density of the finest size of coal dust necessary to propagate an explosion."

[1] "The Explosibility of Coal Dust." By George S. Rice, with chapters by J. C. W. Frazer, Alex Larsen, Frank Haas, and Carl Scholz. United States Geological Survey, Bulletin 425. Pp. 186. (Washington: Government Printing Office, 1910.)

Abstract of the Reports on the Austrian Coal-dust experiments conducted at the Rossitz experimental station 1908–1909 by k. k. Oberbergkommissär, Dr. Czaplinski, and Werksdirektor Jicinsky. Pp. 36. (London: The Colliery Guardian Company, Limited, 1911.)

The apparatus employed is similar to that at Altofts and Liévin. It includes a cylindrical gallery 6 feet 4 inches in diameter by 100 feet long, closed by means of a block of concrete at one end; with a cannon embedded in the concrete, from which shots can be fired for the purpose of raising and igniting the dust; with small glass windows at intervals of 6 feet 8 inches apart on one side; with arrangements for fixing paper diaphragms so as to isolate certain portions of its interior when experiments with firedamp are undertaken, and so on.

The coal dust is prepared by grinding and screening coal of the following composition:—

	Per cent.
Moisture	1·94
Volatile combustible	35·11
Fixed carbon	57·73
Ash	5·22
	100·00
Sulphur	1·25

The method of conducting the experiments, and the records of their results, are both so similar to those that have been described in two previous reviews,[1] that it would be supererogatory to describe them in this place, more especially as they occupy very little space in the volume before us, and are, as has been said, mostly of a preliminary character.

The remainder of the volume is devoted to a history of the subject, in which our author has done ample justice to the work of his predecessors; to dissertations on "The Humidity of Mine Air," "Remedies for Coal Dust," "Tentative Conclusions on the Dust Problem," and "Special Features in Dust Explosions," written by the author himself, and includes special chapters on "Laboratory Investigations of the Ignition of Coal Dust," by J. C. W. Frazer; "Coal Dust Investigations at European Testing Stations," by Axel Larsen; "Exhaust Steam as a Preventive of Dust Explosions," by Frank Haas; and "Use of Steam and Water Sprays at Oklahoma Mines," by Carl Scholz.

All these subjects have already been investigated and commented upon by other earlier writers, and as there is nothing specially new or original in the articles before us, they need not further detain us in this place. The fact that the "selected bibliography" occupies twelve and a half pages, and that the titles of no fewer than two hundred and four of the papers and articles mentioned in it contain either the word "coaldust," or in some cases simply "dust" and "dusty," as applied to mines, explosions, and experiments, is an indication of the growing interest with which the subject is, and has for some time past been, regarded. Finally, considering the source from which the present report has emanated, it is perhaps almost superfluous to add that it is furnished with a complete index.

The Austrian experiments are being carried out under the auspices of the Vienna Permanent Firedamp Committee, which decided to resume them in 1908 after an interval of several years, during which operations at the experimental gallery at Babitz, near Segengottes, had been suspended. The ostensible object of this new series is "to ascertain the conditions under which coal dust—especially that of the Rossitz district—can be caused to explode even in the absence of firedamp, and to test the means hitherto employed, or proposed, for minimising or preventing coal-dust explosions, chief among them being water curtains, wet and dustless zones, and dry stone-dust zones." "Experiments with coal dust in conjunction with explosive gases are also in contemplation."

The Babitz gallery differs from the others previously referred to, first, in being built partly in masonry and partly in brick work, with an arch of the same materials overhead, and a level floor; and, secondly, in being wholly underground. Its depth under the surface is 2 metres at one end and 21·6 metres at the other. The thickness of cover increases at a fairly uniform rate from the shallower end to a distance of rather more than two-thirds of the whole length, where it attains 7 metres, and thereafter more irregularly to the deeper end. Its length is 293·7 m., and its other dimensions are:—at its deeper end, 1·3 m. wide at the sole, 1·4 m. wide at the spring of the arch, 1·74 m. high, and its sectional area 2·2 square metres; and at its shallower end, 2·4 m. high and 3·4 square metres in sectional area.

[1] NATURE, February 9, 1911, vol. lxxxvi., p. 223.

Travelling communication is established with its interior by means of three shafts, one sloping downwards to a point 1·7 metres distant from its deeper end, provided with stairs and ladders, and with a strong door both at its top and bottom; a second, sloping downwards to a point 82 metres distant from the bottom of the first, also provided with stairs and ladders, and with a strong door at its top and bottom; and a third, at its shallower end, provided with a ladder only, and with its top capable of being closed by means of balks of timber.

The space between the bottom of the deepest shaft and the end of the gallery nearest it (called the explosion chamber) is built of concrete, and is 1·7 m. long, measured in the direction of the axis of the gallery, 1·3 m. wide, and 1·82 m. high. Its open side next the gallery can be closed by means of a paper diaphragm pasted to a wooden frame fixed on the periphery of the gallery, and coal dust and firedamp can be admitted to its interior through two pipes, one for firedamp the other for coal dust, which extend down into it from the surface. At distances of 47·8 and 88·2 metres respectively from the explosion chamber, two other pairs of pipes constitute similar links of communication between the surface and the gallery. One pipe of each pair serves for the introduction of coal dust, the other as an open passage in which a shaft with a circular disc fixed to its lower end, which is in, and just below the roof of, the gallery, can be made to revolve rapidly by means of hand mechanism at the surface. The coal dust, introduced through the two pipes just referred to, falls upon the two corresponding revolving discs, and is disseminated in the surrounding air by the centrifugal force imparted to it by the motion of the discs; that similarly introduced into the explosion chamber passes immediately into the interior of a small vertical fan, made to revolve by means of an electric motor, and is thus disseminated through the air in the chamber in a similar manner.

The gallery is lighted by means of shielded incandescent electric lamps standing in niches in the walls, and is ventilated by means of an electric fan fixed in the shaft farthest from the explosion chamber. The fan is capable of exhausting 20 cubic metres of air per minute from the interior of the gallery.

The coal dust employed in the experiments is collected in the screening sheds (?) and in the workings, and only the most suitable kinds are taken. Amongst these, the finest leaves a residue of 3·8 per cent. on a sieve with 3480 meshes, and the coarsest a residue of 19·5 per cent. on a sieve with 1160 meshes per square centimetre. Its composition is as follows:—

	Per cent.
Moisture	0·58 to 4·5
Volatile matter	19·20 to 22·8
Ash	9·17

When an experiment is about to be made, coal dust is strewn about in the gallery, or placed on a series of seven narrow shelves equally spaced above each other, supported horizontally (and transversely as regards the gallery) in rectangular wooden frames suspended at intervals of 5 m. apart, or laid on slanting laths fastened to the walls, or disseminated in the air by means of the fan in the explosion chamber and the revolving discs previously mentioned, or brought into the sphere of action by any one or any combination of these means.

The explosives employed for disturbing and igniting it are cartridges of gelatine dynamite from 150 up to 300 grams, "for the most part hanging free," and fired electrically with 1-gram caps; or 300 grams of black powder placed loosely in a mortar with a bore of 450 mm. long and 27 mm. in diameter, tamped with paper, and fired with a fuse. In some cases the dynamite charges are fired in the mortar.

No account is given as to the position in which the dynamite cartridges are hung, either as regards their height above the floor or their horizontal distance from the end of the gallery or chamber: nor can we gather where, or at what height, or at what angle from the hori-

zontal, if any, the barrel of the mortar usually stands when a charge is fired from it, or whether there are two mortars, one in the explosion chamber, the other movable to any other desired position. The only reference we can find in this connection is to *a* mortar "on the floor of the gallery," fired in this particular instance at a distance of 20 m. from the explosion chamber (p. 26).

An attempt has been made to measure pressure by means of a spring indicator. We say "attempt," because the curves reproduced on pp. 19 and 22 are of identical construction with, and indistinguishable in this respect from, those obtained by the present writer with a similar contrivance in the small Royal Society gallery (1877–8). We put these curves aside at the time (although we still possess them) as altogether untrustworthy, as we were of opinion that the first impulse given to the piston was due to the initial explosion of firedamp, and its subsequent vibrations to the combined action of the momentum of the moving parts and the resilience of the spring, and not to those of the air in the gallery; and we consider the curves now before us to be of quite as little value as our own.

The length to which the flame extends is ascertained by placing a series of sulphur matches set in wooden blocks at intervals of 1 m. apart along the walls of the gallery, and observing how many of them have been burnt.

A bottle filled with water, suspended neck downwards at a distance of 10 m. from the explosion chamber, with its loosely fitting cork attached by a string to the nearest hanging frame, serves the purpose of collecting a sample of the afterdamp. When the hanging frame moves under the impulse of the blast, the cork is displaced, the water runs out, and the air and gases take its place.

The audible and visible phenomena produced by an explosion are stated to be a shock "followed by a return shock after an interval of not more than two seconds"; the shock expels a column of air from the terminal shaft (the one farthest from the explosion chamber), opens the door at the top of the intermediate shaft (when the door at its bottom, which opens *into* the gallery, has been removed), and expels a cloud of "smoke" (? dust-laden air), followed, when the explosion is violent, by a flame several yards in length; the return shock opens the iron door at the explosion chamber, closes the door at the top of the intermediate shaft, and fresh air rushes in at the shafts at both ends of the gallery. Immediately afterwards, "thick, dense, blackish-grey afterdamp" is expelled from the terminal shaft by the fan. The frames with shelves are usually torn away and shattered; and on one occasion the door at the top of the intermediate shaft, together with portions of its frame, was thrown to a distance of 30 m.

Passing over the accounts of tentative and preliminary experiments, both with suspended cartridges of dynamite and with black powder fired from the mortar, we may take the following as fairly typical examples of the best results with both kinds of explosive:—

(1) With suspended cartridges of dynamite.

With 32·5 k. of dust strewn over a length of 90 m. from the chamber, and with dust being disseminated in the air by the distributing fan in the chamber and by the revolving discs at 47·8 and 82·8 m. from the latter, the length of flame in the gallery was 124 m. and that in the intermediate shaft 24 m.

In another explosion, with a strewing of 90 m., conducted, presumably, under the same conditions as the last, but not so specified, the length of flame was 118 m.; the maximum pressure is stated to have been 1·38 atmosphere, and the duration of the explosion 0·013 second.

(2) With 300 grams of black powder fired in the mortar without tamping, when both discs and the distributing fan were at work, and 30 k. of dust "employed" (some of it probably strewn on the floor?), the length of the flame was 147 m. (p. 25).

With even the finest dust, containing 2·2 to 4·5 per cent. of moisture, only relatively slight explosions and short flames could be obtained with either dynamite or black powder; but with even coarse dust, containing only 0·7 to 1·7 per cent., strewn over a distance of 88·2 m., flames up to 147 m. were produced.

In the second series of experiments, which were made after a new door, that could not be opened by the explosion, had been fixed at the bottom of the intermediate shaft, and a third revolving disc placed at a distance of 120 m. from the chamber, a flame of 200 m. in length was obtained in one of the experiments with a charge of 250 grams of dynamite and with 129 grams of coal dust per cubic metre (containing 13·3 per cent. of ash, 0·45 of moisture, and 19·2 of volatile matter), disseminated over a distance of 120 yards. This coal dust left 12·2 per cent. on a sieve with 3480 meshes per square centimetre.

Under the same conditions, except that the dust contained 7·55 per cent. of moisture, no explosion took place.

Coal dust containing 14 per cent. of ash gave violent explosions with flames 150 m. in length, whereas that containing 47·9 per cent. did not explode.

Coal dust mixed with increasing proportions of Roman cement continued to explode until the mixture contained 63·3 per cent. of the latter. The suggested and highly probable explanation of this apparent anomaly is that the cement dust falls more quickly than the coal dust, and leaves the mixture remaining suspended in the air purer than it would otherwise be.

The influence of wet zones, and what are designated "water curtains," was also investigated. "The wet zones were formed by sprinkling in the usual way just before shot-firing, and were intensified at intervals by water curtains" (p. 34). The "usual way" is probably that described on p. 11, that is, by means of hose pipes attached to branches of a supply pipe laid along the floor of the gallery. The water curtains, which consist in sprays of water issuing upwards, downwards, and across the gallery at right angles to its longer axis from perforations or nozzles in pipes fixed on its periphery, are stated to have produced little effect on the length of the flame (p. 35).

A wet zone of 60 m. extinguishes an explosion even when a dry-dust explosion produced under the same conditions extends to 137 m. in the absence of the water. "With wet zones 36 to 57 m. long, the flame projected beyond them failed to ignite the dust in the immediately adjoining second coal-dust zone in which the third atomiser (revolving disc) was in operation."

In comparing the foregoing results with those obtained in the galleries at Altofts and Liévin, it should be borne in mind that the coal dust employed was collected at the screens and in the workings, that it, consequently, contained indefinite proportions of coarse and fine particles, and that it is lower in volatile matter than the coals employed in the two galleries named.

These less favourable conditions seem to account for its apparently lower inflammability and its greater sensitiveness with regard to increasing proportions of uncombined moisture.

From *a priori* considerations as to the nature of combustion, it might have been thought that the two following propositions could have been accepted as axiomatic, namely, that, *caeteris paribus*, (1) the finer the dust, the greater the proportion of volatile combustible matter, the drier the air and the higher its pressure and temperature, and the less the proportion of mineral matter and moisture (combined and uncombined) the more inflammable the dust; and (2) conversely, with all the conditions reversed. As it is, most of them have been verified by the results of all the recent quantitative experiments, including an excellent series on the laboratory scale by Prof. Bedson and Mr. Widdas.[1]

The results of the experiments made by the Prussian Firedamp Commission[2] seemed to contradict the second condition as to the influence of increase in the proportion of volatile matter, in regard to which they make the following remarks on p. 31:—

(3) "Bei einem Gehalte an flüchtigen Bestandtheilen von 18 bis 22 pCt. scheint die Flammenverlängerung am grössten zu sein" (vi., 4, 9, 10, 11).

(4) "Mit einem höheren Gehalte an flüchtigen Bestandtheilen tritt wieder eine entschiedene Abnahme der Flammenverlängerung ein, selbst bei ganz feinem Staube" (vi., 13, 14, 15, 18, 19, 20, 21, 22). "Es bleiben gleichwohl diese gasreichen Kohlen ohne Ausnahme noch sehr

[1] Transactions of the Institution of Mining Engineers, vol. xxxix. Part V. (1910).

[2] Anlagen zum Haupt-Berichte der Preussischen Schlagwetter-Commission, Band IV. Table VI. Pp. 35 (1886).

gefährlich, wenn dieselben hinreichend feinen Staub liefern; falls dieses aber nicht stattfindet—und dieser Fall scheint in der That recht häufig vorzukommen—bieten dieselben wenig Gefahr" (vi., 23, 24, 25).

"Hiernach haben unsere Versuche die früher verbreiteten Ansichten in diesem Punkte bestimmt widerlegt."

In this case, also, the coal dust was taken from the screens or from the mines, and employed without any previous sifting or preparation of any kind. It was thus of the same character as that employed in the Austrian gallery, and therefore subject to the same drawbacks. In by far the larger number of trials the strewing in the gallery was only 10 m. in length, and the charge of explosive was invariably 230 grams of black powder.

It is therefore undoubtedly useful to have some of the more exact numerical data established by the recent experiments in regard to even a few classes of coal, such as the limit of explosibility with decreasing volatile matter, on the one hand, and with increasing incombustible mineral matter on the other, although it is quite certain that both of these limits must necessarily be profoundly modified by the presence of more or less firedamp in the air, and by the higher temperature, lower capacity for heat, and more active oxidising properties of the oxygen in the air under the compression existing in the condensed wave of an explosion in the workings of a mine.

But it requires very little consideration of the number of natural factors that vary to show that even the most elaborate series of experiments that could possibly be carried out can only touch the outer fringe of the subject.

In these circumstances it is to be hoped that in accepting the loan of the experimental tube and other appliances at Altofts from the colliery owners, and in constituting themselves and others into a committee for the purpose of making experiments with them, the Royal Commission on Mines will confine its attention to a few very definite objects, and will, before everything else, including even the treatment of dust in the main haulage ways, bear in mind that the true solution of the coal-dust question lies in the prevention of explosions by the honest application of well-known means, that is to say, of means applied in such a manner as would, in the opinion of the present writer, who examined the scenes of the explosions in both Whitehaven and Hulton Collieries, undoubtedly have saved the lives of 480[1] men in 1910, and not in the slipshod way in which the law has hitherto allowed.

The siren song of the inventors, vendors, and advocates of rescue appliances which, it is said, have never yet saved a single life after an explosion, but have been the means of losing many; the trumpetings of those who are clamouring for the establishment of "zones," and even the counsels of those who beseech us to have mice and little birds ready to test the afterdamp, seem to have almost completely distracted attention from the real point at issue for several years past. Even the Royal Commission on Mines seems to have allowed itself to become entangled, not only in the Circean alliance referred to above, but to some extent also in a Charybdic whirlpool of supposed palliative suggestions.

As has been often said before, great explosions occur exclusively in dry and dusty mines, and are invariably begun either by the intentional detonation of an explosive (shot-firing) or by the accidental ignition and explosion of a certain volume of inflammable gas. If the coal dust lying within a certain radius of the one presumed centre of disturbance or the other were always rendered sufficiently damp beforehand to prevent it from being raised up into the air by the subsequent blast, a great explosion would be impossible in any mine. One efficient means of attaining this end consists in spraying water from the nozzle of a flexible hose attached to the branch of a water-main or to a tank on wheels containing water and compressed air. The means is, therefore, "not in heaven"—neither is it beyond the sea—"but is very nigh"—is, in fact, already in use in many of our mines.

If the Royal Commission on Mines were only strong enough and independent enough, it would specify categorically *in what manner* (by means of pipes or water-tanks) and *to what extent* (distance or radius, and quantity per unit of area) water must be applied in the case of shot-firing in order to render the operation quite safe, and (shall we also add?) in the presence of accumulations of inflammable gas; it would insist with all the weight of its Royal authority that the regulations which it recommends be placed upon the Statute Book and be rigidly enforced in the practice of every dry and dusty mine working coal with, say, 12 per cent. of volatile matter and upwards, whatever may be the nature of its roof and floor; and it would add in the way of serious and impressive advice to all engaged in mines of this class words of similar import to those employed by the great Hebrew lawgiver in similar circumstances:

"And thou shalt teach them diligently unto thy children,
And shalt talk of them when thou sittest in thine house,
And when thou walkest by the way,
And when thou liest down and when thou risest up.
And thou shalt bind them for a sign upon thine hand,
And they shall be as frontlets between thine eyes,
And thou shalt write them upon thy posts, and on thy gates."

W. GALLOWAY.

ENTOMOLOGICAL PAPERS.

AMONG a batch of papers received from the Entomological Bureau of the U.S. Department of Agriculture, perhaps the most generally interesting is one, by Mr. F. C. Bishopp, on the distribution of the Rocky Mountain spotted-fever tick (*Dermacentor venustus*). Now that the fever is known to be principally, if not exclusively, transmitted to man by the tick, the determination of the distributional area of the latter has become a matter of importance. Western Montana is the district where the disease occurs in its most virulent form, but it is also met with, although in a less severe type, in parts of Idaho, Wyoming, Utah, and Nevada, and these areas coincide to a great extent with the maximum abundance of the tick, the whole range of which includes parts of Washington, Montana, Oregon, Idaho, Wyoming, Nevada, Utah, Colorado, and a small tract in New Mexico. In its earlier stages the tick infests small mammals, but later on migrates to the larger domesticated species, and it is in districts where the latter abound and brush-wood is plentiful that it attains its maximum development. Unfortunately, the disease appears to be spreading.

In a second pamphlet Mr. T. L. Patterson records the results of investigations into the habits of the larvæ of certain flies of the family Sarcophagidæ in relation to the pernicious gipsy moth (*Porthetria dispar*). As a rule, the sarcophagid maggots feed only on decomposing pupæ of the moth, but consignments from Europe and Japan suggest that the larvæ of some of the flies may be truly parasitic on the pupæ, in which case it is hoped that an additional means of controlling the ravages of the moth may be obtained.

Other pamphlets deal with the "asparagus-miner" (*Agromyza simplex*), insects affecting stored grain, and the one-spray method of checking the codling-moth and the plum-weevil.

According to the report of the Dominion entomologist, Dr. C. G. Hewitt, issued in the annual Report on Experimental Farms for 1909–10, Ottawa, a new Destructive Insect and Pest Bill was introduced during the period under review into the Canadian Parliament. The necessity for such legislation, owing to the rapidly increasing volume of foreign trade, was pressing, as it was essential to provide means against the introduction, or reintroduction, of such pernicious species as the San José scale and woolly aphis, and the brown-tail and gipsy moths. The brown-tail moth, introduced some years ago, is still the most important enemy against which the Entomological Department has to fight, and it is essential that every possible means should be taken to prevent its spread, as otherwise the financial and other losses caused by its devastations will be appalling. It is satisfactory to learn that there were no serious injuries caused during the year by insects harmful to cereal crops, which form the staple of Canadian agriculture.

Interesting observations on the duration of life in *Samia cecropia*, a common American moth, are recorded by Mr.

Philip Rau in vol. xix., No. 2, of the Transactions of the Academy of Science of St. Louis. The cecropia resembles the emperor and lappet moths, which belong to the same family, in taking no nourishment in the adult condition, but whereas the females of the two latter die immediately after oviposition, while the males perish in the act of sexual intercourse, this is not the case with the cecropias, the males living, on an average, a little more than nine days after separating from the females, although the majority of the latter die before all the eggs are deposited. Moreover, unlike those of the European species, the female cecropias do not remain in a torpid condition for days or weeks previous to fertilisation. As the prolongation of the life of the males after sexual intercourse is useless, it cannot be an adaptation for the good of the species, and it is therefore suggested that such longevity may be a survival from a time when it was beneficial.

The inheritance of polymorphism in the American yellow butterfly, *Colias philodice*, is discussed by Prof. J. H. Gerould in the May number of *The American Naturalist*. In this species the female is dimorphic, the ground-colour of the wings being either yellow or white; the yellow phase is in most places the more abundant, although the albinistic phase is dominant in inheritance. Males differ by the narrower black marginal band on the fore-wings, which is usually free from light spots. Since the colour-pattern of the female obtains in those species of the genus where there is no sexual difference in this respect, it is inferred that this represents the primitive type, which seems to survive in the northern *C. nastes*, the ground-colour of which is dull greenish-yellow suffused with brown. In the author's opinion, "the yellow ground-colour and the solid black marginal band [of *philodice*] probably arose by mutation in an undifferentiated *nastes*-like or white stock, and at once became dominant in the male, while the original colours and colour-pattern remained dominant in the female." Passing southwards and westwards, we enter the realm of *C. eurytheme*, a species with an orange ground-colour and very complicated polymorphism, which probably represents the supreme degree of specialisation.

Two species of Thysanura—a Mediterranean bristle-tail (*Thermobia domestica*) and an apparently new spring-tail (*Proisotoma ultonica*)—are added to the fauna of Ireland by Prof. G. H. Carpenter in *The Irish Naturalist* for May. The Rev. F. D. Morice continues his notes on British saw-flies (Tenthredinidæ, &c.) in the May issue of *The Entomologist's Monthly Magazine*.

The division of labour among ants, with special reference to the view that the smaller forms of workers are more active than their larger brethren, is discussed by Miss E. N. Buckingham in vol. xlvi., No. 18, of the Proceedings of the American Academy of Arts and Sciences. As the result of observation, it has been found that in the case of *Camponotus americanus* the males do not perform the chief duties of the nest, but that the queens may take a share of such duties when the colonies are small. The great bulk of the labour is, however, performed by the small and medium-sized workers. In the genus Pheidole, where the intermediate forms have probably been eliminated, all the work is done by small ants. As a general rule, it appears that big ants, like queens, are more active in small than in large colonies. The general inactivity of the big workers and soldiers is an advantage to the colony, as they are not exhausted by labour, and are thus always available for purposes of defence.

Dr. E. Goeldi is communicating a very interesting series of articles on ant-colonies to *Himmel und Erde*. In the May number he illustrates the manner in which the various kinds of ants inhabiting the flooded lands of Amazonia make their nests in trees, so as to be above the water-level, figuring the long, pendant, skein-like nests of *Azteca barbifex*, the torpedo-like structure formed by a species of Camponotus, and the sheet-like *papier-maché* nest of *A. trigona*. Fungus-growing ants are likewise described, with striking illustrations of the crater-like elevations, leading to the subterranean chambers, to be seen in sandy districts of certain parts of America. To these the ants bring fragments of leaves from long distances, and, after storing them in the subterranean chambers, use them as hot-beds for the cultivation of the mycelium stage of the fungus *Rhozites gongulophora*. Whether the fungus, in its fully developed state, ever reaches the surface through one of the entrance-tubes is a moot point.

In No. 1830 of the Proceedings of the U.S. National Museum, Mr. J. C. Crawford continues his descriptions of new Hymenoptera. The types of several of the fifteen species named were forwarded by correspondents of the Bureau of Entomology, and as these species are of interest in connection with economic entomology, the descriptions were published at the earliest possible date.

Attention may be directed to the description by Mr. J. H. Keys in the June number of *The Entomologist's Monthly Magazine* of a new species of British weevil (*Barypithes duplicatus*), on account of the apparent absence of any allusion as to what constitutes the type. It is even left uncertain whether a spot between Broadstairs and Margate, Blean Woods, Kent, or some other place is the type-locality.

R. L.

THE ROTHAMSTED EXPERIMENT STATION.

THE Society for Extending the Rothamsted Experiments met at Harpenden on June 16, and has issued the following report:—

During the past year the work of the Rothamsted Experimental Station has been considerably extended, more particularly in its investigation of the effect upon the fertility of the soil of heating and treatment with antiseptics which destroy the larger organisms there present. A special assistant has been retained to deal with the investigation of greenhouse soils, which, despite their richness in manure, have become "sick" and unable to carry crops. The same factor appears to be concerned in the sickness of the soils of sewage farms, and this question is also under investigation. The examination of the life-history of the larger organisms in the soil has been undertaken in the Rothamsted Laboratory by Mr. T. Goodey, who was appointed for that purpose to a Mackinnon studentship by the Royal Society.

Papers on this question have been published during the year, also on the ammonia content of the atmosphere, on the weeds of arable land in relation to the soils, on the nutrition of plants by non-nitric sources of nitrogen, and on the experimental error attaching to field trials. The Board of Agriculture has also published on behalf of the station an exhaustive report (207 pp. plus 56 maps and figures) on the soils and agriculture of the south-east of England.

Through this additional work the expenditure of the station has exceeded its income by 1000*l*., and a deficit of 1300*l*. has now accumulated.

The Development Commissioners have promised, through the Board of Agriculture, a grant of 2000*l*. for the current year's work, and it is hoped that some such assistance of the kind will be continued in order to provide for the further extension of the work of the station.

To this end it has become necessary (1) to take a lease of the home farm and so secure further land for experiment, (2) to erect additional laboratory accommodation.

It is estimated that 6000*l*. will be required for these purposes, and on the appeal of the society the following subscriptions have already been received or promised:—Duke of Devonshire, P.C., 300*l*.; Lord Iveagh, 200*l*.; Mr. A. Brassey, 100*l*.; Sir J. T. Brunner, Bart, P.C., 300*l*.; Mr. E. H. Carlile, M.P., 52*l*. 10*s*.; Mr. J. F. Mason, M.P., 500*l*.; Mr. R. Mond, 200*l*.; Capt. J. A. Morison, M.P., 500*l*.; Mr. W. Morrison, 100*l*.; Dr. Hugo Muller, F.R.S., 100*l*.; Sulphate of Ammonia Committee, 50*l*.; Sir J. Wernher, Bart., 250*l*.; Mr. J. Martin White, 100*l*.; Sir A. Henderson, Bart., 10*l*. 10*s*. Total, 2763*l*.

At this critical period in the development of agriculture and agricultural science, the Society for Extending the Rothamsted Experiments appeals most earnestly for further assistance to equip Rothamsted—the pioneer among the experimental stations of the world, with a seventy-year history of continuous experiment upon the same land, an institution also which has hitherto been entirely dependent upon private generosity—in a manner adequate to deal with its new responsibilities.

RADIO-TELEGRAPHY.[1]

THE practical application of electric waves to the purposes of wireless telegraphic transmission over long distances has continued to extend to a remarkable degree during the last few years, and many of the difficulties which at the outset appeared almost insurmountable have been gradually overcome—chiefly through the improved knowledge which we have obtained in regard to the subject generally and to the principles involved.

The experiments which I have been fortunate enough to be able to carry out on a much larger scale than can be done in ordinary laboratories have made possible the investigation of phenomena often novel and certainly unexpected.

Although we have—or believe we have—all the data necessary for the satisfactory production and reception of electric waves, we are yet far from possessing any very exact knowledge concerning the conditions governing the transmission of these waves through space, especially over what may be termed long distances. Although it is now perfectly easy to design, construct, and operate stations capable of satisfactory commercial working over distances up to 2500 miles, no really clear explanation has yet been given of many absolutely authenticated facts concerning these waves. Some of these hitherto apparent anomalies I shall mention briefly in passing.

Why is it that when using short waves the distances covered at night are usually enormously greater than those traversed in the daytime, whilst when using much longer

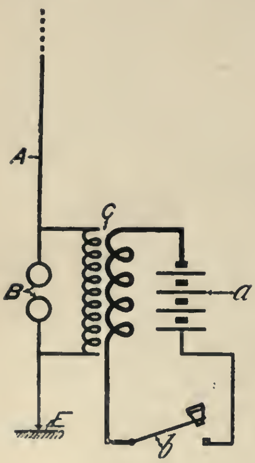

FIG. 1

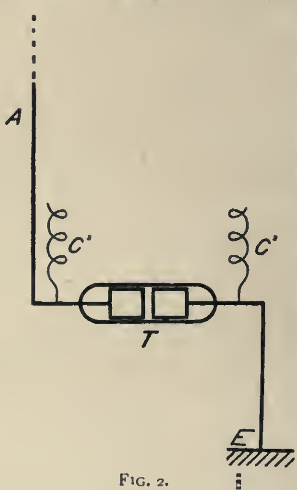

FIG. 2.

waves the range of transmission by day and night is about equal, and sometimes even greater by day?

What explanation has been given of the fact that the night distances obtainable in a north-southerly direction are so much greater than those which can be effected in an east-westerly one?

Why is it that mountains and land generally should greatly obstruct the propagation of short waves when sunlight is present, and not during the hours of darkness?

The general principles on which practical radio-telegraphy is based are now so well known that I need only refer to them in the briefest possible manner.

Wireless telegraphy, which was made possible by the fields of research thrown open by the work of Faraday, Maxwell, and Hertz, is operated by electric waves which are created by alternating currents of very high frequency induced in suitably placed elevated wires or capacity areas. These waves are received or picked up at a distant station on other elevated conductors tuned to the period of the waves, and the latter are revealed to our senses by means of appropriate detectors.

My original system as used in 1896 consisted of the arrangement shown diagrammatically in Fig. 1, where an elevated or vertical wire was employed. This wire sometimes terminated in a capacity, or was connected to earth through a spark gap.

[1] Discourse delivered at the Royal Institution on Friday, June 2, by Commendatore G. Marconi.

By using an induction coil or other source of sufficiently high-tension electricity, sparks were made to jump across the gap; this gave rise to oscillations of high frequency in the elevated conductor and earth, with the result that energy in the form of electric waves was radiated through space.

At the receiving station (Fig. 2) these waves induced oscillatory currents in a conductor containing a detector, in the form of a coherer, which was usually placed between the elevated conductor and earth.

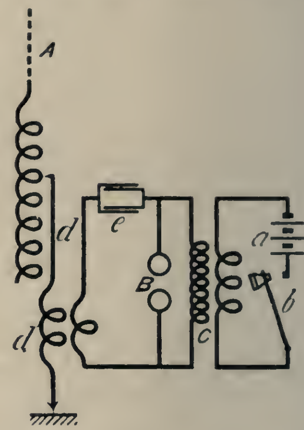

FIG. 3.

Although this arrangement was extraordinarily efficient in regard to the radiation of electrical energy, it had numerous drawbacks.

The electrical capacity of the system was very small, with the result that the small amount of energy in the aërial was thrown into space in an exceedingly short period of time. In other words the energy, instead of giving rise to a train of waves, was all dissipated after only a few oscillations, and, consequently, anything approaching good tuning between the transmitter and receiver was found to be unobtainable in practice.

Many mechanical analogies could be quoted which show that in order to obtain syntony the operating energy must be supplied in the form of a sufficient number of small oscillations or impulses properly timed. Acoustics furnish us with numerous examples of this fact, such as the resonance produced by the well-known tuning-fork experiment.

Other illustrations of this principle may be given, *e.g.* if we have to set a heavy pendulum in motion by means of small thrusts or impulses, the latter must be timed to the period of the pendulum, as otherwise its oscillations would not acquire any appreciable amplitude.

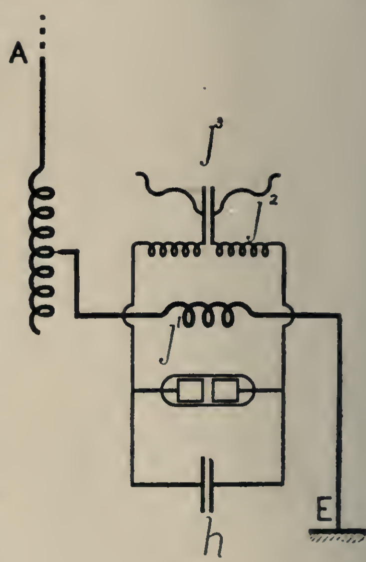

FIG. 4.

In 1900 I first adopted the arrangement which is now in general use, and which consists (as shown in Fig. 3) of the inductive association of the elevated radiating wire with a condenser circuit, which may be used to store up a considerable amount of electrical energy and impart it at a slow rate to the radiating wire.

As is now well known, the oscillations in a condenser circuit can be made to persist for what is, electrically, a long period of time, and it can be arranged, moreover, that by means of suitable aërials or antennæ these oscillations are radiated into space in the form of a series of waves, which through their cumulative effect are eminently suitable for enabling good tuning or syntony to be obtained between the transmitter and receiver.

The circuits, consisting of the condenser circuit and the elevated aërial or radiating circuit, were more or less closely coupled to each other. By adjusting the inductance

in the elevated conductor, and by the employment of the right value of capacity or inductance required in the condenser circuit, the two circuits were brought into electrical resonance, a condition which I first pointed out as being essential in order to obtain efficient radiation and good tuning.

The receiver (as shown in Fig. 4) also consists of an elevated conductor or aërial connected to earth or capacity through an oscillating transformer. The latter also contains the condenser and detector, the circuits being made to have approximately the same electrical time period as that of the transmitter circuits.

At the long-distance station situated at Clifden in Ireland, the arrangement which has given the best results is based substantially upon my syntonic system of 1900, to which have been added numerous improvements.

An important innovation from a practical point of view was the adoption at Clifden and Glace Bay of air condensers composed of insulated metallic plates suspended in air at ordinary pressure. In this manner we greatly reduce the loss of energy which would take place in consequence of dielectric hysteresis were a glass or solid dielectric employed. A very considerable economy in working also results from the absence of dielectric breakages, for, should the potential be so raised as even to produce a discharge from plate to plate across the condenser, this does not permanently affect the value of the dielectric, as air is self-healing, and one of the few commodities which can be replaced at a minimum of cost.

Various arrangements have been tried and tested for obtaining continuous or very prolonged trains of waves, but it has been my experience that, when utilising the best receivers at present available, it is neither economical nor efficient to attempt to make the waves too continuous. Much better results are obtained when groups of waves (Fig. 5) are emitted at regular intervals in such a manner that their cumulative effect produces a clear musical note in the receiver, which is tuned not only to the periodicity of the electric waves transmitted, but also to their group frequency.

In this manner the receiver may be doubly tuned, with the result that a far greater selectivity can be obtained than by the employment of wave-tuning alone.

In fact, it is quite easy to pick up simultaneously different messages transmitted on the same wave-length, but syntonised to different group frequencies.

So far as wave tuning goes, very good results—almost as good as are obtainable by means of continuous oscillations—can be achieved with groups of waves, the decrement of which is in each group 0·03 or 0·04, which means that about thirty or forty useful oscillations are radiated before their amplitude has become too small to affect perceptibly the receiver.

The condenser circuit at Clifden has a decrement of from 0·015 to 0·03 for fairly long waves.

This persistency of the oscillations has been obtained by the employment of the system shown in Fig. 6, which I first described in a patent taken out in September, 1907. This method eliminates almost completely the spark gap and its consequent resistance, which, as is well known, is the principal cause of the damping or decay of the waves in the usual transmitting circuit.

The apparatus shown in Fig. 6 consists of a metal disc *a* having copper studs firmly fixed at regular intervals in its periphery and placed transversely to its plane. This disc is caused to rotate very rapidly between two other discs *b* by means of a rapidly revolving electric motor or steam turbine. These side discs are also made slowly to turn round in a plane at right angles to that of the middle disc. The connections are as illustrated in the figure. The studs are of such length as just to touch the side discs in passing, and thereby bridge the gap between the latter.

With the frequency employed at Clifden, namely, 45,000, when a potential of 15,000 volts is used on the condenser, the spark gap is practically closed during the time in which one complete oscillation only is taking place, when the peripherical speed of the disc is about 600 feet a second. The result is that the primary circuit can continue oscillating without material loss by resistance in the spark gap. Of course, the number of oscillations which can take place is governed by the breadth or thickness of the side discs, the primary circuit being abruptly opened as soon as the studs attached to the middle disc leave the side discs.

The sudden opening of the primary circuit tends to quench immediately any oscillations which may still persist in the condenser circuit; and this fact carries with it a further and not inconsiderable advantage, for, if the coupling of the condenser circuit to the aërial is of suitable value, the energy of the primary will have practically

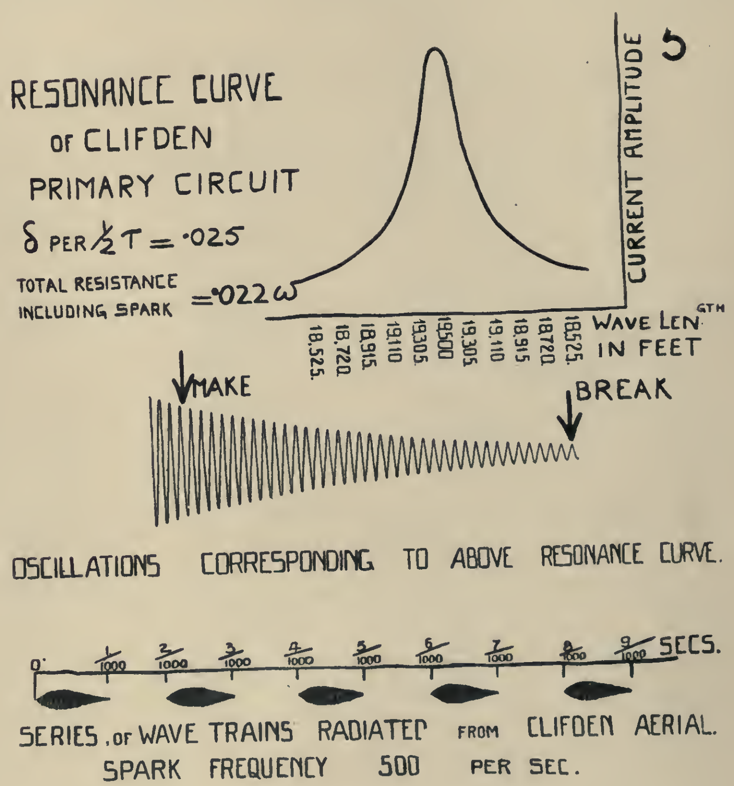

FIG. 5.

all passed to the aërial circuit during the period of time in which the primary condenser circuit is closed by the stud filling the gap between the side discs, but after this the opening of the gap at the discs prevents the energy returning to the condenser circuit from the aërial as would happen were the ordinary spark gap employed. In this manner the usual reaction which would take place between the aërial and the condenser circuit can be obviated, with the result that with this type of discharger and with a suitable degree of coupling the energy is radiated from the aërial in the form of a pure wave, the loss from the spark-gap resistance being reduced to a minimum.

I am able to show a resonance curve taken at Clifden, which was obtained from the oscillations in the primary alone (Fig. 5).

An interesting feature of the Clifden plant, especially from a practical and engineering point of view, is the regular employment of high-tension direct current for charging the condenser. Continuous current at a potential which is capable of being raised to 20,000 volts is obtained

by means of special direct-current generators; these machines charge a storage battery consisting of 6000 cells all connected in series, and it may be pointed out that this battery is the largest of its kind in existence. The capacity of each cell is 40 ampere hours. When employing the cells alone, the working voltage is from 11,000 to 12,000 volts, and when both the direct-current generators and the battery are used together the potential may be raised to 15,000 volts through utilising the gassing voltage of the storage cells.

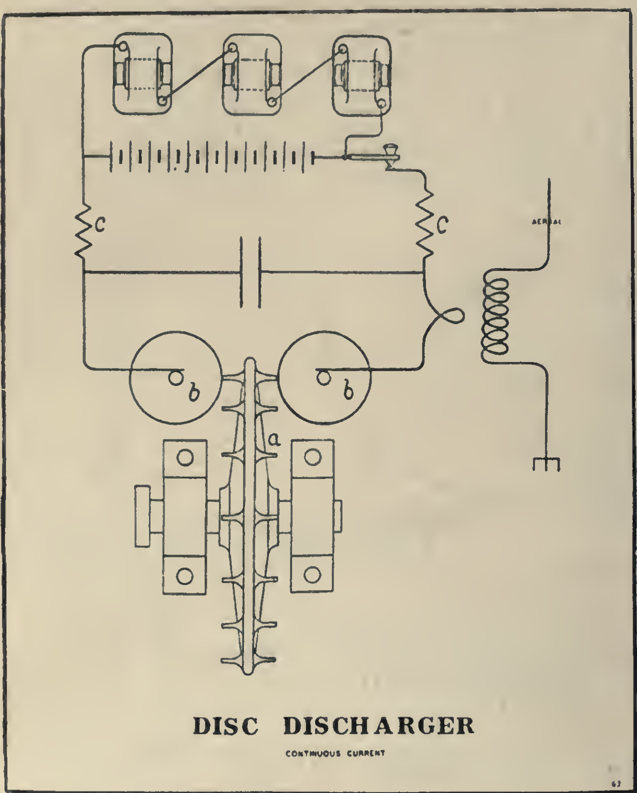

Fig. 6.

For a considerable portion of the day the storage battery alone is employed, with a result that for sixteen hours out of the twenty-four no running machinery need be used for operating the station with the single exception of the small motor revolving the disc.

The potential to which the condenser is charged reaches 18,000 volts when that of the battery or generators is 12,000. This potential is obtained in consequence of the rise of potential at the condenser plates, brought about by the rush of current through the choking or inductance coils at each charge. These coils are placed between the battery or generator and the condenser *c*, Fig. 6.

No practical difficulty has been encountered either at Clifden or Glace Bay in regard to the insulation and maintenance of these high-tension storage batteries. Satisfactory insulation has been obtained by dividing the battery into small sets of cells placed on separate stands. These stands are suspended on insulators attached to girders fixed in the ceiling of the battery-room. A system of switches, which can all be operated electrically and simultaneously, divides the battery into sections, the potential of each section being low enough to enable the cells to be handled without inconvenience or risk.

The arrangement of aërial adopted at Clifden and Glace Bay is shown in Fig. 7. This system, which is based on the result of tests which I first described before the Royal Society in June, 1906,[1] not only makes it possible to radiate efficiently and receive waves of any desired length, but it also tends to confine the main portion of the radiation to any desired direction. The limitation of transmission to one direction is not very sharply defined, but nevertheless the results obtained are exceedingly useful for practical working.

In a similar manner, by means of these horizontal wires, it is possible to define the bearing or direction of a sending station and also limit the receptivity of the receiver to waves arriving from a given direction.

The commercial working of radio-telegraphy and the widespread application of the system on shore and afloat in nearly all parts of the world have greatly facilitated the marshalling of facts and the observation of effects. Many of these, as I have already stated, still await a satisfactory explanation.

A curious result which I first noticed more than nine years ago in long-distance tests carried out on the ss. *Philadelphia*, and which still remains an important feature in long-distance space telegraphy, is the detrimental effect produced by daylight on the propagation of electric waves over great distances.

The generally accepted hypothesis of the cause of this absorption of electric waves in sunlight is founded on the belief that the absorption is due to the ionisation of the gaseous molecules of the air affected by the ultra-violet light, and as the ultra-violet rays which emanate from the sun are largely absorbed in the upper atmosphere of the earth, it is probable that that portion of the earth's atmosphere which is facing the sun will contain more ions or electrons than that which is in darkness, and therefore, as Sir J. J. Thomson has shown,[1] this illuminated or ionised air will absorb some of the energy of the electric waves.

The wave-length of the oscillations employed has much to do with this interesting phenomenon, long waves being subject to the effect of daylight to a very much lesser degree than are short waves.

Although certain physicists thought some years ago that the daylight effect should be more marked on long waves than on short, the reverse has been my experience; indeed, in some Transatlantic experiments, in which waves about 8000 metres long were used, the energy received by day at the distant receiving station was usually greater than that obtained at night.

Recent observation, however, reveals the interesting fact that the effects vary greatly with the direction in which transmission is taking place, the results obtained when transmitting in a northerly and southerly direction being often altogether different from those observed in the easterly and westerly one.

Research in regard to the changes in the strength of the received radiations which are employed for telegraphy across the Atlantic has been recently greatly facilitated by the use of sensitive galvanometers, by means of which the strength of the received signals can be measured with a fair degree of accuracy.

In regard to moderate power stations such as are

Fig. 7.

employed on ships, and which, in compliance with the International Convention, use wave-lengths of 300 and 600 metres, the distance over which communication can be effected during daytime is generally about the same, whatever the bearing of the ships to each other or to the land stations, whilst at night interesting and apparently curious results are obtained. Ships more than 1000 miles away, off the south of Spain or round the coast of Italy,

[1] "On Methods whereby the Radiation of Electric Waves may be mainly confined," &c. Proceedings of the Royal Society, A. vol. lxxvii., 1906.

[1] See *Philosophical Magazine*, August, 1902, ser. 6, vol. iv., p. 253, J. J. Thomson, "On some Consequences," &c.

can almost always communicate during the hours of darkness with the Post Office stations situated on the coasts of England and Ireland, whilst the same ships when at a similar distance on the Atlantic to the westward of these islands, and on the usual track between England and America, can hardly ever communicate with these shore stations unless by means of specially powerful instruments.

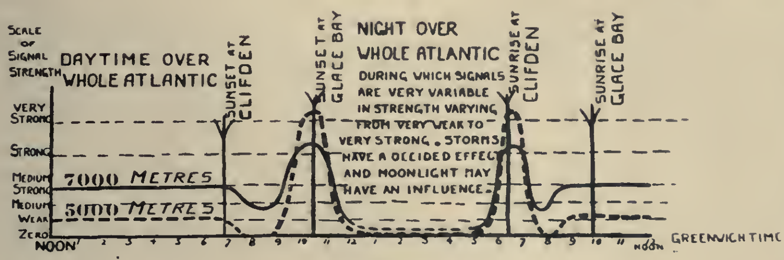

FIG. 8.

It is also to be noticed that in order to reach ships in the Mediterranean the electric waves have to pass over a large portion of Europe and, in many cases, over the Alps. Such long stretches of land, especially when including very high mountains, constitute, as is well known, an insurmountable barrier to the propagation of short waves during daytime. Although no such obstacles lie between the English and Irish stations and ships in the North Atlantic *en route* for North America, a night transmission of 1000 miles is there of exceptionally rare occurrence. The same effects generally are noticeable when ships are communicating with stations situated on the Atlantic coast of America.

Although high-power stations are now used for communicating across the Atlantic Ocean, and messages can be sent by day as well as by night, there still exist periods of fairly regular daily occurrence during which the strength of the received signals is at a minimum. Thus in the morning and the evening, when, in consequence of the difference in longitude, daylight or darkness extends only part of the way across the ocean, the received signals are at their weakest. It would almost appear as if electric waves in passing from dark space to illuminated space, and *vice versa*, were reflected and refracted in such manner as to be diverted from the normal path.

Later results, however, seem to indicate that it is unlikely that this difficulty would be experienced in telegraphing over equal distances north and south on about the same meridian, as, in this case, the passage from daylight to darkness would occur more rapidly over the whole distance between the two stations.

I have here some diagrams which have been carefully prepared by Mr. H. J. Round. These show the average daily variation of the signals received at Clifden from Glace Bay.

The curves traced on diagram No. 8 show the usual variation in the strength of these Transatlantic signals on two wave-lengths, one of 7000 metres and the other of 5000 metres.

The strength of the received waves remains, as a rule, steady during daytime.

Shortly after sunset at Clifden they become gradually weaker, and about two hours later they are at their weakest. They then begin to strengthen again, and reach a very high maximum at about the time of sunset at Glace Bay.

They then gradually return to about normal strength, but through the night they are very variable. Shortly before sunrise at Clifden the signals commence to strengthen steadily, and reach another high maximum shortly after sunrise at Clifden. The received energy then steadily decreases again until it reaches a very marked minimum a short time before sunrise at Glace Bay. After that the signals gradually come back to normal day strength.

It can be noticed that, although the shorter wave gives on the average weaker signals, its maximum and minimum variations of strength very sensibly exceed that of the longer wave.

Diagram 9 shows the variations at Clifden during periods of twenty-four hours, commencing at 12 noon, throughout the month of April, 1911, the vertical dotted lines representing sunset and sunrise at Glace Bay and Clifden.

Diagram 10 shows the curve for the first day of each month for one year from May, 1910, to April, 1911.

I carried out a series of tests over longer distances than had ever been previously attempted in September and October of last year between the stations at Clifden and Glace Bay, and a receiving station placed on the Italian ss. *Principessa Mafalda*, in the course of a voyage from Italy to the Argentine (Fig. 11).

During these tests the receiving wire was supported by means of a kite, as was done in my early Transatlantic tests of 1901, the height of the kite varying from about 1000 to 3000 feet. Signals and messages were obtained without difficulty by day as well as by night up to a distance of 4000 statute miles from Clifden.

Beyond that distance reception could only be carried out during night time. At Buenos Aires, more than 6000 miles from Clifden, the night signals from both Clifden

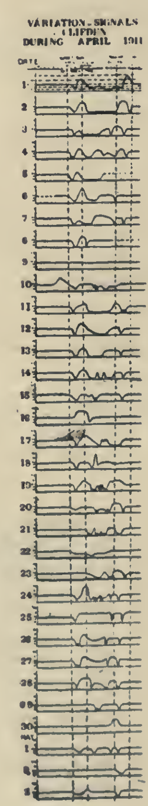

FIG. 9.

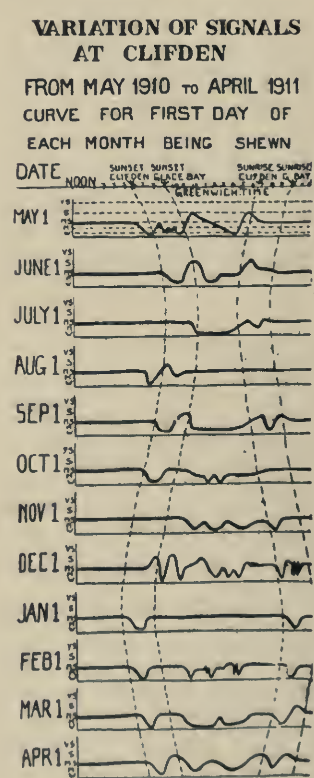

FIG. 10.

and Glace Bay were generally good, but their strength suffered some variations.

It is rather remarkable that the radiations from Clifden should have been detected at Buenos Aires so clearly at night time and not at all during the day, whilst in Canada the signals coming from Clifden (2400 miles distant) are no stronger during the night than they are by day.

Further tests have been carried out recently for the

Italian Government between a station situated at Massaua in East Africa and Coltano in Italy. Considerable interest attached to these experiments in view of the fact that the line connecting the two stations passes over exceedingly dry country and across vast stretches of desert, including parts of Abyssinia, the Sudan, and the Libyan Desert. The distance between the two stations is about 2600 miles.

FIG. 11.

The wave-length of the sending station in Africa was too small to allow of transmission being effected during daytime, but the results obtained during the hours of darkness were exceedingly good, the received signals being quite steady and readable.

The improvements introduced at Clifden and Glace Bay have had the result of greatly minimising the interference to which wireless transmission over long distances was particularly exposed in the early days.

The signals arriving at Clifden from Canada are, as a rule, easily read through any ordinary electrical atmospheric disturbance. This strengthening of the received signals has, moreover, made possible the use of recording instruments which not only give a fixed record of the received messages, but are also capable of being operated at a much higher rate of speed than could ever be obtained by means of an operator reading by sound or sight. The record of the signals is obtained by means of photography in the following manner. A sensitive Einthoven string galvanometer is connected to the magnetic detector or valve receiver, and the deflections of its filament caused by the incoming signals are projected and photographically fixed on a sensitive strip, which is moved along at a suitable speed (Fig. 12). On some of these records, which I am able to show, it is interesting to note the characteristic marks and signs produced amongst the signals by natural electric waves or other electrical disturbances of the atmosphere, which, on account of their doubtful origin, have been called "X's."

Although the mathematical theory of electric wave propagation through space was worked out by Clerk Maxwell more than fifty years ago, and notwithstanding all the experimental evidence obtained in laboratories concerning the nature of these waves, yet, so far, we understand but incompletely the true fundamental principles concerning the manner of propagation of the waves on which wireless telegraph transmission is based. For example, in the early days of wireless telegraphy it was generally believed that the curvature of the earth would constitute an insurmountable obstacle to the transmission of electric waves between widely separated points. For a considerable time not sufficient account was taken of the probable effect of the earth connection, especially in regard to the transmission of oscillations over long distances.

Physicists seemed to consider for a long time that wireless telegraphy was solely dependent on the effects of free Hertzian radiation through space, and it was years before the probable effect of the conductivity of the earth was considered and discussed.

Lord Rayleigh, in referring to Transatlantic radiotelegraphy, stated in a paper read before the Royal Society in May, 1903, that the results which I had obtained in signalling across the Atlantic suggested "a more decided bending or diffraction of the waves round the protuberant earth than had been expected," and, further, said that it imparted a great interest to the theoretical problem.[1] Prof. Fleming in his book on electric-wave telegraphy gives diagrams showing what may be taken to be a diagrammatic representation of the detachment of semi-loops of electric strain from a simple vertical wire (Fig. 13).

As will be seen, these waves do not propagate in the same manner as does free radiation from a classical Hertzian oscillator, but instead glide along the surface of the earth.

Prof. Zenneck[2] has carefully examined the effect of earthed receiving and transmitting aërials, and has endeavoured to show mathematically that when the lines of electrical force, constituting a wave front, pass along a surface of low specific inductive capacity—such as the earth—they become inclined forward, their lower ends being retarded by the resistance of the conductor to which they are attached. It therefore would seem that wireless telegraphy as at present practised is, to some extent at least, dependent on the conductivity of the earth, and that the difference in operation across long distances of sea compared to over land is sufficiently explained by the fact that sea water is a much better conductor than is land.

The importance or utility of the earth connection has been sometimes questioned, but in my opinion no practical

FIG. 12.

system of wireless telegraphy exists where the instruments are not in some manner connected to earth. By connection to earth I do not necessarily mean an ordinary

[1] Proceedings of the Royal Society, vol. lxxi., May 28, 1903.
[2] See J. Zenneck. *Annalen der Physik*, 23. 5. p. 846, September, 1908. *Physikal Zeitschrift*, No. 2, p. 50; No. 17, p. 553.

metallic connection as used for wire telegraphs. The earth wire may have a condenser in series with it, or it may be connected to what is really equivalent, a capacity area placed close to the surface of the ground. It is now perfectly well known that a condenser, if large enough, does not prevent the passage of high-frequency oscillations, and therefore in this case, when a so-called balancing capacity is used, the antenna is for all practical purposes connected to earth.

I am also of opinion that there is absolutely no foundation in the statement, which has recently been repeated, to the effect that an earth connection is detrimental to good tuning, provided, of course, that the earth is good.

Certainly, in consequence of its resistance, what electricians call a bad earth will damp out the oscillations, and in that way make tuning difficult; but no such effect is noticed when employing an efficient earth connection.

In conclusion, I believe that I am not any too bold when I say that wireless telegraphy is tending to revolutionise our means of communication from place to place on the earth's surface. For example, commercial messages containing a total of 812,200 words were sent and received between Clifden and Glace Bay from May 1, 1910, to the end of April, 1911; wireless telegraphy has already furnished means of communication between ships and the shore where communication was before practically impossible. The fact that a system of imperial wireless telegraphy is to be discussed by the Imperial Conference now holding its meetings in London shows the supremely important position which radio-telegraphy over long distances has assumed in the short space of one decade. Its importance from a commercial, naval, and military point of view has increased very greatly during the last few years as a consequence of the innumerable stations which have been erected or are now in course of construction on various coasts, in inland regions, and on board ships in all parts of the world. Notwithstanding this multiplicity of stations and their almost constant operation, I can say from practical experience that mutual interference between properly equipped and efficiently tuned instruments has so far been almost entirely absent. Some interference does without doubt take place between ships in consequence of the fact that the two wave-lengths adopted in accordance with the rules laid down by the International Convention are not sufficient for the proper handling of the very large amount of messages transmitted from the ever-increasing number of ships fitted with wireless telegraphy. A considerable advantage will be obtained by the utilisation of a third and longer wave to be employed exclusively for communication over long distances.

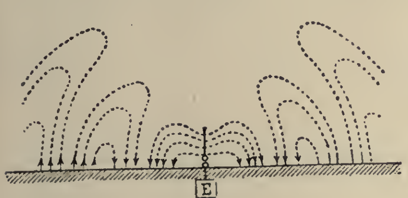

FIG. 13.

In regard to the high-power Transatlantic stations, the facility with which interference has been prevented has to some extent exceeded my expectations. At a receiving station situated at a distance of only eight miles from the powerful sender at Clifden, during a recent demonstration arranged for the Admiralty, messages could be received from Glace Bay without any interference from Clifden when this latter station was transmitting at full power on a wave-length differing only 25 per cent. from the wave radiated from Glace Bay, the ratio between the maximum recorded range of Clifden and 8 miles being in the proportion of 750 to 1.

Arrangements are being made permanently to send and receive simultaneously at these stations, which, when completed, will constitute in effect the duplexing of radio-telegraphic communication between Ireland and Canada.

The result which I have last referred to also goes to show that it would be practicable to operate at one time on slightly different wave-lengths a great number of long-distance stations situated in England and Ireland without danger of mutual interference.

The extended use of wireless telegraphy is principally dependent on the ease with which a number of stations can be efficiently worked in the vicinity of each other.

Considering that the wave-lengths at present in use range from 200 to 23,000 feet, and, moreover, that wave-group tuning and directive systems are now available, it is not difficult to foresee that this comparatively new method of communication is destined to fill a position of the greatest importance in facilitating communication throughout the world.

Apart from long-distance work, the practical value of wireless telegraphy may perhaps be divided into two parts, (1) when used for transmission over sea, (2) when used over land.

Many countries, including Italy, Canada, and Spain, have already supplemented their ordinary telegraph systems by wireless telegraphy installations, but some time must pass before this method of communication will be very largely used for inland purposes in Europe generally, owing to the efficient network of landlines already existing, which render further means of communication unnecessary; and therefore it is probable that, at any rate for the present, the main use of radio-telegraphy will be confined to extra-European countries, in some of which climatic conditions and other causes absolutely prohibit the efficient maintenance of landline telegraphy. A proof of this has been afforded by the success which has attended the working of the stations recently erected in Brazil on the Upper Amazon.

By the majority of people the most marvellous side of wireless telegraphy is perhaps considered to be its use at sea. Up to the time of its introduction, ships at any appreciable distance from land had no means of getting in touch with the shore throughout the whole duration of their voyage. But those who now make long sea journeys are no longer cut off from the rest of the world; business men can continue to correspond at reasonable rates with their offices in America or Europe; ordinary social messages can be exchanged between passengers and their friends on shore; a daily newspaper is published on board most of the principal liners giving the chief news of the day. Wireless telegraphy has on more than one occasion proved an invaluable aid to the course of justice, a well-known instance of which is the arrest which took place recently through its agency of a notorious criminal when about to land in Canada.

The chief benefit, however, of radio-telegraphy lies in the facility which it affords to ships in distress of communicating their plight to neighbouring vessels or coast stations; that it is now considered indispensable for this reason is shown by the fact that several Governments have passed a law making a wireless telegraph installation a compulsory part of the equipment of all passenger boats entering their ports.

THE PROPOSED TEACHERS' REGISTRATION COUNCIL.

IT would seem from the recently published Parliamentary Paper (Cd. 5726), entitled "Further Papers relating to the Registration of Teachers and the proposed Registration Council," that the formation of the much desired Teachers' Council, with which will rest the responsibility of preparing a Register of Teachers, will not be long delayed.

The papers include a summary of proceedings at the conference of November, 1909, convened by the Federal Council of Secondary School Associations in conjunction with other important educational associations; the alternative proposals discussed in Parliament in 1906, and other minutes and important data concerning the formation of such a council of teachers. The most important section, however, is that containing a report by Sir Robert Morant, secretary to the Board of Education, upon three informal conferences held recently at the Board of Education to discuss the whole matter, together with the outline of a scheme for the formation of a Teachers' Council.

This scheme lays great emphasis upon the question of the unification of the teaching profession, and makes provision for full representation upon the council of the universities of England and Wales. On this point Sir Robert Morant says:—

"From the point of view of a council which is to be, above all things, representative of the whole teaching profession, it is obvious that there must be a university group just as much as an elementary group and a secondary group. To speak of a professional council of the teaching profession without a full inclusion of the universities would obviously be absurd."

"Now the number of universities in England and Wales is eleven, and it is obvious that it would be quite impossible for these eleven universities to combine as an electoral college to name (say) five or six individuals to represent them, collectively, on such a council as is here in question, and the only conceivable method of meeting the case is that each of the eleven should have one representative.

"If, then, this group is to be composed of eleven members, this must be equally so in regard to the other three groups, according to the principle already proposed and accepted. . . . The council would thus be composed of four groups, each having eleven members."

The four groups which are each to be represented by eleven members are the university, elementary, secondary, and technological and specialist. In defining the last-named group, Sir Robert Morant remarks:—

"From some of the difficulties that have specially arisen in respect of that part of the scheme, it would seem that its nomenclature is, in some senses, inappropriate, and that what is really in question, on this side, is the need of representation of what may be called 'specialist teachers' (as well as technological teachers), as contrasted with what are usually regarded as teachers in the field of general education, or as 'general practitioners,' as was suggested at my second conference."

"It would therefore seem essential that the Teachers' Council, to be really representative of the whole profession, must comprise a representation of university teachers just as much as of elementary teachers, of secondary teachers, and of technological and specialist teachers; a council composed of these four elements would, in fact, be *representative of the whole teaching profession*, which otherwise would not be the case."

Again to quote the secretary of the Board of Education:—

"It will probably, however, be the case, from the very fact that the council will comprise representatives of widely different points of view as belonging to widely different branches of the profession, that its deliberations will best be managed under the chairmanship of someone not identified with any one of the several branches or sections; and from this point of view it would probably be desirable that the Order in Council should provide one vacancy for a chairman, to be chosen by the council from outside their numbers, who would doubtless be a man of distinction and possessing the characteristics requisite in an effective president of a body of this kind, whose deliberations would constantly be upon matters in which divergent interests and opposing points of view would frequently occur."

"This would bring the total number of the council to forty-five—a large body, but by no means too large to represent adequately the whole of so vast and important a profession as the teaching profession, nor, on the other hand, too large for arriving at effective decisions on the points likely to come before it, seeing that many of the more technical points would first have been thrashed out in special committees, and in meetings of one or more special committees meeting together, before coming before the council to be decided finally."

Mr. Runciman appends a note to the report signifying his agreement, and requesting Sir Robert Morant to have a draft made, as soon as possible, of an Order in Council on the lines outlined above.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Harkness scholarship for 1911 has been awarded to Mr. T. C. Nicholas and Mr. J. Romanes. The Frank Smart prizes have been awarded to Mr. S. R. Price (botany) and Mr. S. T. Burfield (zoology).

Mr. C. T. R. Wilson has been reappointed demonstrator of experimental physics for a period of five years from Michaelmas, 1911.

Mr. F. T. Brooks has been appointed senior demonstrator of botany, and Mr. D. Thoday junior demonstrator of botany, both for two years ending September 30, 1913.

We learn from *The Times* that Mr. Robert Christison, of Burwell Park, Lincolnshire, and late of Lammermoor, Queensland, has telegraphed to Sir William MacGregor, the Governor of the State of Queensland and Chancellor of the University of Brisbane, his willingness to contribute a further 1000*l*. (having already given 1000*l*.) for the foundation of a chair for tropical and sub-tropical agriculture.

It is announced in *Science* that Mr. Morton P. Plant has offered to give an endowment of 200,000*l*. for the woman's college which is to be established at New London, Conn.; it is a condition that the name shall be changed to the Connecticut College for Women. From the same source we learn that the General Educational Board has made public a list of its latest grants for colleges and schools, amounting in all to 126,800*l*. All the gifts to colleges are conditional and are applied to endowment only. Other gifts may be applied to current expenses. The grants include:—

College	Appropriation £	To be raised £
Converse, Spartansburg, S.C.	10,000	20,000
Drury, Springfield, Mo.	15,000	65,000
Franklin, Franklin, Ind.	15,000	65,000
Franklin and Marshall, Lancaster, Pa.	10,000	45,000
Huron, Huron, S.D.	20,000	20,000
Pennsylvania, Gettysburg, Pa.	10,000	30,000
Totals	80,000	245,000

Science also states that Brown University receives a bequest of 17,000*l*. from Dr. Oliver H. Arnold, of Providence.

SOCIETIES AND ACADEMIES.

London.

Royal Society June 15.—Sir Archibald Geikie, K.C.B., president, in the chair.—Prof. T. G. **Brodie**: Croonian lecture: A new conception of the glomerular activity. All the more recent work upon the kidney has proved conclusively that Ludwig's explanation of the glomerular function, viz. that the glomerulus is a filtering mechanism, is incorrect. The structural details of this highly characteristic portion of the renal apparatus strongly suggest that in some way or other the blood pressure is made use of in the work of the glomerulus. Having excluded filtration in this connection, there is yet another way in which it could be directly utilised, viz. in setting up a pressure-head by means of which the watery part of the urine could be driven through the very long and narrow tubule. In reference to this side of its activity, it is suggested that the glomerulus be termed a "propulsor." An approximate calculation of the pressure-head necessary to drive the fluid along the tubule during the height of activity proves that one about equal to that present within the glomerular capillaries is required. Evidence of the action of a high intra-tubular pressure is at once obtainable from the microscopic examination of a kidney after activity. The capsules of Bowman are greatly distended and approximately spherical in shape, the glomeruli are moderately enlarged and no longer fill the capsular spaces. The tubules are straightened out, stretched, and possess a conspicuous lumen. All these changes are exaggerated by any procedure which favours the action of this intra-tubular pressure, such as a high arterial blood pressure, obstruction to the outflow of urine from the ureter, or the stripping of the capsule from the kidney. Further, the kidney during activity is tense and hard, and distends its capsule to the utmost. This conception of the glomerular function affords a complete explanation of the existence of a firm and inextensible capsule surrounding the kidney, as also of such phenomena as the maximum ureter pressure, the dependence of the rate of discharge of urine from the kidney upon the general blood pressure, and the degree of dilatation of the renal arterioles, &c. Applying

this theory to the study of the action of diuretics in animals in which the blood pressure has been lowered so far that propulsion can no longer occur, we obtain evidence as to the parts of the renal tubules acted upon by these different substances.—A. R. **Cushny**: The action of Senecio alkaloids and the causation of hepatic cirrhosis in cattle. Various species of Senecio (ragwort) have been shown to induce fatal poisoning in cattle and horses in South Africa, Canada, and New Zealand. The alkaloids of one of these species were isolated by Watt, and their pharmacological examination shows that they induce the same symptoms as the entire plant. The Senecio species in this country proved non-toxic, except the common groundsel (*S. vulgaris*), and extracts from the ragwort grown in Canada, where the plant is poisonous, proved devoid of action also. This may, however, be due to the season at which the plant was gathered.—G. **Buchanan**: Note on developmental forms of *T. brucei* (*pecaudi*) in the internal organs, axillary glands, and bone-marrow of the gerbil.—Captain W. B. **Fry**: A preliminary note on the extrusion of granules by trypanosomes.

Physical Society, June 9.—Prof. H. L. Callendar, F.R.S., in the chair.—W. **Mason**: The Lüders' lines on mild steel. Previous investigations have shown that Lüders' lines on specimens of mild steel and wrought iron, strained in tension, are inclined at about 50° to the axis of pull. For tests in compression the information available is not precise, and though the angle of the lines with the direction of the compression is commonly understood to be about 40°, some doubt has been thrown on this point. The author had found previously that the lines are well developed on the surface of mild steel tubes. Since it was easy to obtain a compressive stress of practically uniform distribution in tubes under end pressure, while at the same time a hoop tensile stress could be induced by internal fluid pressure, the author confined his attention to the lines on tubular specimens. These were of mild steel, either hot or cold drawn, and most of them were annealed. The Lüders' lines on the outer surface appeared at the yield point indicated by the extensometer, *i.e.* their appearance coincided with the commencement of the large "yield" strain. In all cases where there were lines on the inner and outer surfaces of a tube, an inner and outer line, and also the ends of these lines, were found to be radially opposite, showing that the lines were traces of surfaces or canals of disturbance which passed through the tube wall, and indicating, moreover, that the disturbance spread spirally onwards, and not outwardly from a line initially formed on the more severely stressed inner surface. The conclusion is drawn that the Lüders' surfaces have the same, or approximately the same, inclination to an axis of simple pull or simple push. With stresses of opposite sign at right angles to each other, the lines and surfaces are more inclined to the stress of greater intensity, and with equal intensities the surfaces are at about 45°.—Prof. S. P. **Thompson**: A new method of harmonic analysis by averaging selected ordinates. Assume with Fourier that the curve representing any periodic single-valued function of x may be expressed by the harmonic series

$$y = A_1 \sin x + A_2 \sin 2x + A_3 \sin 3x + \ldots\ldots + B_1 \cos x + B_2 \cos 2x + B_3 \cos 3x.$$

Then to find the coefficient of any term, A_n or B_n, it suffices—subject to a limitation stated below—to measure off on the curve $2n$ equidistant ordinates over one period, that is, spaced at successive intervals apart of π/n. Then, having reversed the sign of every alternate ordinate, the simple algebraic mean of them gives the coefficient sought. For cosine-coefficients the first ordinate must be taken at the origin, while for sine-coefficients the first ordinate must be taken at a point $\frac{1}{2}\pi/n$ from the origin. The process is much facilitated by the use of templates of transparent celluloid having equispaced vertical lines engraved upon them. They are laid down on the curve, and the values of the selected ordinates are thus readily measured off. For analysis of valve-motions, of alternating-current curves, of tidal observations, and diurnal magnetic variations, the method presents certain advantages, as it requires no multiplication of ordinates by sines or cosines.—Prof. S. P. **Thompson**: Demonstration of the subjective nature of the difference tone. Two tuning-forks of frequencies 3328 and 3584 were sounded loudly. On striking the second the difference tone was heard, but while the notes from the two forks seemed to come in a definite direction from an external source, the difference tone seemed to be located in the ear itself.—Sir George **Greenhill**: Spinning tops and gyroscopic apparatus. A 52-inch Otto bicycle wheel was shown mounted on an axle with ball bearings, and spun by hand with the point in a small cup, to serve as a spinning top visible to a large audience. The gyroscopic apparatus was made of an ordinary 28-inch bicycle wheel, the axle screwed into a stalk of a short length of rifle barrel, suspended from a lug on a bicycle hub; the hub is fastened to an iron bracket, which is bolted to the under side of a beam or sleeper, large enough to absorb vibration, and resting on two step ladders. The wheel is spun by hand, and the axle is projected to obtain any desired gyroscopic motion, undulating, looped, or with cusps. The wheel can be detached by unscrewing the pin through the lug, and can then be used like the large wheel as a spinning top, or as the "Top on the top of a Top" described in Maxwell's "Life." Put the wheel out of balance by a bar through the spoke and hold the axle, and it will serve as a pendulum, making oscillations however large, or complete revolutions, and the effect may be investigated of varying the angle of the axle with the vertical.—Prof. H. N. **Allen**: A model illustrating the passage of a light wave through quartz. If a crystal is so cut, and a wave sent through it in such a way as to avoid separation of the two component waves by double refraction, it is easy to construct models showing how a vibration gradually alters in form as it passes through the crystal. The model exhibited illustrates the passage of a wave originally plane polarised through a crystal which rotates the plane of polarisation of light sent along its axis (quartz).—Prof. A. **Anderson** and J. E. **Bowen**: The measurement of contact differences of potential. The paper describes two methods of measuring the contact differences of potential of pairs of metals. The first, or deflection, method depends on the property which a radio-active source has of destroying a field of electrostatic force in air, and the second, or null, method on the possibility of determining by means of such a source whether such a field exists between two plates at zero potential. Measurements were made on ten different metals, and it was found that both methods gave practically the same results provided that the time which was allowed to elapse between the two measurements was sufficiently small. The addition law was verified.—A. **Johnstone**: A short table of circular and hyperbolic functions for complex values of the argument.

Zoological Society, June 13.—Mr E. T. Newton, F.R.S., in the chair.—H. G. **Plimmer**: Report on the pathological examination of rats caught in the Regent's Park and in the society's gardens. Five hundred rats had been examined between January 1 and May 17, all in a precisely similar manner. The spleen, lungs, glands, and blood were examined microscopically, and from any animal which looked in any way unhealthy cultures were made. The results were summarised as follows:—5 rats were caught in the park, and 495 in the gardens; 283 of these were males and 217 females. Three rats had tubercle, 10 had tapeworm cysts in the liver, 49 had *Trypanosoma lewisi* in their blood, 2 had empyema (not tubercular), 1 had a tumour of the lower jaw (the result of an old injury), and 1 had pleuritis and hydrothorax (not tubercular). Bacteria were found in 71 rats: in 40 in the lungs and in 31 in the spleen. Saccharomycetes were found in the lungs of 16 rats. Fleas were found on 4 rats, and lice on 3 rats. The general condition of the rats was very good, and in none was anything at all suspicious found.—Dr. R. E. **Drake-Brockman**: Antelopes of the genera Madoqua and Rhynchotragus found in Somaliland. The author made general remarks on all the dik-diks, and gave a short account of the species and subspecies, including the description of a new form.—Hon. Paul A. **Methuen**: An amphipod from the Transvaal. A detailed description of a new fresh-water gammarid of the genus Eucrangonyx found in caves in the Transvaal.—R. **Lydekker**: Three African animals. The first specimen was the skull of a

Somali rhinoceros, a race for which the author adopted the name *Rhinoceros bicornis somalicus*, Potocki. A klipspringer skull from northern Nigeria, characterised by its great width and the peculiar form of the lacrymal bone, was described as the type of a new race, *Oreotragus saltator porteusi*. Finally, a gazelle from Algeria was referred to a new species, *Gazella hayi*, agreeing approximately in size with *G. dorcas*, but distinguished by the much straighter and non-lyrate horns, each of which carried only about a dozen rings. The face-markings were approximate to those of *G. cuvieri*.—C. E. **Hellmayr**: A contribution to the ornithology of western Colombia. This memoir was based on a collection made by Mr. M. G. Palmer in 1908 and 1909, which, though numbering hardly 700 specimens, was of considerable interest and contained many rare species, and also furnished information of importance to students of zoogeographical problems.—Angel **Cabrera**: Subspecies of the Spanish ibex. The author dealt with the geographical distribution of, and the differences between, the various races, and described a new subspecies from the Sierra de Gredos, the type-specimen of which was in the Madrid Museum.

Linnean Society, June 15.—Dr. A. B. Rendle, F.R.S., vice-president, in the chair.—Miss H. M. **Cunnington**: The anatomy of *Enhalus acoroides*, Rich.—Prof. **Imms**: The life-history of *Croce filiformis*, Westw.—Papers on insect collections from the islands of the Indian Ocean, communicated by Prof. J. Stanley Gardiner. Eight papers were brought forward, four dealing with various groups of Hymenoptera, one with Lepidoptera, and three with Diptera. The first was by Prof. J. J. **Kieffer**, on parasitic Hymenoptera of the family Cynipidæ, or gall-wasps. This family appears to be poorly represented in the Seychelles; only eight species (all new) were found, none belonging to the gall-forming section of the family, but all to the zoophagous sections; their size as compared with that of many zoophagous Cynipidæ in other parts of the world is very small. The second paper was by the same author, dealing with the group of small and minute parasitic Hymenoptera known as Proctotrupoidea. A rich material of these was obtained, representing seven of the families into which the super-family Proctotrupoidea is divided, and consisting of sixty-six species, all new to science. These insects are very incompletely known, and several of the genera enumerated in the paper are also new. The third paper was on the bees obtained by the expedition to the Seychelles and Aldabra in 1908–9, by Prof. T. D. A. **Cockerell**, of the University of Colorado. It adds considerably to the previously known bee fauna of these islands, fifteen species being enumerated, eight of which are new to science. The author shows that the bees of the Seychelles consist of (i) an endemic element, composed partly of species without close allies elsewhere, and partly of species closely allied to forms found in other parts of the world, and (ii) certain widely spread species, perhaps introduced by man. The Aldabra bee fauna also contains an endemic element, as well as a single Madagascar species. This paper was followed by that of Mr. G. **Meade-Waldo** on the wasps (Diploptera) obtained by the expedition; it enumerates five kinds, but adds no species to the previous lists. Mr. J. C. F. **Fryer's** paper deals with all the Lepidoptera obtained by the expedition of 1908–9, excepting the plume-moths and the Tortrices and Tineina, which were worked out some time ago by Mr. Bainbrigge Fletcher and Mr. Meyrick respectively. Almost all the material from Aldabra, and some of that from the Seychelles, was collected by the author himself. The total number of Lepidoptera known from the Seychelles (including those dealt with previously by Mr. Fletcher and Mr. Meyrick) is now 240, of which more than 120 are peculiar to the islands. Mr. Fryer's own paper deals with 123 species, of which thirty are new. He states that these thirty are for the most part very distinct and well separated from their allies, while the non-peculiar species are mostly widely distributed, with a slight preponderance of African forms. With regard to Aldabra, sixty-six species are known from there, seven being, so far as is known, peculiar, while the rest all belong to African or Madagascar forms. The next two papers were by Mr. J. E. **Collin**, on two families of small and obscure flies, the Borboridæ and Phoridæ. All the material of these families is from the Seychelles Islands proper. There are nine species of Borboridæ, one of which is new, while the others are apparently of very wide distribution, some being identical with European and even with British species, while one is known from the East Indies, from Africa, and from South America. Of the Phoridæ there are twenty species, fourteen of which have not previously been described. The last paper was by Mr. F. V. **Theobald**, on the mosquitoes obtained by the expedition. There are nine kinds of Culicidæ known from the islands, five of them being new to science. One of these new forms was found by Mr. Fryer in Aldabra, and is named after him *Culicelsa fryeri*; the other four were found in the Seychelles, two of them being included in a new genus (Pseudoficalbia). Other species are of very wide distribution, one of them being the almost world-wide *Stegomyia fasciata*, notorious as the carrier of yellow fever. None of the malaria-conveying forms were found in the Seychelles.—F. **Summers**: Coast vegetation of south-west Lancashire.

PARIS.

Academy of Sciences, June 12.—M. Armand Gautier in the chair.—A. **Haller** and Edouard **Bauer**: 2:6-dibenzoyl-2:6-dimethylheptane and αα'-tetramethylpimelic acid. The sodium derivative of a dialkylacetophenone,

$$RR'CNa—CO.C_6H_5,$$

is treated with a dibromide, $Br.(CH_2)_n.Br.$, and the resulting diketones converted into benzene and the amide $NH_2.CO.C(RR').(CH_2)_n.C(RR').CO.NH_2$ by means of sodium amide. An example of this general method has been worked out, in which R and R' are methyl groups, and the bromide $Br.(CH_2)_3Br$.—Pierre **Termier** and Jean **Boussac**: The exotic character of gneiss and granite complex known as the crystalline *massif ligure*, and the separation of the Apennines and the Alps.—M. Zaboudski was elected a correspondant for the section of mechanics in succession to the late M. Sire, and E. Perroncito a correspondant for the section of rural economy in succession to the late M. J. Kühn.—M. **Luizet**: The form of the curve of light of the variable star δ Cepheus obtained from the observations of Argelander. The discontinuity in the curve of luminosity of this star deduced by Argelander from his observations is shown not to exist. A curve is given embodying the results of various observers, and this is without a break. It is shown, moreover, that Argelander's own observations fall on this curve.—Marcel **Riesz**: A method of summation equivalent to the method of arithmetical means.—J. **Le Roux**: Incurvation and flexion in finite deformations.—Louis **Wertenstein**: An extremely absorbable ionising radiation emitted by radium C. Radium C gives off an ionising radiation which is relatively intense, with penetrating power analogous to that of radio-active projections, and slightly deviable by the magnetic field. It is probably the projection of radium D by radium C.—G. **Reboul**: Conductivity accompanying chemical reactions.—Luigi **Giuganino**: The action of terrestrial translation upon the phenomena of light.—G. **Moreau**: The corpuscular ionisation of saline vapours and the recombination of the ions of a flame.—Georges **Meslin**: Circular double refraction in sodium chlorate. The author has constructed a triprism of sodium chlorate similar to the quartz triprism of Fresnel. Sodium chlorate possesses rotatory power, but differs from quartz in having no ordinary double refraction. The expected separation of the green mercury line into two components was clearly proved.—Miroslaw **Kernbaum**: The decomposition of water by metals. A repetition of Traube's experiments on the simultaneous production of hydrogen and hydrogen peroxide by the action of zinc and other metals upon water. The non-production of hydrogen in the absence of dissolved oxygen is confirmed, but, contrary to Traube's results, some hydrogen always appears to be formed.—J. B. **Senderens** and J. **Aboulenc**: The catalytic preparations of fatty esters in the wet way. The addition of potassium bisulphate to an equimolecular mixture of acetic acid and ethyl alcohol causes a marked increase in the amount of ethyl acetate formed in a given time. The use of sulphuric acid in the preparation of esters is discussed from this point of view.—Jean **Nivière**: The action of isobutylamine and di-isobutylamine upon

α-bromobutyric acid. Isobutylamine gives α-isobutylaminobutyric acid; di-isobutylamine gives only α-oxybutyric acid. —G. **Vavon**: The addition of hydrogen to limonene. In presence of platinum black hydrogen is added to limonene in two phases, a dihydride being first formed and a tetrahydride the final product. Some reactions of the dihydride are given.—André **Meyer**: Azomethines derived from phenylisoxazolone.—Ch. **Mauguin**: The orientation of liquid crystals by the magnetic field.—Fernand **Guéguen**: A new organ differentiated from the thallus of Mucor.—A. **Prunet**: Various methods of plant pathology and therapeutics.—Marcel **Dubard**: The classification of Lucumæ with functiform radicle.—L. **Gain**: Two new species of Nostoc from the South American Antarctic region.—Marc **Bridel**: Meliatine, a new glucoside hydrolysable by emulsin extracted from *Menyanthes trifoliata.* —B. **Sauton**: Germination *in vivo* of the spores of *Aspergillus niger* and *A. fumigatus.*—L. **Launoy**: Can the guinea-pig be accustomed to strychnine? The tolerance of the guinea-pig to strychnine can be increased experimentally to a considerable extent.—K. **Landsteiner,** C. **Levaditi,** and C. **Pastia**: Research on the virus contained in the organs of an infant attacked by acute polymyelitis.—M. **Maisonneuve**: The ovarian apparatus of Cochylis.—P. A. **Dangeard**: The fecundation of the ciliated infusoria.—A. **Magnan**: The relation between the ventricle and gizzard in birds.—A. **Desgrez**: The toxicity of two new nitriles and the antitoxic action of sodium hyposulphite towards one of them.—A. **Chauchard** and Mlle. B. **Mazoué**: The action of ultra-violet light upon amylase, invertine, and on a mixture of these two diastases. —A. **Joly**: The existence of limestones with flints (Eocene) in the Zarez Mountains, Algeria.—Raoul **Blanchard**: The glacial deposits at Rives.—Louis **Gentil**: A panorama of the Middle Mlouya (eastern Morocco).

June 19.—M. Armand Gautier in the chair.—J. **Boussinesq**: Simple construction (having recourse only to the two ellipsoids, inverse and direct) for light rays for each of the two systems of plane waves of given direction propagated in a transparent crystal.—C. **Guichard**: Certain triple orthogonal systems deduced from curves several times isotropic.—E. **Vessiot**: The kinematics of continuous media of n dimensions.—J. **Hadamard**: Slow permanent movement of a viscous sphere in a viscous liquid medium.—E. **Delassus**: The material realisation of linkages.—Louis **Roy**: Discontinuities of the first order in the movement of flexible threads.—Jules **Courmont** and Ch. **Nogier**: Progressive diminution of output in the ultra-violet with quartz mercury lamps working at high temperatures. The chemical, physical, and physiological actions of the light from mercury vapour lamps in quartz tubes falls off steadily when they are used at high temperatures. This seems to be due partially to the formation, on the interior surface, of a greyish coating (possibly a silicate of mercury). The lamps should be cooled during use.—Henri **Malosse**: Photometer for the control of the illuminating power of public or private lamps.—A. **Guillet**: A regulator depending on synchronisation.—A. **Leduc**: New method for determining γ, the ratio of the specific heats of vapours.—L. **Decombe**: The heat of Siemens.—C. **Caudrelier**: Frequency of electric oscillations in sparks.—F. **Grenet** and P. **Boulenger**: Porcelain filtering funnels.—J. **Meunier**: Spectra produced by the combustion of hydrocarbons and of various metals. The spectra produced by the combustion of magnesium, zinc, cadmium, nickel, copper, lead, bismuth, and antimony are described.—Georges **Baume** and F. Louis **Perrot**: Melting-point curves for mixtures of gases: systems formed from carbon dioxide and sulphuretted hydrogen with methyl alcohol and methyl ether. Melting-point curves for the systems $(CH_3)_2O—CO_2$,

$CH_3OH—CO_2$, $(CH_3)_2O—H_2S$, and $CH_3OH—H_2S$

were obtained, but only in the case of $(CH_3)_2O—H_2S$ was the existence of an oxonium compound, $(CH_3)_2O+H_2S$, indicated.—Paul **Bary**: Osmotic phenomena in non-conducting media. Experiments on solutions of indiarubber and acetyl-cellulose proved that such colloids are to be considered as solid solvents, and that the permeability, for a given substance of a colloidal membrane, will be proportional to the solubility of that substance in the colloid. —Pierre **Jolibois**: The allotropic modifications and the melting point of arsenic. Grey arsenic is stable at all temperatures up to 850°; arsenic deposited as a mirror is unstable, and changes to grey arsenic at about 280° with production of heat. The melting point of grey arsenic determined by two methods is 850°±10.—Max. **Wunder** and B. **Jeanneret**: The action of syrupy phosphoric acid on various alloys obtained in the electric furnace. Many metals and alloys thus obtained, although very resistent to the action of most reagents, are attacked by hot phosphoric acid of specific gravity 1·75. Silicon, zirconium, ferro-silicon, ferro-titanium, ferro-vanadium, manganese silicide, titanium nitride, nickel boride, and even carborundum are all attacked. If carbon be present it remains wholly or partially undissolved.—Mlle. Pauline **Lucas**: Dehydration of alkyl and benzyl-isobutylphenylcarbinols. Tertiary alcohols are produced by the action of organo-magnesium compounds on trialkyl acetophenones. These on dehydration give hydrocarbons containing a double bond.—L. H. **Phillipe**: Glucodecose and glucodecite.—Jakob **Erikson**: The mildew of mallow (*Puccinia malvacearum*); its nature and phases of development.—Jacques **de Lapparent**: The Permian eruptive rocks of the Pic du Midi d'Ossau.—Paul **Godin**: Variations in the size of the bodies of males during post-fœtal growth.—J. **Le Goff**: Glycosuria and saccharosuria in healthy subjects, following the absorption of saccharose.—V. **Balthazard** and Maurice **Nicloux**: Coefficient of toxicity in poisoning by carbon monoxide.—Mme. Marie **Phisalix**: Effects of the bite of a venomous lizard from Arizona (*Heloderma suspectum*).—F. **Picard**: Some points in the biology of *Conchylis ambiguella* and of *Polychronis botrana.*—P. **Sisley,** Ch. **Porcher,** and L. **Panisset**: The action of micro-organisms on some types of colouring matters.—L. **Cayeux**: The transformations of the *massif* of the Cyclades at the end of the Tertiary and the beginning of the Quaternary epochs.—Maurice **Lugeon**: A local inversion of the slope of the rocky bed of the Rhone, below Bellegarde.—E. A. **Martel**: The exaggerations of glacial theories.

CALCUTTA.

Asiatic Society of Bengal, June 7.—Rai B. A. **Gupte**: Folklore of the origin of the constellation Mrigashirsha. The folklore seems to have been based on the shape of the constellation known as Mriga Nakshatra in India and Orion in the west. It says that on the borders of the southern land there was a hunter who was locked up by his creditors in a Shiva's temple, and had to fast. His creditor was paid out of a subscription raised in the temple, and he was released. He went to *Shikār.* During the night one antelope came to the *Bael* tree on which he was sitting. She spoke to him in the human voice, and was allowed to go on promising that she would return. Another came; she promised return, and was allowed to go. Then came a black buck. He was also allowed to go. Lastly came a doe with young ones. They were members of one united family. They held consultation, and decided that they should all present themselves before the hunter for being killed. But the sun rose, and with it there came a change in the disposition of the hunter, due to the fact that he had to fast and to keep up all the night on the sacred Shivarātra-day, dropping *Bael* leaves on a *lingam.* Shiva's agents came to the spot, took the hunter to Kailás, and sent the antelope family to the Starry Heaven, that is, Nakshatralök, and blessed them, saying that they would form in heaven a constellation which should be known as Mriga Nakshatra. In examining the constellations and the signs of the Zodiac in connection with this story, the author found that the position of Sagittarius the hunter suggests the origin of the Shivapanchāyatan, or five in one, in the four signs of the Zodiac, viz. Taurus the Bull, Gemini the Ugma of Shiva, Cancer his *Gands,* with their chief or *ish* Ganesh, and Leo the Lion. Comparing these signs with the group of Shiva and Pārvati, the resemblance becomes so striking that it would be difficult to call it a coincidence. Shiva and Pārvati therefore have their origin in a myth based on the Zodiac.—W. **Kirkpatrick**: A vocabulary of the Pâsi Boli or Argot of the Kunchandiya Kanjars. Kanjar

is the generic name for a number of Indian tribes of a gypsy character, from Sanskrit kánana chará, in the sense of a wanderer in the jungle. Like the gypsies of Europe, the Kanjar and other wandering tribes of known predatory habits have a secret language or cant of their own. The collection given appears to be chiefly based on Hindi, with certain inflections which are attached to the verbal root implying that there is consistence and character in the cant, and perhaps that some of the inflections are from an old form of language now obsolete in modern colloquial Hindustani. Many of the words, however, seem to have no connection with known languages spoken or written in India, nor with any of the various slang or secret codes of other recognised wandering tribes of Dravidian origin. The Argot of European gypsies known as Romanes or Romni similarly has numerous words identical with modern Hindustani, while its Oriental, if not Indian, origin is generally accepted. The Romanes word for dog is *Jookel* or *Jukal*, while the Kanjar word is *Jhukal*. There are other resemblances and exactly identical words apparently common only to Romanes and Kanjar cant. A bibliography of references to the Kanjar and allied tribes is appended, with a list of various secret codes and slang languages, and also gypsy vocabularies.—Lieut.-Colonel D. C. **Phillott**: Some notes on Urdu grammar.

FORTHCOMING CONGRESSES.

JUNE 28, 29.—Conference on Education and Training of Engineers. London. President: Mr. Alexander Siemens, President of the Institution of Civil Engineers. General Secretary: Dr. J. H. T. Tudsbery.

JULY 18-22.—International Association of Seismology. Manchester. President: Prof. Arthur Schuster, F.R.S.

JULY 25-28.—British Medical Association. Birmingham. President: Sir H. T. Butlin, Bart.

JULY 26-29.—First Universal Races Congress. University of London. President: Lord Weardale. General Secretary: G. Spiller, 63 South Hill Park, Hampstead, London.

JULY 29-AUGUST 5.—Congress of French Geographical Societies. Roubaix. President: Prince Roland Bonaparte.

JULY 30-AUGUST 2.—Annual Meeting of the Swiss Society of Natural Sciences. Soleure. President: Dr. A. Pfaehler. Inquiries to Secretaries: Dr. Küng (German) and Prof. Brönnimann (French).

JULY 31-AUGUST 5.—French Association for the Advancement of Science. Dijon. President: M. Charles Lallemand. Secretary: Dr. Desgrez, 28 Rue Serpente, Paris.

AUGUST.—Centenary of the Foundation of the University of Breslau.

AUGUST 12-18.—First International Congress o Pedology. Brussels. President: M. Alexis Sluys. Secretary: M. Vital Plas, 35 Avenue Paul de Jaer, Brussels.

AUGUST 13-20.—Prehistoric Society of France. Nîmes.

AUGUST 31-SEPTEMBER 6.—British Association. Portsmouth. President: Sir William Ramsay, K.C.B., F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

SEPTEMBER 4-6.—Centenary of the University of Christiania. President of Festival Committee: Prof. Brögger.

SEPTEMBER 9-20.—International Congress of the Applications of Electricity. Turin. President of the Committee of Honour: H.R.H. the Duke of the Abruzzi. Honorary Secretary of the Committee: Signor Guido Semenza, Via S. Paolo 10, Milano International Secretary: Col. R. E. Crompton, C.B., R.E., Crompton Laboratory, Kensington Court, W.

SEPTEMBER 24-30.—International Congress on Tuberculosis. Rome. Address for inquiries: Honorary Secretary of the National Association for the Prevention of Consumption, 20 Hanover Square, W.

OCTOBER 2-7.—Third International Congress of Hygiene. Dresden. General Secretary: Dr. Hopf, Reichsstrasse 4, Dresden.

OCTOBER 15-22.—Tenth International Geographical Congress. Rome. President: Marquis Raffaele Cappelli. General Secretary: Commander Giovanni Roncagli, Italian Geographical Society, Rome.

DECEMBER 27.—American Association for the Advancement of Science. President: Dr. C. E. Bessey, University of Nebraska. Permanent Secretary: Dr. L. O. Howard, Smithsonian Institution, Washington, D.C.

DIARY OF SOCIETIES.

THURSDAY, JUNE 29.

ROYAL SOCIETY, at 4.30.—On a New Method of Estimating the Aperture of Stomata: Francis Darwin, F.R.S., and Miss D. F. M. Pertz.—Memoir on the Theory of the Partitions of Numbers. Part VI. Partitions in Two-dimensional Space, to which is added an Adumbration of the Theory of the Partitions in Three-dimensional Space: Major P. A. MacMahon, F.R.S.—The Kinetic Theory of a Gas constituted of Spherically Symmetrical Molecules: S. Chapman.—Radiation in Explosions of Coal Gas and Air: W. T. David.—The Mechanical Viscosity of Fluids: Dr. T. E. Stanton.—A Silica Standard of Length: Dr. G. W. C. Kaye.—The Properties of Oil Emulsions: R. Ellis.—(1) On a Class of Parametric Integrals and their Application in the Theory of Fourier Series; (2) On a Mode of Generating Fourier Series: Dr. W. H. Young, F.R.S.—Pendulum Clocks and their Errors: A. Mallock, F.R.S.—On Ceratopora, the Type of a New Family of Alcyonaria: Prof. S. J. Hickson, F.R.S.—Note on the Sensibility of the Eye to Variations of Wave Length: Prof. W. Watson, F.R.S.—And other Papers.

FRIDAY, JUNE 30.

PHYSICAL SOCIETY, at 5.—On the Effect of a Narrow Saw-cut in the Edge of a Conducting Strip on the Stream Lines in the Strip and on the Resistance of the Strip: Prof. C. H. Lees, F.R.S.—The Capacity Coefficients of Spherical Electrodes: Dr. A. Russell.—Exhibition of the Benkö Primary Battery: W. R. Cooper.

MONDAY, JULY 3.

ARISTOTELIAN SOCIETY, at 8.—Emotional Experiences of some Higher Mystics: Rev. A. Caldecott.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Explorations in Dutch New Guinea: Capt. C. G. Rawling, C.I.E.
